4. Moderate currents only should be employed in the vicinity of nervous centres.

5. The Gaiffe pile is a satisfactory instrument for the operation.

Abdominal Section.—At a recent meeting of the Midland Medical Society, Mr. Lawson Tait read a paper entitled "General Summary of Conclusions from 1000 Cases of Abdominal Section." Mr. Tait first considered the question of anæsthetics, and stated that he preferred a mixture of two parts of ether and one part of chloroform given in a Clover's apparatus; this mixture he found did not cause bronchitis, and did not diminish the excretion of urine, and was less often followed by vomiting than any other anæsthetic he had used. He defined the term "abdominal section" as an operation in which the peritoneum was involved. Mr. Tait also presented an analysis of his cases, in all of which the peritoneum had been involved. The general death-rate was 9.3 per cent. Mr. Tait gave as the explanation of the much lower death-rate of his later operations the following reasons: 1st. Greater experience; 2d. The complete discontinuance of the clamp in ovariotomy and of the ligature in hysterectomy; 3d. Also the earlier stages of the disease at which operation is now done. Mr. Tait laid great stress upon the last factor in influencing the mortality after operations.—*Lancet*, February 21, 1885.

Diagnosis of Renal Disease.—The advance that has been made in the diagnosis of renal diseases was well exemplified in a case brought before the students, at the Western Infirmary, by Professor George Buchanan. The patient was a woman, the chief feature of whose ailment was the presence of a large quantity of pus in the urine. The interesting point about the case was that, previously to adopting operative measures, steps had been taken to demonstrate satisfactorily that the right kidney was the seat of mischief, and that the other one was sound. This was accompished by the use of a recently invented German instrument, by the introduction of which into the bladder, the urine from each kidney is collected separately, and the seat of suppuration determined. The correctness of this diagnosis was verified by the subsequent nephrotomy, performed by Professor Buchanan.—*British Med. Journal*, Feb. 28, 1885.

The Treatment of Lupus.—Dr. Walter G. Smith, after an exhaustive discussion upon lupus and its treatment, concludes that the treatment by linear scarification, introduced by Squire, and that of the curette, or sharp spoon, proposed by Volkmann, and which is best followed by immediate cauterization of the raw surface, are the two methods most worthy of trial. He summarizes the individual features of the two methods as follows:

Erasion, or scraping—

1. Differentiates sound from diseased tissue, for healthy skin will not give way to the spoon.

2. It is rapid of execution.

3. It is, as a rule, not followed by much after-pain.

4. The scraped surface heals wonderfully quickly.

5. It leaves a level and tolerably sightly cicatrix.

Scarification—

1. Is applicable to some situations, and, in some cases, where erasion is unsuitable or inadvisable.

2. It is less painful, and, to some persons, a less repellant operation.

3. There is a minimal loss of substance.

4. It is especially adapted for diffuse non-ulcerating infiltrations.

5. The scar left is scarcely distinguishable from the healthy skin, and it is said not to be liable to cheloid growths, which sometimes develop upon the scars left by scraping operations.

Hence, in lupus of the face, where æsthetic considerations have especial force, linear scarification deserves a full trial in the promise it affords of effecting the desired object with the least amount of consequent deformity.—*Dublin Journal of Medical Science*, February, 1885.

Alleged Dangers in the Use of Corrosive Sublimate as an Antiseptic Agent.—Dr. Fraenkel, of Hamburg, draws attention (Virch. *Arch.*, 99, ii.) to an almost unsuspected danger arising from the too free use of corrosive sublimate as an antiseptic agent. His remarks are in the first place based upon a case recorded by Stadfelt, of death with dysenteric symptoms following upon intrauterine injection of a solution of sublimate (1 to 1500) after adherent placenta, and are supported by the results of post-mortem examinations of surgical cases in which this solution was employed. In all these cases (fourteen in number) severe ulcerative lesions were found in the large intestine, but Dr. Fraenkel admits that in only two of these could the lesion be said to have caused the death of the patient. The appearances presented by the diseased bowel resembled those of acute dysentery—viz., more or less extensive areas of necrosis of the mucous membrane, with intense surrounding inflammation. He combats the notion that the intestinal lesions depended on septicæmia, mainly on the ground that in no case were any other of the lesions characteristic of septicæmia or pyæmia present, nor did the cases run the clinical course of blood-poisoning. Although the paramount value of corrosive sublimate as an antiseptic must be admitted, its employment is nevertheless not free from risk. Its immoderate use as an external application is liable to excite the diphtheritic-like inflammation of the large and sometimes of the small intestine, which is recognized clinically by tenesmus, colic, and bloody stools. But so far the renal changes supposed to be characteristic of sublimate poisoning have not been observed in surgical practice. The intestinal affection is most liable to occur in individuals whose nutrition is defective, or who are very fat, especially those with fatty hearts; and particularly if the sublimate has been in contact with large exposed and absorbing surfaces, as the peritoneum or uterus; therefore care should be taken to use only the weakest solutions consistent with their antiseptic property, and especially not to use them too frequently as intrauterine injections.—*Lancet*, February 28, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, MARCH 21, 1885.

INTERMEDIATE HOSPITALS FOR THE TREATMENT OF INSANITY.

In the issue of *The American Journal of the Medical Sciences* for January, 1885, there is an important paper by Dr. Van Bibber of Baltimore, on "Intermediate Hospitals for the Treatment of the Insane," which formulates certain conceptions that have been fermenting in the minds of alienists and neurologists for several years past. There has been developing a conviction that our existing asylums for the insane, in their therapeutical management, do not represent those advances in our knowledge which have demonstrated the dependence of psychical derangements on changes in the organic substratum of the mind. That these institutions, in their organization and management, are adequate for that conception of insanity which regards it as a merely psychical derangement, may be admitted ; but if the modern belief that it is a malady caused by alterations in the physical basis of the mental functions be true, then the present merely moral and hygienic methods do not suffice. The accumulating evidence of physical changes underlying psychical derangements, renders necessary a new departure in the therapeutical management of insanity.

For the most part, our asylums are mere boarding-houses for people with disordered intellects, and the superintendent performs the functions of a boarding-house keeper. With the best intentions towards the scientific side of asylum management, the superintendent cannot escape the necessities of his position as the mere keeper of a lodging-house. The study of the structural changes in the brain in his fatal cases, must yield to the demands of his living inmates for a supply of potatoes and cabbages. Although at the outset of his career as an alienist, he may have been zealous to achieve accuracy in his diagnosis and an enlightened skill in his therapy, circumstances at last compel him to regard these as quite secondary to confinement under hygenic conditions. Instead of contributions to knowledge based on the observations and experiences of the asylum practice, he contents himself with an annual report in which the kitchen garden, the games indulged in by the patients, the contributions of flowers and pamphlets by benevolent ladies, and columns of ingenious statistics, figure as the ultimate expression of alienistic wisdom.

The present system, is, obviously, unequal to the demands of modern science. How shall it be modified to render the therapeutics of insanity conformable to that conception which regards it as a symptom of a change in the physical basis of the mind ? Dr. Van Bibber proposes the organization of intermediate hospitals, where the insane yet capable of benefit from remedial agencies can be subjected to treatment by a suitable staff.

Considered from the merely therapeutical point of view, the insane may be divided into two great classes : the acute cases, and those affected with forms of mental derangement, for which a reasonable expectation of benefit from appropriate treatment may be entertained ; the incurable of every kind.

As respects the latter—unfortunately a large group—the present boarding-house system is probably well devised to give them the maximum comfort consistent with security. Requiring no immediate medical supervision, the superintendent of the asylum containing them may devote himself to the cares of the farm and the kitchen, and to the compilation of those entertaining statistics which illustrate, at the same time, the skill of the doctor and the wisdom of the Board of Trustees or Managers.

Far different organization and methods are demanded for those asylums which receive the acute cases and those requiring treatment. These should be true hospitals, officered and managed as such institutions should be. We have here to encounter the burning question of superintendents with the manifold executive powers now possessed by that official in the existing insane asylums. It requires but little acquaintance with the needs of hospital administration to see how anomalous the position of superintendent is, if an asylum is to be a real hospital, devoted to the medical care and cure of insane patients. For the business and merely executive management of an hospital for the insane, a lay administrator, acquainted with the special functions of such a place, entirely suffices. Such an administrator properly enough, and doubtless, preferably, may be a medical man ; but the performance of such duties are manifestly incompatible with the actual charge of

the insane patients. It is quite possible to combine the duties of a medical superintendent with those of a house physician, acting in individual cases under the prescribed direction of an attending staff.

To a properly organized attending staff of neurologists and alienists, should be committed the remedial management of the inmates of such an hospital for the insane. In other words, the arrangements for the treatment of insane patients should be approximated to those that now obtain in the general and special hospitals of the present day. The attending staff should be organized from amongst those members of the profession who have given most attention to disorders of the nervous system. Insanity can no longer be relegated to the merely psychic realm, and hence the treatment of those mental affections dependent on physical alterations should properly be entrusted to those who have made themselves familiar with the diseases of the brain and nervous system.

Furthermore, as cerebral affections may manifest themselves in, or spring from, diseases of the organs of special sense, a properly organized staff for such an hospital should include the specialists devoted to such maladies. A scheme of this nature given its fullest development, may be so enlarged as to include the employment of other specialists for the treatment of accidental and intercurrent affections. The staff might thus be constituted of attending and consulting members—the latter to be called on in cases of difficulty, or of an extraordinary character.

It is greatly to be desired that the plan outlined by Dr. Van Bibber, in his timely paper, be submitted to the test of experience. Surely, the progress of our knowledge in brain diseases should have adequate expression in the remedial management of the insane cases in our asylums. Are we still to wear the bonds of an immovable conservatism, and continue worn-out expedients no longer adapted to the enlarging needs of modern society? If change is not necessarily progress, we are surely in a position where radical changes are indispensable to enlightened progress in the treatment and cure of insanity.

THE TREATMENT OF DIPHTHERIA.

Judging from a recent discussion at the Berlin Medical Society, succeeding the reading of Henoch's paper on diphtheria, we are forced to conclude that the therapeutics of this disease is not more definitely fixed in the minds of German physicians than in our own. At the same time, the discussion evolved some important practical points which should interest our readers.

While Fränkel was satisfied that it is quite possible to dissolve off diphtheritic membrane from the fauces by the use of acid solutions of pepsin, he did not believe anything was gained by so doing, since, in the first place, it is the false membrane in the bronchi, which cannot be reached by the pepsin solutions, which tends to produce stenosis and suffocation. That the vegetable organisms which are found associated with diphtheritic membrane, and which are always superficial in this situation, have anything to do with its causation or virulence is by no means proven. Fränkel compared diphtheria with erysipelas in its mode of extension and in our inability by any local measures to prevent its spread, unless it be by the saturation of the parts with corrosive sublimate solution, which, in the case of the pharynx, it would be impossible to do. He, therefore, limits the treatment of the disease to combating the fever by quinine, and to the use of supporting measures, making local treatment altogether secondary.

Falk contended that while gastric juice must be admitted to have some effect in destroying infectious substances, it is through its hydrochloric acid, and not its pepsin. Further, its effect is different upon different organisms. Thus upon the tubercle bacillus it is inoperative, while it destroys the bacillus of anthrax and the cholera fungus.

Guttmann took ground against Fränkel's view, that treatment of the diphtheritic membrane is unnecessary. He believes that the vegetable organisms in false membrane are the infectious agent, and that they are the medium of descent of the process into the larynx and trachea. This he considers proven by the fact that in 165 autopsies he has never known the larynx to be overleaped in the extension of the process, the membrane having always travelled from the pharynx through it to the parts below.

It is true that Koch's experiments discovered but a small number of disinfectants which destroyed the spores of anthrax within twenty-four hours. Such were solutions of corrosive sublimate 1 in 1000; freshly prepared chlorine water, two per cent.; iodine water, two per cent.; bromine water, five per cent.; permanganate of potassium solution; and one per cent. solution of osmic acid. A five per cent. solution of carbolic acid requires forty-eight hours to destroy the spores. While it is impossible to keep any of these agents in contact with the diphtheritic membrane for twenty-four hours, advantage might still accrue from their frequent use. Guttmann has employed papayotin in the strength of a four per cent. solution, making hourly applications to the fauces, but without effect. He had found, too, that its direct action upon false membrane immersed in it was exceedingly slow. He had obtained in one instance an astonishing effect from turpentine, which was found by Koch to be slightly more efficient in destroying bacteria than a three per cent. solution of carbolic acid. Guttmann gave it in a dose of a teaspoonful. A short time after its administration large masses of membrane were

discharged from the larynx and trachea. Subsequent use of the same remedy had not, however, been followed by similar results. Among the most ineffectual substances, so far as their action upon the spores of anthrax are concerned, may be mentioned potassium chlorate in five per cent. solution, salicylic acid, and benzoic acid.

Patchkowski earnestly recommended the treatment by ice, internally and externally. This should be maintained uninterruptedly, a fresh piece being immediately substituted for one just dissolved; and this must be done continuously night and day. Since it is unnecessary even to awaken the child, he denies that the treatment can have any fatiguing or prostrating effect. He rightly holds, too, that the ice bag is often carelessly applied, being allowed to lie simply against the front of the throat instead of being drawn closely up to the lobe of the ear on both sides. This statement we can confirm from our own knowledge, having seen efforts at carrying out the ice treatment rendered useless by inattention to this point.

Güterbock also believed that the ice treatment is the most useful, not because it contributes in any way to the solution of false membrane, since it fulfils very different indications. Children die not from membrane on the true vocal cords, where it is very seldom present, but from œdema of the aryepiglottic ligament and of the false vocal cords. For the prevention of such secondary infiltration, ice is most efficient.

From a review of the above discussion, it would seem that antipyretic and supporting measures by quinine and allied means, and the use of ice, constitute the treatment received with most favor in Berlin, while the use of disinfecting agents to the fauces has also some supporters. On the other hand, the local and general use of chlorate of potassium and iron, and the administration of large doses of calomel, which may be said to represent the special treatment of this country, do not enter largely into German therapeutics.

THE LIFE HISTORY OF EPITHELIOMA OF THE TONGUE.

Although scirrhous carcinoma of the tongue is occasionally met with, the most important of the neoplasms of that organ is epithelioma, the natural history of which has a special interest at this time, in connection with the case of a distinguished citizen, in which minute examination has disclosed that the disease is a cancer of that type.

Lingual epithelioma, as a rule, rapidly progresses towards a fatal termination. When left to itself, the life of the patient from the first appearance of the disease varies, in accordance with the estimates of different observers, from 10.5 to 13 months, the average being 11.7 months. Death ensues, first, from the generalization of the disease; secondly, from septic pneumonia, from the inhalation of the putrid emanations which result from the decomposition of the products of the ulcerated surface; thirdly, from starvation, through the pressure of the infected lymphatic glands and surrounding parts upon the œsophagus, thereby interfering with deglutition: and, lastly, from hemorrhage proceeding from the ulcerated lingual arteries, or the vessels of the neck.

The duration of life of those who survive an operation averages 19 months. Not only does operative interference prolong life and relieve suffering, but it effects a final cure in 14 per cent. of all cases. In attaining these results it must, however, be remembered that excision of the tongue is attended with a mortality of 23 per cent., the principal dangers being shock, hemorrhage, œdema of the glottis, septic lung affections, pyæmia, and erysipelas, some of which risks can be avoided by taking careful precautions during the operation, and by the perfecting of antiseptic measures during and after the procedure.

When, in addition to disease of the tongue itself, the palate and the tonsil are involved, the prognosis is far more grave, whether the disease be permitted to pursue an unaided course, or whether it be subjected to the knife. In the latter event, not only will the tongue have to be extirpated, but the disease of the palate and tonsil will have to be reached either by Langenbeck's or Mikulicz's method of operation. In the former, the jaw-bone is divided just in front of the masseter muscle, while, in the latter, the ramus of the jaw is resected. For carcinoma of the tonsil alone, temporary section of the inferior maxilla has been practised by Cheever, Gensmer, and Von Bergmann. In Cheever's case, the disease continued to progress; in Gensmer's there was freedom from recurrence for thirty-three months; while we are not aware of the fate of Von Bergmann's patient. In Mikulicz's case of resection of the ramus, the patient was well at the expiration of six months.

So far as we can learn, there is no example of the performance of the double operation on record; and it is, in our opinion, not justifiable. The only available measures are those directed toward the relief of suffering, the prevention of septic complications, and supporting the powers of the system. Should deglutition be greatly interfered with, gastrostomy might be resorted to; but this procedure, under the circumstances, is of such a questionable nature, that the prudent surgeon would doubtless not take it into consideration.

GENERAL GRANT'S CONDITION.

Since our report of last week the progress of the disease in the case of General Grant has been marked by no important change. There was a local

exacerbation on Wednesday, during which the last bridle of tissue on the inner side of the ulcer of the anterior pillar was destroyed, and the gland in the neck became enlarged. The inflammatory thickening of the mucous membrane of the hard palate has somewhat diminished, but the enlarged gland in the neck, which is deeply situated behind the angle and ramus of the jaw, appears more firmly adherent.

There has been but little pain, and the most prominent feature of the case during the week has been insomnia, which is exceptionally difficult to treat because of the sensitiveness of the patient to the disturbing secondary effects of the common remedies.

The General has driven out once or twice during the week, but has not yet felt able to resume the preparation of his memoirs.

Although, as we have before stated, an operation for the removal of the disease is not contemplated, the association with the case of such eminent surgeons as Professors Markoe and Sands is an ample guarantee to the profession that the question has not been overlooked, and that, if any operation should be deemed advisable, it would be performed with the utmost skill and soundest judgment.

A NEW PHASE OF PROFESSIONAL ADVERTISING.

THE medical public can scarcely be expected to regard with complacency some recent phases of professional propriety exhibited during the past few weeks in connection with the case of General Grant. The public at large has been taken into the professional confidence of the medical attendants with a degree of freedom quite surprising to those who regard the knowledge obtained in this relation as a sacred trust. Even the law, which requires of all witnesses "the truth, the whole truth, and nothing but the truth," so far respects the office of the physician as to permit him to withhold the information imparted to him in his professional capacity. Hitherto, the unwritten law, no less than the formal statement of our code, has enjoined on the physician the utmost reticence in all the affairs of his patients. The simplest sentiment of honor, as well as the plainest dictate of self-interest, require the medical man to observe the proprieties of his position, in the absence of precedent or legislation. But some of our colleagues appear to be indifferent to these long-recognized sentiments and proprieties. They have blazoned forth in the secular press every detail of General Grant's case, and pictorial illustration has been invoked to render their account more impressive.

It may be said, and indeed we believe this justification has been put forth, that because of the eminence of the patient, and the place he holds in the esteem of the nation, there is a demand for full information. That this plea should be extended to include facts which can be appreciated only by those who have had a technical training, is certainly erroneous, and one of the most influential papers of the day (*Harper's Weekly*) energetically protests against this assumption. A daily bulletin, free from technical details, would much more aptly satisfy the public anxiety than the elaborate descriptions fit only for medical journals. It looks as if other and different considerations than an amiable desire to satisfy the public curiosity have induced the publication of professional details. Elements have been at work which have apparently lowered the standard of professional morality. As any chain is no stronger than its weakest link, so any measure which lessens the binding force of our medical code at any point, weakens it throughout. In the latest example of questionable professional ethics, we find ample evidence of the undermining action of those provisions of the "new code" which have abolished the barriers between legitimate medicine and all kinds of irregular practice.

The ethics of a proper professional status once ruptured, there is no limit to the disintegration which will ensue, and it behooves the profession, at once, to place its emphatic disapproval upon this disregard of the rights of patients. Medical men should not allow themselves to be interviewed by the daily press, to break down the barriers which surround the confidential relation of physician and patient, and to give to the public minute details of the progress and treatment of a disease, even though it be in the case of a most distinguished citizen, in whose welfare fifty millions of people feel a deep interest.

INFANTILE OVARIAN HERNIA.

IN the *St. Petersburger Medicinische Wochenschrift*, No. 4, 1885, may be found the record of an incarcerated hernia of the ovary in an infant seven months old. A small tumor existed in the left inguinal region, which disappeared on pressure, but returned on withdrawing the pressure, and gave rise to no general symptoms. When next seen by DR. SCHMITZ, the tumor, which was of the volume of a pigeon's egg, and seated at the outer ring, had been irreducible for eight days, and was extremely painful. Efforts at the taxis, under chloroform, having failed to reduce the tumor, it was extirpated, the sac ligated and excised, and the broad ligament tied and returned. At the expiration of ten days the wound had completely united.

The occurrence of ovarian hernia in infants is very uncommon, and, unless we mistake, this is the second operation for that lesion on record, the first, which proved fatal from peritonitis, having occurred to Guersant. It is also interesting to note that Dr. Schmitz found an ovarian hernia, as large as a pea, in a child of the same family five weeks old.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, March 5, 1885.

The President, B. F. Baer, M.D., in the Chair.

Dr. William Goodell read a paper entitled

A YEAR'S WORK IN LAPAROTOMY.

(See page 313.)

The President presented a

GANGRENOUS FIBROID TUMOR OF THE UTERUS,

and made the following report of the case: Mrs. J., a patient of Dr. Ira D. Canfield, of Renova, Pa., 52 years of age, married, has had one child eighteen years ago; she has not been pregnant since. Her abdomen had been rather prominent for years, and about five years ago she discovered that it was becoming quite firm and hard over the lower protuberant portion. About the same time her menses began to appear more frequently than usual and to continue longer, until during the last year she flooded continuously three weeks out of every four. She thought she sometimes lost a quart of blood in twenty-four hours. There was great tenderness over the abdomen, so that the weight of the clothing was intolerable and she had a constant feeling of painful distention, a sensation of bursting sometimes. These symptoms increased in severity, and in the latter part of January, 1885, labor-like pains supervened. Paroxysms of uterine tenesmus occurred several times a day, resulting finally in a discharge of serous fluid and gas which must have been considerable in quantity, for the next morning there was marked subsidence of the previously distended abdomen. However the large, dense, round, and evidently, uterine tumor still remained, tolerating now comparatively rough manipulation, the tenderness having almost entirely disappeared. The quasi-labor-pains increased in frequency and strength, and shreddy putrid masses were occasionally expelled from the vagina. The patient began to show evidences of acute septicæmia. Dr. R. Honesbourg, of Lock Haven, was now called in consultation, when it was determined that nature was endeavoring to cast off a decomposing uterine fibroid, and an effort was made to assist. Symptoms of blood poisoning became alarming.

On February 15th I was hurriedly summoned, and with the patient anæsthetized we found the following condition: Abdomen distended and tympanitic; a globular and symmetrical mass outlined within the lower portion of the abdomen, extending two inches above the umbilicus, about the size and consistence of the pregnant uterus at the seventh month of gestation. Hanging from the vaginal orifice was an elongated mass of toneless decomposing tissue, which resembled the appearance which might be presented by a great mass of amniotic membrane which had been allowed to remain in the parturient canal for several days after labor. It had a purplish ashy color, and was as thick as my forearm. The odor emitted was sickening. Passing my hand beside this mass, for I could not easily separate it, I found the os uteri so dilated that the vaginal and cervical canals were almost of the same calibre, and the rim of the os could scarcely be defined. Advancing my hand within the cavity of the uterus, it passed among an immense quantity of semi-friable soft and shreddy tissue, and discovered several large tumors of firm consistence embedded in, and apparently one with, the uterine wall. Indeed, it was difficult to define the uterine wall, so irregular and thick was it at some points and so thin at others. The tissues at the attenuated portions—the uterine wall proper—appeared so weak that I feared the manipulations necessary to enucleate the tumor would make rupture of the uterus imminent. But their immediate removal was imperative, and fortunately their attachments were softened by the process of degeneration which had caused the grave symptoms. I, therefore, introduced Thomas's spoon-saw, and with that and my fingers I separated and removed section after section until there was nothing left of the uterus but the merest shell. The aggregated quantity removed, a portion of which I present this evening, almost half filled a wooden bucket. The uterus did not contract well after the operation and very free hemorrhage occurred, but it was controlled and the uterus made to contract by large and repeated injections of pure vinegar. The after-treatment was carefully and judiciously conducted by Dr. Canfield, and consisted of injections, into the uterine cavity, of vinegar twice daily, until all fetid discharges had ceased. The improvement in the temperature and pulse of the patient was remarkable, and within a few days she expressed herself as feeling better than she had for years. She is now sitting up, apparently restored to health.

Dr. Harris inquired the cause of the gangrenous change in the structure, Was it confined to the new tissue?

Dr. Goodell thought that the process of auto-enucleation was the cause of the degeneration of the tumor. The latter is a low grade of formation, and the contractions of the uterus and the constriction caused by the cervix uteri around the already extruded portion interfered with the circulation in the tumor and caused its death. In one case he removed a tumor in which this process had just commenced; the removal of the tumor was followed by a gush of near half a pint of broken-down blood which was very offensive in odor. A sharp attack of erysipelas followed.

Dr. Baer could give no other reason than that advanced by Dr. Goodell. The tumor was of slow growth; no ergot was given, but labor-like pains supervened and may have cut off the circulation. The degeneration was apparently confined to the new growth.

The President presented the specimen and read the following report of a rapidly growing

PAPILLOMATOUS OVARIAN CYST.

Mrs. G., æt. 41, widow for eight years, has had eight children, the youngest being nine years. She always enjoyed robust health until September, 1884, three months before I first saw her. At that time a slight metrorrhagia began without pain or other disturbance. Previous to that time her catamenial periods had been regular. In October she noticed that the lower portion of her abdomen was slightly enlarged a little to the left of the median line. She thought nothing of it then, but thought that she was growing fat. The hypogastrium, however, continued to distend and she began to

lose flesh. Her physician, Dr. A. R. Blair, of York, Pa., brought her to see me on January 3, 1885. Her abdomen was then as large as at the sixth month of gestation, symmetrically developed, perfectly smooth, dull on percussion over the distended portion, but resonant in flanks and epigastrium, and there was marked fluctuation. Dark bloody discharge from uterus, not fetid. It was thought she was pregnant and that the metrorrhagia was due to threatened miscarriage. But she was losing flesh, and there were no rational or physical signs of pregnancy except abdominal enlargement. The uterus was slightly prolapsed and retroverted, rather softer than natural, os patulous, cervix granular; sound two and a half inches; uterus not easily moved because of a mass pressing upon it from above. I diagnosticated a rapidly growing ovarian cyst, and advised immediate operation; but she was not ready. I saw her again on February 7. The tumor had increased to double the size it was at first examination. It was still symmetrical and occupied the same relation to the uterus. She was losing flesh and strength. She now complained of pain all over anterior surface of abdomen, and her pulse and temperature were slightly elevated. She at no time suffered pain in the tumor.

On February 18th she entered my private hospital. Had increased greatly in size during the intervening ten days. Circumference at umbilicus forty-six inches, veins in abdominal wall distended. Tumor still symmetrical and markedly fluctuating. Metrorrhagia has continued daily since its first appearance in September. Suffers from dyspnœa. Pain over surface as before, and abdominal wall seems to be one with the tumor. I suspected, from this circumstance, adhesions of tumor to peritoneum. Urine normal.

Operation.—February 20th, 11 A.M., assisted by Drs. D. J. M. Miller, J. C. Gabell, in the presence of Drs. A. R. Blair, J. W. Kerr, and F. B. Hazel. Incision three inches; tumor almost universally adherent to anterior wall of abdomen and omentum, and very vascular. I passed my hand and separated adhesions, and then tapped the cyst; the fluid had the color and consistence of healthy pus, and was more than an ordinary wooden pailful in quantity. Solid portion of tumor, larger than the fœtal head at term, was delivered through the small incision. The tumor proved to be of the left ovary and had a very short and vascular pedicle, which held it in close contact with the uterus. Ligated and amputated omentum, transfixed and ligated the pedicle with fine Chinese silk, cut and dropped. The right ovary being perfectly healthy, was not removed. The uterus was soft and congested. Peritoneum purple from congestion, but there had been no ascitic fluid and the peritoneal cavity was found almost free from liquid. Probably ten minutes were spent looking for bleeding vessels and finishing the "toilette of the peritoneum." Abdominal wound then closed with eight silk sutures. The patient recovered from the anæsthetic without any evidence of shock; pulse 98; temperature normal; and she continued to do well until the second day, in the evening of which her temperature reached 100°, its highest point; pulse 108, and strong. She complained of being tired and looked worn. She had not passed flatus from the anus, but there were occasional eructations of foul gas. There was no tympany and no pain, but at about 11 P.M. she vomited or rather regurgitated about a pint of very fetid yellowish liquid of a decidedly fecal odor. The large quantity (she had not taken a teaspoonful of anything since the operation) and the odor, together with the fact that she had not passed flatus from the anus, caused me to suspect intestinal obstruction. Her temperature fell soon after this to 96°, and her pulse rose to 150, and became very weak. There was no pallor of countenance, or distention of abdomen or Douglas's cul-de-sac, or I should have thought this depression, bordering on collapse, was due to hemorrhage. Neither were there any other symptoms of intestinal obstruction than the apparent fecal vomiting and the non-escape of flatus from the rectum.

Under the influence of active stimulus, by the rectum and hypodermically, she slowly rallied, but the temperature did not reach the normal point until the fifth day after the operation when flatus began to escape from the rectum. Her recovery was rapid after this. The sutures were removed on the eighth day. Union complete and solid. She sat up on the thirteenth day. There has not been any bloody discharge from the uterus since the operation.

The tissues of the cyst wall are very friable, and the internal surface is studded with an exuberant papillary growth presenting an appearance not unlike cauliflower excrescence.

The very rapid growth of this tumor to the great size which it attained in five months, the constant metrorrhagia and the character of the tumor, place this case quite out of the usual course of development of ovarian cysts, and make it worthy of record. These are characteristics of malignant disease. Is this a malignant tumor? I think not, in the sense that it will necessarily return, now that it has been removed before the cyst wall had broken down and discharged its contents into the peritoneal cavity. This is the course of papillomatous ovarian cysts. But even when this has occurred and the peritoneum become involved, the disease may not return after removal. Some years ago I assisted Dr. Goodell in the removal of a papillary growth of the ovary in which the cyst had ruptured and discharged its contents into the peritoneal cavity. The peritoneum was greatly involved, being thickly studded at various points with hard papillary nodules. The patient recovered, and the disease has not returned. Dr. Emmet records a like experience. He says: "I have never regarded the condition as malignant in character or in any respect more than a benign growth, accidental to ovarian tumors and accompanied by an ascitic accumulation (ascites complicates a later stage of the disease than my case had reached). I have, however, sometimes observed in this supposed malignant disease that patients bore the shock of the operation badly, and died from apparently trivial causes" (*Prin. and Prac. Gynec.*, 3d ed., p. 683). It is probable that ovarian cysts of very rapid development often have this papillary character. One of the specimens which I presented to this Society at its last meeting was of this description, though less marked; and it had attained a size of thirty pounds in nine months. It is also probable that the constitution is more profoundly affected by these growths than by the ordinary slow-growing ovarian cysts. For these reasons operation should never be deferred in such tumors.

Dr. Harris inquired whether any microscopic ex-

amination of the tumor had been made. He always suspected malignancy in rapid growths, and in papillomatous tumors the decision cannot be made from appearances, as of two such having the same apparent characters, one may prove to be malignant and the other benign.

Dr. Goodell remarked that the question of malignancy in ovarian tumors was a most interesting one. As regards papillomatous cysts, Doran has divided them into two classes: One springing from the hilus of the ovary and not necessarily malignant, while papillary growths in cysts of the broad ligament usually indicate malignancy. Some years ago he removed a collapsed papillomatous ovarian cyst upon which the late Dr. Hodge had refused to operate in consequence of supposed malignancy. It was complicated by ascites and the peritoneal cavity had become infected with secondary growths; yet the woman got well and has probably remained well. On the other hand, benign-looking growths are sometimes malignant; for instance, he removed a large tumor having many adhesions, twenty-four ligatures were left in the abdominal cavity. It was wholly benign in appearance and the patient got up and about, but soon she became oppressed by rapid breathing. Effusion into the right pleura was discovered, together with malignant growths affecting that cavity and scattered throughout the abdominal cavity. The tumor was evidently malignant, but it did not look so. In another case of apparently benign cyst, in which the clamp was used, menstruation occurred from the cicatrix, and later papilloma of the stump and abdomen sprouted out from the cicatrix and the patient died. He said that all his cases of colloid tumors, three in number, have become malignant afterwards. In one case, five years after the first operation, the second ovary became diseased, the sac burst and the whole contents of the peritoneal cavity became infected. In another, two years after the removal of both ovaries, the disease returned in the broad ligament, probably from the stump of the ovary. In another case the cicatrix burst open a few weeks after the operation, and a large papillomatous growth sprouted out, the lady dying soon after. Tait considers that among the causes of malignancy are tapping and delay in operating, the age of the cyst tending to malignancy. Dr. Goodell doubted if the microscope can distinguish between benign and malignant papillomata. Virchow states that although benign at the beginning, they may become malignant in the later stages.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 24, 1885.

The President, Robert F. Weir, M.D., in the Chair.

Dr. A. C. Post narrated a case, that of a boy, nine years of age, who was brought to his clinic with a

BURSAL SWELLING AT THE BACK PART OF THE WRIST,

and in which he made an effort to rupture the sac by striking it sharply with a wooden bat. The first blow did not rupture the swelling, and he repeated it several times, and found that a dangerous degree of force would be required to rupture it in that way. He then punctured the cyst, and pressed out exceedingly viscid contents, much more viscid than is the vitreous humor. After squeezing out the contents through a small opening he applied an antiseptic lotion, and afterwards applied a compress made of cork, which he bound over the swelling with a bandage, and this was allowed to remain for a week, when the patient returned, and on removing the dressing he found that the cork had made a marked depression of the surface where it had been applied, but that there had not been the slightest inflammation, and the case was progressing favorably.[1]

Dr. Sands inquired how frequently the members of the Society had performed cutting operations for the cure of this disease. The treatment by rupture, as described by Dr. Post, had doubtless often yielded good results, but not unfrequently the relief afforded proved to be temporary. Another method of evacuating the cyst was to open it subcutaneously with a broad needle. His own experience with this method had been generally favorable, yet he had known it to fail to accomplish a permanent cure. He had lately seen a patient who had been treated in this manner by an eminent surgeon in New Haven. The operation being followed by a recurrence of the swelling, the surgeon again emptied the cyst in the same way, and as the contents flowed out through the puncture, he inserted a hypodermic needle into the opposite wall of the sac, and injected it with a strong solution of carbolic acid. This procedure was also unsuccessful, and when Dr. Sands saw the case, the tumor was of irregular shape and nearly as large as an English walnut, constituting a very conspicuous deformity. Dr. Sands advised a trial of iodine injection, and had since heard that this had been successfully employed. His knowledge of the extirpation of such ganglia was limited to two cases. The first one he himself treated by excision, a good many years ago, and was able to dissect out the cyst without opening the sheath of the tendon, the patient making a good recovery.

The other case occurred in the practice of a medical friend, before the days of antiseptics. Excision was performed, the parts being rendered insensible by ether spray. Violent inflammation followed the operation, and rendered the hand nearly useless. Dr. Sands saw the patient several years afterward, when she was unable to flex the fingers, and there was but little motion of the hand. In that case the sheath of one of the extensor tendons of the thumb was opened, and it was feared at the time of the operation that mischief would follow. Probably at the present day there would be but little risk of phlegmonous inflammation following such an accident, and, in some instances, an operation for the complete removal of the swelling might be indicated as the only effectual means of accomplishing a cure.

The President referred to the fact that Dr. Abbe in the out-patients' department of the New York Hospital had shown him three cases, in two of which he had resorted to puncture, and in the third to an incision, packing the sac with iodoform. In all instances the cases had done perfectly well. The operation of incision and packing with iodoform had struck him as one worthy of trial.

[1] The patient was seen again after the lapse of another week, and there was nothing to indicate a return of the swelling.

DR. STIMSON said that he had recently made subcutaneous puncture by means of a flat needle in two cases, both of which did well.

DR. SANDS thought that the subcutaneous puncture was always safe.

DR. POST remarked that he attempted subcutaneous puncture in his case, but the cyst was so thick that the fluid was oozing out before it was complete.

THE PRESIDENT referred to one case in which a ganglia had been injected with carbolic acid with severe reaction for which he was called upon to dissect the tumor out. The wound thus made healed promptly.

DR. PETERS remarked that one of the earliest operations he performed was subcutaneous puncture of one of these swellings upon the wrist of a very old gentleman, and the result was good.

REMOVAL OF THICKENED BURSA FROM OVER THE TROCHANTER MAJOR.

THE PRESIDENT presented a specimen removed from over the trochanter major of a married woman which appeared shortly after her confinement with her last child, two years ago. It did not seem to be associated with labor, and was not noticed until after she was up and about. The swelling was treated by counter-irritation without relief; increase in size slowly took place; finally a tumor about the size of an egg was revealed. He then thought it was probably a fibro-sarcoma; and, from its not being quite certain whether or not it was movable on the femur, that it might be of periosteal origin. At the operation performed three weeks since, it was found to be a bursa over the trochanter major under the gluteus maximus muscle, with walls nearly an inch in thickness, and constituting a mass as large as a goose egg. The central cavity was about the size of an almond. Recovery was prompt.

LITHOTRITY UNDER COCAINE.

THE PRESIDENT referred to a case in which he had performed lithotrity within the last ten days under the influence of cocaine. The patient was a man 72 years of age, with marked cardiac lesions, and his condition was such as to preclude general anæsthesia. He had long suffered from prostatic trouble, and a number of years ago submitted to an operation of prostatotomy by Dr. Gouley, with marked benefit. The calculus was about three-quarters of an inch in diameter, and phosphatic in character. Lithotrity, practised after the old method, was twice tried, with considerable suffering to the patient, but his condition was so poor that further efforts in this way could not be entertained. The patient's vesical sufferings were so great that he finally determined to see whether cocaine would be of sufficient service to enable him to remove the remainder of the calculus. He, therefore, on February 5, injected into the bladder, previously washed out with warm water, three drachms of a four per cent. solution, and allowed it to remain fifteen minutes, when an additional quantity of water was thrown in and the lithotrite was introduced. Although the urethra was still somewhat sensitive, the pain in this part was very much lessened, the bladder was entered without distress, the stone seized, from five to eight crushings rapidly made, Bigelow's apparatus No. 29 curved catheter introduced, and the aspiration effected. The entire operation occupied not more than eight to ten minutes. While the procedure was not absolutely painless, the cocaine reduced the sensibility of the invaded urinary tract to such a marked degree that the patient endured the operation without special difficulty. In the *Lancet* of January 17, received the day Dr. Weir operated, there is a report of a similar operation in which the cocaine had been used with much more satisfactory results. The patient was operated upon at St. Peter's Hospital, and the stone had been crushed and withdrawn in less than fifteen minutes in a painless manner. In this case, four drachms of a four per cent. solution were injected into the bladder.

DR. MARKOE inquired if there were any cases on record in which unfavorable effects had been produced by cocaine when applied to the unbroken mucous membrane.

Dr. WEIR replied that he knew of none.

DR. HALL remarked that he had seen constitutional symptoms produced by an injection into the urethra of two drachms of a four per cent. solution of cocaine. He had discovered also what did not appear to have been previously noticed, namely, that while small quantities produce vaso-motor spasm, and consequently anæmia of the part, large quantities produce vaso-motor paralysis and congestion. In the same way, when a dose just large enough to cause constitutional symptoms was given, the patient had dilated pupils, with pallor of the face, nausea, and a small hard pulse; while, after much larger doses, the pupils were not more dilated, nausea and pallor were absent, the pulse was full and soft, and a dreamy mental condition was produced.

THE PRESIDENT remarked that, had he been compelled to consider the subject of lithotomy, in his case he should have attempted to perform the operation by the aid of the local anæsthetic effect of cocaine. His experience in the removal of superficial tumors and in several quite deep incisions for pus had satisfied him that such an operation as lithotomy might be accomplished by the use of cocaine.

DR. BRIDDON had seen considerable relief follow the injection of one drachm of a two per cent. solution into the bladder for the relief of vesical tenesmus associated with prostatic trouble. He had one patient under observation in the Presbyterian Hospital who had used it every night, with the result of obtaining about two and a half hours of rest, for which no opiate or any other treatment afforded more than half an hour of relief.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, March 6, 1885.

PROF. T. G. RODDICK IN THE CHAIR.

PROF. GEORGE ROSS read a paper on a case of

PULSATING EMPYEMA,

simulating aneurism; spontaneous rupture, and recovery.

G. W., æt. 37, express driver, was admitted to the Montreal General Hospital, December 29, 1884, suffering from a sharp pain in the left side, a short cough, and feverishness. Four years ago had an attack of pneumonia, but with this exception has always been healthy. No history of rheumatism or syphilis. On December

24th, he got a severe wetting; on the 26th, had a chill followed by a stitch in the side. When admitted into hospital his skin was hot and dry, and he had an herpetic eruption on his lips, complained of severe pain in the left lower axillary region, increased by inspiration and pressure over the part; cough short and accompanied by expectoration of glairy mucus; temperature 103°; pulse 120, small and weak; respiration 24, short and shallow; tongue moist and coated. Examination showed somewhat deficient expansion of left side, dulness of base of left lung, and weak respiratory murmur with diminished resonance and fremitus of same area.

Patient continued much the same for several days, with high temperature and pulse always above 120. On the 2d of January there was dulness to angle of scapula and through lower axillary region. During the following week he suffered a great deal of pain in the left side which prevented him from sleeping, the fever still continued and he was inclined to sweat a great deal. On January 8th, the dulness in lower area of left side was much less. On percussing the front of the chest, a flat note was found, commencing at the upper margin of the second left costal cartilage and continuous with that of the heart. This dull area was bounded externally by a line drawn through the nipple and passed across the sternum a little to the right side. Expansion of left side of chest much impaired, second and third intercostal spaces were prominent and presented a quite perceptible pulsation synchronous with the systole of the heart. These pulsations were felt quite strongly on palpation. In this dull area vesicular murmur was almost absent.

During the next two weeks the case appeared to be stationary; temperature was always above normal; the patient sweated a good deal and emaciated considerably; the pain was persistent and rendered intolerable by any attempt to lie on the left side; the physical signs remained as before. On the 22d of January a rough friction sound was heard along the right margin of the sternum from near the clavicle to the third rib; all this time he had increased fever with nausea and vomiting, and pain was very much complained of in the dull region under the left clavicle. On the night of the 2d of February he had a severe fit of coughing, which was immediately followed by the outflow of about a pint of pure inodorous pus, which was brought up in the course of a few minutes. When seen next morning, he had a loose cough, every effort serving to bring up a large mouthful of pus; in this way half a pint or more was expectorated during the day. The percussion note, previously dull, at once changed to a clear and somewhat tympanitic note. The pulsating tumor had entirely disappeared. For a few days a loose cough with some purulent expectoration continued, and then ceased entirely. The temperature fell to normal, percussion became pulmonary in quality, the respiratory murmur became normal, and sleep and appetite soon returned. He left the hospital on the 2d of March strong and well.

Prof. Ross, in his remarks on the case, said it was evident from the history of this case that a considerable collection of pus was formed in the upper part of the chest, upon the left side, as a result of an acute pleuritic inflammation. He explained the occurrence of pulsation as due to the fact that the empyema was so situated that it communicated very distinct pulsations, either from the heart itself or the aorta, to the surface of the thorax, and that the empyema discharged itself by opening into the air-passages. He went on to remark that the symptoms resembled closely those met with in aneurism of the thoracic aorta, viz., localized dulness well defined, to one side of and beneath the upper portion of the sternum, prominence of the spaces, and above all pulsations, very distinct and easily felt and seen. In addition, there was very decided enfeeblement of the respiratory murmur. On the other hand, there was no bruit, no intensification of the second sound, no fulness or palpable pulsation behind the manubrium, and no downward traction on the trachea. These points, as well as the clinical history, Dr. Ross thought, at the time, decided against aneurism.

The most difficult thing to explain was the great obscuration of the vesicular murmur throughout the entire lung, and as the percussion note was not obviously altered from that of the opposite side, the conclusion was inevitable that the absence of tidal air must be explained by the existence of pressure upon the main branches. Dr. Ross stated that he had never met with this condition as a result of an advancing collection of fluid, but had often seen it brought about by the advancing pressure of a growing neoplasm or aneurismal tumor. Although Dr. Ross looked upon the affection, at the time, as probably an empyema, the possible existence of some obscure neoplasm (not an aneurism) was not to be lost sight of, as perhaps complicating the case,

Dr. Ross thought that if the case had been seen for the first time on January 8th, with an imperfect clinical history, it might easily have been mistaken for aneurism. The symptom of pulsation in connection with empyema, although very rarely seen, has been known for a long time. Le Roy many years ago recognized it, and says that it closely simulates aneurism. In the case narrated, Dr. Ross thought that the pulsations observed were communicated from the aorta, as this vessel, being filled by each successive systole, would necessarily compress a sac of fluid in immediate contact with it, and, if the latter touched the thoracic parietes, would cause visible pulsations upon the surface; on the other hand, when pulsations are observed in the side of the chest from the heart itself, these must be produced by the lateral movement of the heart from right to left, during the systole, because with the contraction the heart does not increase in bulk, and could not, therefore, produce compression in an adjacent body of fluid. In conclusion, Dr. Ross remarked that the full explanation of these communicated pulsations is an interesting subject, and one which is not very satisfactorily dealt with in medical literature.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

The College Commencements.—The classes graduated by our colleges this year have been unusually small. The Medical College of Ohio conferred the degree upon about sixty, the Miami College upon about half that number. The commencement exercises of the former institution were held on Thursday evening,

March 5th, and were witnessed by a large and appreciative audience. After the conferring of the degree by the President of the Board of Trustees, the Hon. M. F. Force, a large list of prizes were awarded, and the successful candidates for the position of resident physician to the hospitals, three to the Cincinnati and two to the Good Samaritan, were announced. The valedictory address was delivered by Professor J. T. Whittaker, his subject being, "A Chapter from the History of Medicine."

The commencement of the Miami Medical College occurred Tuesday evening, March 10th. The subject of the valedictory by Prof. F. W. Langdon, was "The Germ Theory of Disease."

The Sanitary Council of the Mississippi Valley met at New Orleans on Tuesday, March 11, and was called to order by Dr. Joseph Holt, President of the Louisiana State Board of Health, and Colonel D. P. Hadden, President of the Council, took the Chair.

Dr. Pinckney Thompson, of Kentucky, introduced the following resolution, which was adopted:

Resolved, That Drs. Kedzie, Holt, Robertson, Rauch, Chaillé, and the President of the Council, be appointed a committee to formulate a system of coöperation of the States represented in the Council, to prevent the introduction of yellow fever or cholera in the Mississippi Valley, and also a plan of coöperation should either of these once gain admission to the Mississippi Valley.

On Wednesday this committee reported, recommending that the Secretary of State be petitioned to cause the consuls and consular agents of all ports from which ships clear for the United States, to furnish not only the usual information embraced in bills of health, but all particulars in regard to the existence of contagious, infectious, or epidemic diseases, which may endanger the public health by importation by vessels reaching our shores.

The Sanitary Council regards the exclusion of all vessels unmistakably infected with cholera or yellow fever from the Mississippi River as vital to the safety of the West, South, and the Northwest. It therefore petitions the Secretary of the Treasury to place a revenue cutter at the mouth of the Mississippi River to prevent the entrance of all such infected ships, and to send them to Ship Island or other refuge stations for quarantine and purification.

If, however, an infected vessel, or one suspected to be infected, enters the Mississippi River, the State Board of Health of Louisiana shall remand such vessel to a station of detention and absolute isolation until all danger of the spread of the disease by ship, cargo, crew, and passengers, has been entirely removed; the ship to be thoroughly cleansed and disinfected; the cargo to be disinfected; the baggage thoroughly disinfected, and the crew and passengers kept under observation until free from all suspicion of danger to the public health.

In view of the threatened invasion of cholera, the President is earnestly requested immediately to place the emergency epidemic fund in the hands of the National Board of Health, to be used in aid of State and Local Boards of Health in preventing the introduction and spread of cholera and yellow fever in the expectation that an adequate portion of this fund (not less than $50,000) shall be placed at the disposal of the State Board of Health of Louisiana, to hold this gateway of the South and West.

In the event of an epidemic of cholera or yellow fever, the first consideration of concert of action among health officers is confidence. This can be secured only by early, full, and free information of all the essential facts at points of outbreak. To secure such information, each and every health organization represented in this Sanitary Council pledges itself to furnish promptly to each other all information in regard to the appearance of cholera and yellow fever, or suspicious cases of yellow fever or cholera.

For the purpose indicated in the above resolution the following groups of symptoms shall be considered to indicate yellow fever and suspicious cases:

I. The following groups of symptoms shall be considered to indicate *yellow fever:*

Group 1.—A person after a sudden attack has fever of one paroxysm, attended with marked congestion or blood stasis of capillaries of surface, conjunctivæ, and gums, with a history of probable exposure to infection, and no history of a previous attack of yellow fever.

Group 2.—A person after a sudden attack has a fever of one paroxysm, followed by unusual prostration, albuminous urine, yellowness of conjunctivæ or skin, and having no positively authenticated history of previous attack of yellow fever.

Group 3.—A person has a fever of one paroxysm, albuminous urine, black vomit, suppression of urine, general hemorrhagic tendency under circumstances where exposure to infection is a possibility.

II. *Suspicious cases of yellow fever.*—The following symptoms, associated with a fever of one paroxysm, in a patient who has apparently been exposed to infection, and has never had yellow fever, shall be held to justify in either of the six following cases a suspicion of this disease, viz.:

1. Suddenness of attack either with violent pain in the head and back, injected eyes and face, or with marked congestion of the superficial capillaries.
2. Want of that correlation between pulse and temperature usual to other forms of fever.
3. Albuminous urine.
4. Black vomit.
5. General hemorrhagic tendency.
6. Yellowness of the skin.

The following cases shall also be deemed suspicious:

7. Any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not yellow fever.
8. Any case respecting which efforts are made to conceal its existence, full history, and true nature.

In the event of death of a suspicious case a postmortem examination should be made, when practicable. Both before and after death, yellow fever is specially and preëminently characterized by the fact that it is par excellence a hemorrhagic fever, marked by capillary congestion and its sequelæ, hence postmortem evidence of a general hemorrhagic tendency in internal organs, especially in the digestive, in preference to the urinary tract, shall be held to confirm the suspicion.

The following conditions shall be held to justify a *suspicion of cholera* and to require from sanitary au-

thorities the same preventive treatment as if known to be cholera:

1. Any case of disease resembling cholera and attended with "rice water evacuations," shall be reported and treated either as cholera or as a suspicious case.

2. Any case respecting which reputable and experienced physicians may disagree as to whether the disease is true Asiatic cholera or not, shall be reported and treated as suspicious.

3. Any case rumored to be cholera, and respecting which efforts are made to conceal its existence, full history, and true nature, shall be reported and treated as suspicious.

4. Any notable and exceptional increase in the number of cases of, and of deaths by, such bowel disorders, as cholera morbus and diarrhœa, shall be promptly reported.

Sanitary inspection of steamboats carrying passengers and freight from the Gulf ports into the interior, in the case of an outbreak of cholera or yellow fever.

Proposition 1.—Every captain or commanding officer shall keep in a book of permanent record the sanitary history of his steamboat. Such captain or commanding officer, before leaving a seaport city or town, shall obtain a certificate from a medical inspector, which certificate shall be entered upon and form a part of said record, certifying that he has personally examined the steamboat, and that all the rules and regulations adopted by this Council, relating to the cleansing and disinfection while at the docks and wharves of such city or town, have been complied with. Said certificate shall also state that the cargo of freight, of whatever description, is in good sanitary condition, and may be safely transported to its point of destination.

Proposition 2.—The captain or commanding officer shall daily enter upon this record all facts relating to the health of the passengers and crew, and the amount and kind of sanitary cleansing during the passage, and such captain or commanding officer shall verify by affidavit, at the time of inspection, the correctness of the daily record.

Proposition 3.—The reinspection of said boat shall be required only at the point of destination (except as hereinafter provided), at which point the medical inspector shall examine, before she discharges her cargo, the sanitary record of the boat and the boat itself. If such record has been neglected, and the boat is in a bad sanitary condition, the medical inspector shall require proper sanitary cleansing and disinfection before the cargo is discharged or a new cargo is put on board. On the return passage the same rules apply.

Proposition 4.—All boats navigating the Mississippi River shall undergo inspection and reinspection, in the same manner as above provided, upon arrival at New Orleans, Vicksburg, Memphis, Cairo, St. Louis, and the point of destination.

Boats navigating the Ohio River shall undergo a like inspection and reinspection at Evansville, Louisville, and Cincinnati.

Proposition 5.—Whenever cholera or yellow fever prevails at any of the Gulf ports, the medical inspector shall certify on the record the precautions that have been taken, and the danger to be apprehended from cargo, passengers, and crew. The reinspection must be made at least one mile from a town, at a point suitable for the care of the sick, detention of the well, and the disinfection and cleansing of cargo and boat.

Proposition 6.—The foregoing rules and regulations shall also apply to tugs, tows, and barges.

Proposition 7.—River craft found infected, or suspected of infection, shall be promptly isolated and cared for at the nearest quarantine and refuge stations, of which an adequate number shall be provided for on the Mississippi River and its chief tributaries.

Sanitary supervision of railroads, and of travel and traffic by railroads during an epidemic of cholera or yellow fever.

Proposition 1.—Whenever a railroad train departs from an infected station, no person with cholera or yellow fever shall be allowed to take passage on such train. The baggage from such infected station shall be thoroughly disinfected before leaving such railroad station, by the use of the bichloride of mercury. At a point not less than fifty nor more than seventy-five miles from the point of departure from an infected place, there shall be an entire transfer of passengers and baggage to another train of cars, which train shall never enter an infected district. This transfer shall be made under the supervision of a medical officer. No person with cholera or yellow fever shall be allowed to proceed on this train, but shall be returned to the point of departure, or be treated in hospital at the place of transfer.

Your committee further recommends that a special committee of three on general sanitation, and the details of precautionary measures for the prevention of epidemic diseases, and especially of Asiatic cholera, be appointed by the Sanitary Council, with power to publish in behalf of the Sanitary Council.

The report was received and ordered published as the report of the Council.

On motion of Dr. Kedzie, in compliance with the report, Drs. Rauch, Holt, and Thompson, of Kentucky, were appointed as the Committee on General Sanitation.

On motion of Dr. Chaillé, the following resolution was adopted:

Resolved, That the Secretary request from the Chairman of the Committee on Disinfectants, appointed at the last meeting of the American Public Health Association, a plain, practical paper on disinfection and disinfectants for popular use and distribution, to be furnished to the Chairman of the Special Committee of this Council on General Sanitation.

At the election of officers for the ensuing year, Dr. Pinckney Thompson, of Kentucky, was elected President, and Dr. John H. Rauch, of Illinois, Vice-President and Secretary of the Council.

The American Journal of the Medical Sciences.—Our venerable contemporary, *The Edinburgh Medical Journal* (March, 1885), in speaking of the career of the American publishing house now known as Lea Brothers & Co., says, "Its imprint will be found on the works of many of the most notable of our professional brethren in America, and its famous periodical, *The American Journal of the Medical Sciences*, of which the late Dr. Isaac Hays was editor for more than half a century, has been eminently instrumental in gaining for American medicine a world-wide respect."

THE INDEX MEDICUS.—We are in receipt of a circular from Drs. Billings and Fletcher, announcing that Mr. George S. Davis, of Detroit, has undertaken to continue the publication of the *Index Medicus* on the same general plan, and with the same regard to typographical accuracy and finish, as heretofore.

On account of the delay required to perfect this arrangement, the first number of the journal for the current year will comprise the literature of January, February, and March, after which it will appear monthly as usual.

At the end of the year, in addition to the usual annual index of names, subscribers will be furnished with an index of subjects to the volume.

So many expressions of regret and urgent remonstrances in regard to the threatened discontinuance of the *Index Medicus* have been made, that the profession is to be congratulated on Mr. Davis's public-spirited determination to carry on the enterprise in spite of the fact that thus far it has not been pecuniarily remunerative.

It is requested that all exchanges, and books and pamphlets for notice, be sent to *The Index Medicus*, Washington, D. C.

STARLING MEDICAL COLLEGE.—The Thirty-eighth Annual Commencement of this institution was held at Columbus, Ohio, on March 4th, and the degree of M.D. was conferred on thirty graduates. The medical class, we are informed, was one-fifth larger than last year.

THE COLLEGE OF PHYSICIANS AND SURGEONS OF BALTIMORE, on the 13th inst., graduated a class of 154.

THE WOMAN'S MEDICAL COLLEGE OF PHILADELPHIA held its annual commencement on the 11th inst., and conferred the degree of M.D. on twenty-two candidates. The valedictory address was delivered by Dr. W. W. Keen, Professor of Surgery.

OVARIOTOMY.—On February 8, DR. E. MARTELLI, at the Hospital of Novara, successfully performed ovariotomy upon a woman aged 46, who had previously been operated upon two years ago. Primarily the left, and latterly the right ovary, was the seat of disease.

LAPAROTOMY.—PROF. A. FASSANO recently removed a fibro-sarcoma five pounds in weight from the right ovary without Listerian precaution. On the sixteenth day the woman had recovered.—*Gazetta Med. di Torino*, Feb. 15, 1885.

PLANS FOR THE NEW VIENNA HOSPITAL have already been determined by the Sanitary Committee, and approved by the Government authorities. It will be constructed according to the pavilion system, with all modern improvements and appliances, at an estimated cost of two million gulden.

PROFESSOR HYRTL will complete his half century in medicine during this month, and we learn that the Senate of the University and other learned bodies in Vienna are making arrangements to celebrate the event, and present their congratulations to the venerable anatomist.

PROF. NUSSBAUM.—On the 6th of January, the anniversary of the twenty-fifth year of service of Prof. Nussbaum as University Professor and Chief Physician of the City Hospital, was celebrated in Munich. The Burgomaster and representatives of the civil and military physicians delivered congratulatory addresses, in which due appreciation of Dr. Nussbaum's professional ability and private character was manifested.

DEATH OF PROF. FRERICHS.—A Berlin cablegram dated March 14, records the death of Dr. Frederick Theodore v. Frerichs, the distinguished medical professor and author. He was born at Aurich, in Hanover, March, 14, 1819, and was educated at Göttingen. He occupied a chair at the University of Kiel, then at Breslau, and in 1859 was called to the University of Berlin. During the Franco-German war he was Physician-in-chief of the army. In 1854 he received from the King of Prussia the decoration of the Red Eagle, and the title of Privy Councillor. Dr. Frerichs contributed extensively to Wagner's "Dictionary of Physiology," to Liebig, Poggendorf & Woehler's "Dictionary of Chemistry," was the author of a well-known work on the Diseases of the Liver, and one of the Editors of the *Zeitschrift für Klinische Medicine*. He was a man of fine ability, and his death a serious loss to German Medicine.

ON MALIGNANT ENDOCARDITIS.

Delivered at the Royal College of Physicians, London, on Tuesday, March 3, 1885.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

LECTURE II.

IN considering the *symptoms* of endocarditis, it is important to bear in mind the manifold conditions under which the disease may develop. A limited number of cases may be grouped together as forming a primary, substantive disease; but in the great majority the affection is either an associated pathological state, or is of the nature of a secondary malady arising in the course of some other disease.

In the primary cases, individuals in perfect health may be attacked, or, more frequently, the disease affects those with chronic valvular endocarditis, with perfect or failing compensation. When the affection occurs after an injury, or in the puerperal state, the cardiac condition may be regarded as part of the general sepsis, and is of the same nature as the pyæmic foci and the inflammation of serous membranes. The existence of the endocarditis in these cases appears to have no special influence on the disease.

When the endocarditis supervenes in the course of some particular affection, as rheumatism or pneumonia, it is usually a secondary process, though, indeed, it may be regarded as directly produced by the causes which have excited the original diseases.

The different modes of onset, and the extraordinary diversity of symptoms which may arise, render it very difficult to present a satisfactory clinical picture. The general symptoms are those of a febrile affection of variable intensity, which may be ushered in, like any acute fever, with rigors, pain in the back, vomiting, headache, etc. Arising in the course of some other disease, there may be simply an intensification of the fever, or a change in its features. The pyrexia is constant, but variable in type and intensity, and more likely than any other symptom to lead to misinterpretation. Prostration of strength, delirium, sweating, and other signs of severe constitutional disturbance are usually present.

Cardiac symptoms may be marked from the outset; pain, palpitation, sense of distress, and murmur; in many instances, there has been old valvular disease, but in a considerable number of cases the heart symptoms remain in the background, hidden by the general condition, and giving no indication; or they may be so slight that they are not even detected on special examination.

The embolic processes give a special prominence to local symptoms which may divert attention from the general malady. Thus delirium, coma, or paralysis may arise from implication of the brain or its membranes; pain in the side and local peritonitis from involvement of the spleen; bloody urine and pain in the back from affection of the kidneys; loss of vision from retinal hemorrhages; and suppuration in various organs or gangrene from the distribution of emboli.

So diverse are the features of malignant endocarditis, that a consideration of the symptoms is greatly facilitated by arranging the cases in groups, according as they display special characters. Dr. Kirkes, in 1852, called the attention of the profession to the occurrence of a typhoid-like condition in acute endocarditis, and he subsequently pointed out the fact that inflammation of the valves might lead to pyæmia. The investigations of Charcot and Vulpian,[1] of Virchow,[2] of Jaccoud,[3] and others, gradually led to the recognition of these two great types of the disease. Of late, still further separation has been made of the cases with features closely resembling ague or intermittent, and also of cases in which the cardiac symptoms are most prominent, and I shall call attention to certain cases in which the symptoms are those of an acute affection of the cerebro-spinal system.

And first let me direct your attention for a few moments to those cases in which the endocarditis is merely a part of the septic or pyæmic state, the result of an external wound, a puerperal process, or an acute necrosis. Somewhat over 18 per cent., of the cases I have analyzed were of this nature, the majority of them occurring in connection with puerperal fever, 11 per cent.; the others in association with various wounds and injuries, or acute necrosis of bone. The puerperal cases appear most frequent after abortions, and the first symptoms usually develop within a week or ten days of delivery, beginning with rigors and fever, and running a course not essentially different from ordinary puerperal septicæmia or pyæmia without endocardial complication. Sometimes the onset of the symptoms may be much delayed, and the patient up and about her duties when the attack comes on. Usually, there is local inflammation of uterus or ligaments; membranous —diphtheritic—endometritis, and phlebitis are common. Occasionally there may be no special affection of the generative organs, as in a very severe case reported by Dr. Moxon,[4] in which there was extensive endocarditis of the right heart, and sloughing patches in the lungs. The woman had been delivered within the month, and the uterus appeared in a state normal for the period. The endocardial lesions are not necessarily ulcerative, but may be vegetative, and occasionally suppurative. It is very evident, from the records, that valves with

[4] Pathological Society's Transactions, xxi.

sclerotic changes are most often affected. The visceral lesions are always suppurative, but do not appear to be more numerous than in cases of puerperal sepsis without endocarditis. The heart-symptoms may be completely masked by the general condition, and the attention may be directed to them only by the occurrence of embolism. In this connection, it may be remarked that malignant endocarditis may attack pregnant women, and run a rapid course leading to abortion. In two cases of this kind, Litten[1] found no differences in the clinical features or anatomical condition, as regards valves and metastases. In other instances, there may be rigors, sweats, and irregular fever, leading to abortion, without the occurrence of any suppurative foci, as in a case reported by Guyot.[2] Dr. Trueman, of Maccan, New Brunswick, has also sent me notes of a case which developed during pregnancy.

The cases of ulcerative endocarditis in traumatic and operative septicæmia are of a similar nature, but do not appear to occur so frequently as in the puerperal condition. Many of the cases occur after very slight injuries, as paring a hangnail or a corn, a sloughing pile, passage of a sound through a stricture. There are usually suppurative infarcts in the lungs; and even with extensive ulcerative changes in the left heart, the pyæmic foci may be all in connection with the venous system and right heart. This was well illustrated in the case of a man, aged 25, who was admitted to the Montreal General Hospital, May 31st, with a wound of the radial artery. Phlebitis followed, and cellulitis of the arm, rigors, septic pneumonia, thrombosis of the femoral vein, and symptoms of pyæmia. At the necropsy, there were numerous foci in lungs, and a suppurating thrombus in femoral vein. The mitral valve presented, on the ventricular face of anterior segment, a patch, the size of a sixpence, swollen and grayish-white in color, and opposite to it on the auricular face was an ulcer big enough to contain a small pea. There was another also on the wall of left auricle. There were no infarcts in the arterial system. In these cases of puerperal and traumatic septicæmia, the right heart is more frequently affected than in any other group of cases. Thus, of the thirty-seven cases of this kind, there were thirteen in which the tricuspid or pulmonary valves were involved.

In the acute necrosis of bone or acute osteo-myelitis, a secondary endocarditis may develop, and in some instances the clinical features may strongly resemble malignant endocarditis, as was well illustrated in the case of a lad, aged 10, who died after an illness of less than a week's duration, characterized by high fever, rigors, sweats, etc. No local trouble was complained of, and at the post-mortem examination there was ulcerative endocarditis of the right side, and a purulent focus in the septum, and it was only after most careful search that the primary trouble was found in a small spot of acute necrosis of the tibia.

These forms do not strictly come within the province of the physician, but they must be taken into account in any description of malignant endocarditis. The source of the poison is very evident in the external wound; the metritis, etc., and the lesions, are chiefly in the territory of the venous system and right heart.

In the *pyæmic* group, the clinical features are of a decided pyæmic type, and here the source of infection is at the heart, and the metastatic lesions are chiefly in the territory of the arterial system, rendering very applicable the name of *arterial pyæmia* given by Dr. Wilks to this class of cases. We may recognize two types of the pyæmic form: first, the cases in which the symptoms resemble closely those of ordinary pyæmia, with rigors at intervals, sweats, and other signs of septic infection; and, secondly, an important group, in which intermittent pyrexia is a striking feature, occurring in regular paroxysms like ague, with cold, hot, and sweating stages. These forms may develop as primary independent affections, or come on in the course of rheumatic fever, pneumonia, etc. In our Montreal cases, they have not been so marked as the typhoid type. The following case, with illustrative chart, is a fair example of pyæmic symptoms due to endocarditis developing in the course of pneumonia.

M. W., aged 43, well-built man. Admitted under Dr. Ross, February 26, 1880. Served his time in the army; has had syphilis, and has quite recently had syphilitic ulcers; has also been a hard drinker. In October, 1879, he was in hospital with pneumonia, and had severe cerebral symptoms. On February 23d, severe rigor, followed by fever, cough, and pain in the side. On admission, 26th, signs of consolidation at left base. On 28th, was delirious. On the 1st, the crisis seemed to take place; temperature fell to 98°, remained low for three days, and he seemed to be doing very well At 1 P.M. on the 4th, he had a severe chill, with vomiting, and followed by sweating. On the 5th, was delirious; had another severe chill at 2 P.M., in which the temperature rose to nearly 104°. Had five stools; no indications pointing to heart. On the 6th, morning temperature normal, patient very prostrate, sweats a great deal, and there is low wandering delirium. From the 6th to the 9th, the temperature rose a degree each evening, reaching 105.3°, its highest point. Pulse over 120, and feeble. From this time until the 14th, he gradually sank, remaining unconscious. The lung-symptoms did not extend, but rather improved. The post-mortem examination revealed extensive ulcerative vegetations on aortic valves, purulent meningitis, and resolving pneumonia of left base.

The attack may be ushered in with a single rigor, or more often a series of chills, which from the outset may constitute a marked feature, and, with the sweating, prostration, and diarrhœa, give a septic character to the case. A light jaundice may develop, and still further intensify the resemblance. Sometimes the case may run on for a couple of weeks with marked typhoid symptoms, and then pyæmic features develop—rigors, sweats, etc.

But by far the most remarkable cases of the pyæmic group are those which present a marked intermittent type of pyrexia, simulating a quotidian or tertian ague. They may occur without any signs or indications of heart disease, or the symptoms may develop in individuals the subjects of chronic valvulitis. The cases are not nearly so frequent as those of the typhoid type; but they have been specially studied by Drs. Wilks,

[1] Charité Annalen, iii., Berlin.

[2] Bulletin de Soc. d'Anatomie, 1879.

Bristowe, and Coupland in this country, Lancereaux in France, Leyden and others in Germany. The paroxysms may have the absolutely typical features of intermittent; the chills, hot stage, and sweating succeeding each other with regularity; and in the intervals there may be an entire absence of the fever. The quotidian type is the most common; the tertian has occasionally been described; and in rare instances two paroxysms have recurred within the twenty-four hours. The cases may be much prolonged, even for three or four months. One of the first references I find to cases of this kind is in a foot-note to one of Dr. Ormerod's Gulstonian Lectures,[1] in which a case of Dr. Bond, of Cambridge, is narrated—an instance of chronic valvular disease, with intermittent fever and diarrhœa, two paroxysms occurring in the day. The case lasted four months. In a remarkable case (Dr. Ray) described by Dr. Wilks,[2] during a six or seven weeks' illness, rigors recurred with such regularity that a tertian ague was suspected for a time, although the patient was known to be the subject of heart disease. In some instances, the existence of ague previously has rendered the condition much more puzzling. In several of Lancereaux's cases[3] the patients had had intermittent fever a short time before; so also with one of Leyden's cases.[4] But the most extraordinary case of the kind is recorded by Dr. Bristowe.[5] A patient had ague in October, chills once or twice a day; ill for six weeks; and, after an interval of two or three weeks, they recurred in the second week of December, and continued until December 23d. She was well for a few days, and then the attacks recurred after sleeping in a cold bed, and persisted until her admission to hospital on February 12th. For the four weeks previous to entrance, the attacks came every twelve hours regularly. A murmur was noticed; but the history of ague was so clear, and the attacks so characteristic, that a suspicion of malignant endocarditis was at first not entertained. It was only after the failure of quinine and a variation in the character of the paroxysms, that a diagnosis was reached.[6] In Dr. Coupland's[7] cases the intermittent pyrexia was also well marked. In none of our Montreal cases was the aguish type very pronounced, though in one or two cases there were regularly recurring paroxysms of chills, fever, and sweating; but the conditions under which the attacks developed rendered the clinical features more like ordinary pyæmia. The majority of these cases appear to arise independently of other affections, and occur among what I have referred to as the primary class of cases, though, as already mentioned, some develop in chronic valvular disease, and others appear associated in some way with ague.

The *typhoid* type is by far the most common, and the majority of the cases present features which come under this heading. The disease may set in with a single rigor or a series of chills, most frequently the former, often a period of *malaise* or ill health has preceded the attack, and in very many instances the symptoms develop in the course of some fever. The characters of this form are irregular temperature, early prostration, and involvement of the nervous system, delirium, somnolence and coma, dry tongue, relaxed bowels, sweats, petechial and other rashes, and occasionally parotitis. Perhaps the majority of cases are mistaken for typhoid, as the heart symptoms may never be prominent, or even when sought for not found.

The following cases illustrate the chief features of this form:

Ann O., aged 36, large, well-nourished woman, admitted under Dr. Wilkins, June 5, 1881. She had been a healthy woman. Dr. Blackader saw her on the 2d, when she complained of severe pains in the back, loins, and hips, which were relieved by poultices. Pulse rapid, tongue furred, no diarrhœa. Admitted supposed to be suffering from typhoid fever. No reliable history, family or personal, could be obtained, but she had been out of sorts for four or five days previous to the onset of the attack. On admission, temperature 104°; pulse 110, respiration 52; no eruption; lungs normal; no heart-murmur; no albumen in urine. On the 6th she passed a restless night. Temperature 104°; pulse 120, dicrotic; abdomen distended; two stools. Passed eighteen ounces of urine, slightly bloody, which may have been from the menses, which began to-day. On 7th, morning temperature 103.2°; pulse weak, 120; respiration 54, shallow; loud sonorous *râles* over chest; bowels and bladder emptied involuntarily; stools frequent, high colored; patient cannot be roused. The legs and general surface seem tender, which causes her to cry out when moved. Urine drawn off by catheter contains much blood, fifty per cent. by volume of albumen, and many granular casts. Pupils unequal; head drawn to the right. Some rigidity of muscles of arms, most marked on the left; increasing coma, and death at 3.30 P. M. of the 7th, the sixth day of her serious illness. At necropsy no hypertrophy of heart; mitral valves a trifle thick, with small superficial losses of substance on both curtains. Aortic valves normal; infarcts in spleen. Numerous small hemorrhagic emboli in kidneys and throughout the intestines. Six or eight suppurating infarcts in brain, chiefly near longitudinal fissure and on median surfaces.

This case is a good example of the primary malignant endocarditis occurring in a healthy individual, and running a rapid course, with symptoms of a typhoid character. The diarrhœa was not profuse, though the intestinal lesions were well marked.

In the following instance, occurring in connection with pneumonia, the profuse diarrhœa and severe nervous prostration were very suggestive of typhoid fever.

J. H., aged 40, drayman, a large, well-built man, was admitted, May 13th, with pneumonia. He had been a pretty healthy man, though he had had two previous attacks of inflammation of the lungs. Had been in the habit of taking stimulants. Present illness began on the 11th, with the usual signs of pneumonia, for which he consulted Dr. Blackader. On admission, was delirious, temperature 105°, respiration 60, pulse 110; consolidation of lower two-thirds of right lung, with the usual physical signs of hepatization. On the 6th day,

[5] British Medical Journal, 1881.

[6] Dr. Bristowe mentioned to me, in speaking of this case, that he now regarded it as one of ulcerative endocarditis from the outset. The woman had not had ague before, and the place of her residence was not malarious.

[7] Med. Times and Gazette, 1882, vol. i.

the delirium was less marked and the temperature had fallen to 101.5°. On the 9th day, the fever was 103°, and the condition of lung remained about the same. On the 12th day, I saw him with Dr. Molson. The dulness appeared to be diminishing at the right base; I could detect no murmur at either apex or base of heart. The condition of the patient resembled closely other cases of pneumonia in which ulcerative endocarditis had developed, and I suggested the possibility in this instance. Tongue was furred, no abdominal distention; no spots; diarrhœa had come on in the past few days; stools thin, yellowish in color. Patient was dull and heavy, not actively delirious. On the 18th day, temperature rose to 104.5°, and for the next four days kept about that height. On the 20th day, diarrhœa, which had been checked, began again. On 23d day (June 1st), temperature 104.5°, pulse 96, respiration 30. Dulness diminished at right base, still evident in scapular region at lower part; moist *râles* over back of lung; rhonchi, sibilant, and sonorous, heard in front. A single large dose (30 grains) of quinine, at 4 P.M., did not affect the temperature, which at 10 A.M. was 105.5°. On 26th day, much the same, temperature was kept about 104°; two or three loose stools each day, low delirium, restless at night. For the next three days the fever was not quite so high, the diarrhœa ceased, and he became somewhat rational. Still deficient resonance in right lung behind. Respirations kept about 30, and pulse under 100. On the night of June 8th, patient very restless, required constant watching; temperature 105°; pulse more rapid, 130. On the 10th, patient more drowsy, pulse feeble, 140; large moist *râles* heard over both lungs. In the evening he had a rigor; temperature rose to 105°, and death took place on the morning of the 11th, just a month from the onset of the disease. Petechiæ had appeared on the skin during the last few days of his life.

Necropsy, five hours after death. Body not emaciated, petechiæ on skin in various regions. In abdomen, patches of dark extravasation noticed upon coils of intestines, both large and small. In thorax, right lung intimately adherent.

Heart. Subpericardial ecchymoses. Numerous petechial spots beneath lining membrane of the cavities; some of them are as large as split peas, and on section present a grayish centre, as if they were small infarcts. The mitral segments were natural looking on the ventricular surface, but on separating the edges, large masses of vegetations were seen blocking the orifice. They were attached to the auricular faces, about 2 to 3 millimetres from the edge; that in the anterior segment was about 2 centimetres in extent, and projected 12 millimetres. It was roughened on the surface. The growth on the posterior segment was smaller, irregularly divided into two bulbous portions, the surfaces of which were smooth. The aortic orifice was blocked with a clot; right anterior valve presented an enormous mass of vegetation, which occupied the entire curtain, except the edge, and infiltrated the whole thickness, appearing in the sinus as small nodular masses. Two perforations existed between the outgrowths, each about the size of a crow-quill. The posterior segment presented a flattened vegetation, which encrusted the centre of the valve, and extended to the corpus Arantii. All of these masses had the same appearance; color grayish-yellow, except where coated with adherent blood-clot; those on anterior mitral segment and on posterior aortic were roughened, and the granular substance exposed; three others presented smooth surfaces, as if covered by a thin membrane. They were soft, on section granular, uniform throughout, and the consistence of pith. Coronary arteries free.

Lungs. Right closely bound to chest-wall by old fibrous adhesions. Posterior part of organ heavy, but crepitant, except at upper part of lower lobe, which, with a band about 3 centimetres in breadth, of the lower part of the upper, and part of the middle lobes, were firm, airless, and granular on section. Color liver-red, interspersed with small opaque areas, the plugs in the air-cells undergoing fatty change. Left lung healthy.

Spleen weighed 185 grammes, pulp soft. No infarctions.

Kidneys of average size; numerous small infarcts, chiefly in cortex; small hemorrhagic areas with gray centres.

Intestines. The deeply ecchymotic patches seen externally corresponded with small infarcts situated in the submucosa, and surrounded by a zone of deeply hemorrhagic tissue, above which the gray pale glandular layer could be distinctly seen. The infarct itself was about the size of a split pea, a little elevated, on section deep red or grayish-red, not in any instance purulent, and surrounded by a zone of extravasation from 1 to 3 centimetres in diameter. They were most abundant in the ileum, about twenty in number. Peyer's glands not swollen.

Liver pale, swollen, and soft.

Brain. Vessels of pia mater full, parts at base normal. Thick, purulent lymph beneath arachnoid, covering central part of fissures of Sylvius on both sides, over both frontal lobes at anterior part, over the left intraparietal fissure, and on upper part of cerebellum, close to great transverse fissure. A good deal of serosity beneath the membranes. No infarcts in substance of brain.

In some instances, the clinical features are mixed; typhoid and pyæmic characters may alternate, as in the following case:

J. B., aged 38, admitted January 7, 1880, has been a healthy man. Ten years ago, had a severe attack of pneumonia. On the night of January 4th, he felt uneasy, and did not rest well; got feverish, and in the morning had pain in the side and cough. No rigor. Symptoms continued, and he came to hospital on 7th. On admission, temperature was 103°, pulse 128, and respirations 40. Signs of pneumonia in right lung, lower three-fourths. Characteristic expectoration. During the first week in hospital, nervous symptoms appeared; he became delirious, and passed urine and feces in bed; tongue dry; and on the 9th and 10th, there was troublesome vomiting. The temperature was irregular, ranging from 100° to 104°; the evening record usually high, but twice it was lower than the morning. Pulse 120 to 148; respirations 32 to 50. During the second week, the intensity of the symptoms abated; the temperature kept lower, not once reaching 101°. The nervous prostration continued, with tremor of whole body, and the discharges were passed involuntarily. Tongue very dry. A very disgusting fetor emanated from the body. He lay like a patient in the third week

of severe typhoid fever; took food and stimulants well. On the 19th, a painful swelling appeared in left parotid region, and he began to have chills, and sweated a great deal each day. No objective indications of heart trouble. The lung cleared very much in the third week, but the prostration continued. During the fourth week, the swelling of the parotid increased, and on February 1st an abscess was opened in this region. On 30th, there were severe chills, with blueness of face and fingertips. Much sweating, of a profuse drenching character. Became brighter after the abscess was opened, and the nervous symptoms were less marked. Temperature ranged from 98° to 103°, rising with the chills. In the fifth week, he remained in this state, with but little change, occasional chills and profuse sweats, the picture being more like severe pyæmia. In the sixth week, the prostration increased, and he lay in a heavy unconscious state. No chills, but most profuse sweats. On February 13th and 14th, the temperature rose very high, reaching 105°, and death took place on the 15th, after an illness of forty-two days.

The necropsy revealed extensive mitral endocarditis, as the only special lesion. The base of the right lung was a little firmer than the left, but not granular on section. Only one infarct found, which was in upper part of spleen. Intestines healthy; no meningitis. The parotid abscess had almost healed.

Cardiac Group.—Under this heading may be arranged, as suggested by Dr. Bramwell,[1] those cases in which patients, the subjects of chronic valve-disease, are attacked with febrile symptoms and evidences of a recent endocarditis engrafted upon the old process. I have already remarked on the great frequency with which ulcerative changes are found in connection with sclerotic endocarditis. Many of such cases present features of the pyæmic, typhoid, or cerebral types, and may be of the most acute character; but, in others, the process appears much less intense, and the course more chronic. In a considerable series of cases, the history is somewhat as follows: The patient has, say, aortic valve-disease, and is under treatment for failing compensation, when he begins to have slight irregular fever, an evening exacerbation of two or three degrees, some increase in cardiac pain, and a sense of restlessness and distress. Embolic phenomena may develop; a sudden hemiplegia; pain in region of spleen, and signs of enlargement of the organ; or there is pain in the back, with bloody urine. In other instances, peripheral embolism may take place, with gangrene of foot or hand. There may be hebetude or a low delirium. Instances such as these are extremely common; and while, in some, the process may be very intense, in others it is essentially chronic, and may last for weeks or months, so that the term malignant seems not at all applicable to them; still, in a large series of cases, all gradations can be seen between the most severe and the milder forms. Dr. Green[2] referred to a case which lasted six months, and to another in which, during eighteen months, there were attacks of irregular fever. I have known the febrile symptoms subside for weeks, to recur again with increased severity; and there are cases which render it probable that the process may subside entirely. The ulcerative destruction, in these cases, may be most extensive; and I have seen the aortic ring with scarcely a trace of valve-substance left. The process in the chronic cases is also mycotic, and it is to be carefully distinguished from the atheromatous changes. In very many instances, there is no history of rheumatic fever or other constitutional disorder; but the endocarditis appears to attack the sclerotic valves as a primary process, and a very considerable number of the most typical cases are of this kind. A good example was the following case, in which the disease attacked deformed and hardened valves, and the clinical symptoms were prolonged for nearly three months: H. M., aged 38, admitted September 8th, under Dr. Ross. Good family and personal history; has always enjoyed excellent health. A month ago had chilly feelings, fever, and sweating, with vomiting. Kept about until ten days before admission, when he took to bed, with pains at heart, and fever. On admission, marked aortic incompetency; temperature 100°; seemed dull and heavy. On 15th, there was iliac tenderness, and some diarrhœa. For the next two weeks, remained in same state, temperature rising at times to 103°. During the first week of October, the prostration increased, and there was slight delirium at night; temperature not higher than 102°. On the 14th, there was an eruption of petechiæ. From this time the temperature kept lower—100° to 101°—the delirium and prostration increased, and death took place on the 23d. Two of the aortic cusps had fused, and there were old sclerotic changes; there were recent soft grayish vegetations; spleen presented six or eight infarcts, one suppurative. These are the cases of ulcerative endocarditis which present fewest difficulties in diagnosis. The existence of the chronic heart disease excites attention; and even if compensation has previously been perfect, the ulcerative process may be the very cause of disturbing the balance and producing marked symptoms. In my experience, the existence of fever is invariable when the ulcerative processes are due to micrococci, whereas most extensive destructive changes may occur in atheromatous disease without any elevation of temperature. It may be possible that the granular detritus discharged from atheromatous foci on the valves, or on the aorta, may have irritating properties, yet, in two instances, I have met with most extensive atheromatous ulcers on valves and aorta, from which large quantities of material must have been discharged, and the patients were not febrile. Dr. Sansom,[1] however, has referred to a case of ulcerative endocarditis in which there was no elevation of temperature throughout.

The Cerebral Group.—A considerable number of cases of malignant endocarditis come under observation, in hospital practice, perhaps, for the first time, with symptoms of cerebral, or even cerebro-spinal, trouble. In three of the Montreal cases, the patients were brought to hospital unconscious, and presented the appearance of profound cerebral affection. One of the first cases I saw was of this kind. The patient, a woman, aged 29, was admitted on October 22d in an unconscious state, and no history could be obtained. On the 24th, she became partially conscious, and complained of great pain in the head and back of the neck. Symptoms of

[1] Diseases of the Heart, Edinburgh, 1884.

[2] Lancet, 1884, vol. i.

[1] The Lancet, 1884, vol. i.

slight apex-pneumonia were detected. Temperature up to 104°. On the 25th, she passed urine and feces involuntarily. There was strabismus of right eye, and commencing ulceration of left cornea. Death took place on the 26th. The symptoms were those of an acute meningitis. The post-mortem examination revealed apex-pneumonia, a patch of endocarditis on mitral, and suppurative meningitis, involving chiefly the cortex. Another case, almost the counterpart, was admitted last year, under Dr. Molson, in an unconscious state, and died eighteen hours after admission, when the necropsy revealed apex-pneumonia, extensive endocarditis, and suppurative meningitis. There may be early unconsciousness or delirium without any meningeal implication, as in a case of primary endocarditis admitted June 5, 1881. The patient may be wildly delirious or unconscious at the first visit of the medical man, as in a case narrated by Eberth.[1] Very many of these cases die within two or three days of admission, and the question of diagnosis has usually to be suspended; indeed, in looking over the records of eleven instances in which these cerebral symptoms were early, they appear to run a more rapid course than other cases.

In two remarkable cases, there was cerebro-spinal meningitis. Homolle[2] records a case of a lad who was admitted with symptoms at first like those of typhoid, and then of a marked cerebro-spinal character. There was also a pulmonary affection and endocarditis. Patient lived five days. At the necropsy, there was suppurative meningitis of brain and cord, pneumonia of one lung, and extensive ulcerative endocarditis, with old sclerotic changes.

A still more remarkable case is reported by Heineman.[3] Boy, aged 14, admitted November 19th. For two days previous he had suffered with pains in back and legs, chills, fever, loss of appetite, vomiting, and constipation; was rational on admission; tongue coated; temperature 105.2°; condition of heart and lungs negative.

November 20th: Temperature, morning, 103.4°; evening, 105.6°. Feces and urine passed involuntarily.

November 21st: A purpuric eruption noticed on the chest, then on the face, and afterwards on legs and arms. Temperature 104.8°; pulse very feeble; delirium; hyperæsthesia along the spine; no opisthotonos; pericarditis suspected. At 11 P.M. of this day, a second crop of purpuric spots came out; temperature 106°; convulsive movements. 22d, 3 A.M., second convulsive seizure, and death. At necropsy, there was purulent exudation on brain, and the meninges of cord were congested, opaque, and inflamed. Congestion of lower lobe of lungs. Recent vegetations on mitral, and near apex on anterior wall of left ventricle, a small cavity, indicative of probable abscess and destruction of tissue. Purulent serum in pericardium; kidneys presented embolic abscesses.

Certain clinical features may be specially referred to in a few words. The fever, as will have been gathered from the previous statements, is of a very variable character. Irregularity is the prominent feature; periods of low may alternate with periods of high temperature, or a remittent may become an intermittent. A remittent type is most frequently met with, but the remissions do not occur with any regularity. Occasionally there may be a continuous high fever, the thermometer not registering below 103° for a week at a time. The pyæmic and aguish types have been sufficiently noted.

The occurrence of a rash has been described by many observers, and, in some instances, has led to errors of diagnosis. The most common form is the hemorrhagic, in the form of small petechiæ, distributed over the trunk, particularly the abdomen, less often in the face and extremities. They may be most abundant over the whole body, and at times are large and present small white centres. When severe nervous symptoms are also present, the resemblance of the cases to cerebro-spinal meningitis, or typhus, may be very close. In one instance, the case was thought to be hemorrhagic variola (Duget and Hayem[1]). An erythematous rash has also been observed.

In a case of Dr. Cayley's,[3] there was a mottled red rash on the skin. Colson[3] describes a case in which the rash was erythematous, and in spots distinctly papular.

The mental symptoms may be of a very varied character. By far the most frequent conditions are low delirium, and dull, semi-conscious, apathetic state. There may be at the outset active delirium, or even maniacal outbursts. In a case of Dr. Habershon's,[4] there was a condition described as mental eccentricity. When there is extensive meningitis, there is usually a condition of deep coma.

Sweating is a very frequent symptom, and is worthy of special notice, from the peculiarly drenching character, which is, as Dr. Henry Thompson remarks,[5] second only to that of ague, and usually far beyond the average mark of phthisis or pyæmia.

The diarrhœa is not necessarily dependent on any recognizable lesion, and may not be very marked, even when the infarcts on the mucosa are most abundant. As noted in several of the cases, it may be profuse, and still further add to the resemblance which some of the cases bear to typhoid fever.

Jaundice may be present, but appears to be a rare symptom. Cases, some of which were mistaken for acute yellow atrophy, are reported by Schnitzler,[6] Gubler,[7] Luys,[8] and Mattice and Chalvet.[9]

The heart symptoms may early attract attention, from the complaints of pain and palpitation; but, as a rule, they are latent, and unless sought for are likely to be overlooked. In those cases with chronic valve disease, there is usually no difficulty, but where the affection sets in with marked constitutional symptoms, the local trouble is very apt not to attract attention. Even with extensive vegetations there may be no murmur present, or it may be variable. There are many instances on record, by careful observers, in which the examination of the heart was negative.

The *course* of the disease presents many variations, well illustrated by the records I have given; very acute cases may run their course within the week, as in the patient Ann O., already referred to, while in others the duration may be even two or three months. Except in certain cases in which the disease attacks patients the subjects of chronic valvulitis, the course is rarely prolonged beyond four or five weeks. Some cases of the pyæmic group, particularly those with intermittent pyrexia, appear very prolonged, even two or three months. The most rapidly fatal case is described by Eberth,[1] in which a man, who had enjoyed previous good health, was attacked on the evening of the 25th, with rigors, followed by high fever and rapid unconsciousness. The temperature that night, when seen by a physician, was 41° C., and the case seemed like one of typhus with meningitis. On the 27th, he was removed to the hospital, where he died at 5 P.M. Temperature was 42.4° C. There were extensive ulcers in the aortic valves, and suppurative infarcts in the brain. The duration in this case was scarcely two days. In a considerable number of instances, the disease terminates within a week or ten days.

VII.

SULPHUR DIOXIDE.

BY GEORGE M. STERNBERG, M.D.,
SURGEON U. S. A.

Vallin, to whom we are indebted for the best practical "treatise upon disinfectants and disinfection"[2] which has yet been published, says: "Sulphurous acid, obtained by the combustion of sulphur in free air, occupies almost the first place among the veritable disinfectants." (*Op. cit.*, p. 243.)

This is the deliberate judgment of one who had carefully considered the experimental evidence accessible at the time this opinion was formulated (1882).

The use of sulphurous acid gas as a disinfecting agent has come down to us from remote antiquity, and it is safe to say that no gaseous disinfectant known is more extensively used, or has a higher place in the confidence of leading sanitary authorities at the present day. So well established is the belief that the fumes of burning sulphur will destroy the infection of smallpox, scarlet fever, yellow fever, etc., that it is probable that many believers in the germ theory of disease would be disposed to abandon this belief rather than to give up their faith in the disinfecting power of sulphurous acid gas, in case the experimental evidence relating to the germicide power of this agent should be in conflict with the results of their experience.

It is the object of the present paper to present the experimental evidence for the consideration of sanitarians, and, as the subject is one of great practical importance, the paper will necessarily be one of considerable length.

Before the modern methods of isolating and cultivating pathogenic microörganisms had been perfected, various efforts had been made to determine by experiment the disinfecting power of sulphurous acid gas. One of the first of these experiments upon record is that which the Russian physicians are said to have made at the time of the pest in Moscow, in 1771. According to Dr. A. Wolff, ten cloaks (*pelisses*) which had been worn by soldiers seized with the plague, during their sickness, were exposed to fumigation (*une forte fumigation*) with sulphur and saltpetre. Ten criminals, condemned to death, were then required to wear these garments, and not one of them contracted the malady. In the absence of any control-experiment in which similar garments not disinfected were proved to communicate the disease, we cannot admit that disinfection was accomplished in this instance, as claimed by the Russian physicians, by the fumigation resorted to. The same criticism may be made with reference to most of the evidence relied upon at the present day, which is supposed to establish the value of the agent in question. It is negative in character, and we have no control-experiments. Moreover, accompanying or following the fumigation, other measures are commonly adopted, such as free ventilation and cleansing of apartments, exposure of clothing and bedding to an abundance of fresh air, etc. As in clinical experiments a fictitious value is often assigned to remedies by reason of the failure of the experimenter to recognize the influence of the *vis medicatrix naturæ*, so there is reason to believe a "disinfectant" may often establish a temporary reputation, at least, upon the real virtues of an abundance of fresh air, together with a free use of hot water and scrubbing brushes, with perhaps a judicious use of the whitewash brush in addition. These remarks are made not to throw discredit in advance upon the agent under consideration, but with a view to showing that a careful survey of the experimental evidence is necessary, and that a spirit of scientific conservatism is required when the attempt is made to estimate the value of negative evidence in a case of this kind.

In vaccine virus we have an infectious material which seems especially well adapted as a test of disinfecting power, and the inference seems justified that an agent which will destroy the specific virulence of this material may also be relied upon for the destruction of the smallpox infection. The writer applied this test in a series of experiments made in 1880 and 1881, and published in the *Bulletin* of the National Board of Health. The results obtained have been summarized by Vallin, and, as his work is before me, I quote from it as follows:

"Dougall and Baxter have shown the neutralizing power of sulphurous acid upon different kinds of inoculable virus. Both exposed for ten minutes, in an atmosphere saturated with sulphurous fumes, ivory points charged with dry vaccine virus. At the end of this time the neutralized virus was inoculated by three punctures

[1] Virchow's Archiv, lvii.

[2] E. Vallin, Médecin Principal de 1re Classe de l'Armée, Professeur d'Hygiène a l'école de Méd. Militaire du Val-de-Grace, etc. Traité des Désinfectants et de la Désinfection, Paris, 1882.

in the arm of a non-vaccinated infant; while in the other arm, at the same time, three punctures were made with ivory points charged with the same virus, but not exposed to sulphurous acid. The last-mentioned punctures were all followed by perfectly developed vesicles, the punctures upon the other arm gave no result. Unfortunately the quantity of the acid, or of sulphur burned, is not mentioned; this time, by exception, Baxter leaves us in doubt.

"Dr. Sternberg, surgeon in the United States Army, has taken up these experiments in an ingenious manner and with greater precision. This author burned a determined quantity of sulphur in a wooden box having a capacity of ten litres. He submitted to the vapors thus produced liquid vaccine virus, placed in a watch-glass, for a period of twelve hours. The following day unvaccinated infants were inoculated in one arm with the disinfected virus, and in the other with a portion of the same virus not exposed to the disinfectant.

"Liquid virus thus exposed for twelve hours to the action of the fumes from 3 centigrammes of sulphur burned in the air-chamber—that is, 24 cubic centimetres of gas to 10 litres of air, or a little more than two parts in a thousand—produced but a single vesicle, while the non-disinfected virus in the other arm gave a successful result in every instance. Upon doubling the amount of sulphur—that is, 6 centigrammes to 10 litres, or 6 grammes per cubic metre, or 5 volumes of sulphurous acid to 1000 volumes of air—and reducing the time of exposure to four hours, the vaccine still remained inactive after exposure.

"It suffices, then, to burn 5 grammes of sulphur in a cubic metre of air, in order to neutralize *liquid* vaccine, but this vaccine coagulates almost immediately upon contact with sulphurous acid gas; and this contributes, perhaps, to destroy, or to modify, its inoculability. We shall see, further on, that experiment made in spaces of such small dimensions may lead to grave errors.

"In order to disinfect dry vaccine, Sternberg found that a considerably larger quantity of sulphur was required, viz., 16 grammes per cubic metre, which corresponds with the classical proportion of one volume of sulphurous acid gas to 100 volumes of air; in this regard the experiments of Sternberg confirm those which have been obtained by many other authors."

Baxter has also tested the power of an aqueous solution of sulphur dioxide to disinfect the virus of glanders, and of an infectious form of septicæmia—induced—in guinea-pigs. Four parts of SO_2 by weight, added to 1000 parts of the diluted virus of glanders, neutralized its infective properties, as determined by inoculation experiments. The septic virus was destroyed by 3 parts by weight in 100, while 6 in 1000 failed. The time of exposure to the disinfectant in these experiments is said to have been from thirty minutes to three hours; but this is considered by Baxter to be a matter of secondary importance, and, according to him, disinfection is complete at the end of five minutes, when the virus has been intimately mixed with the disinfecting solution.

The wide limits (3 : 100 and 6 : 1000) between success and failure in these experiments of Baxter, and an evident want of precision in the conditions, especially as to time, induced Vallin, from whom we have quoted the above results, to undertake additional experiments with the virus of glanders. He says:

"I had, in January, 1881, an opportunity to repeat these experiments. A patient in the service of our colleague, M. Gaujat, at Val de Grace, was attacked with glanders—*abcès farcineux multiples*—and furnished an inoculable pus, with which Dr. Kiener produced in several animals, guinea-pigs, cats, etc., the characteristic lesions of glanders. A small quantity of this pus, obtained directly from the patient, and placed in a watch-glass, was exposed for twelve hours in a wooden box having a capacity of exactly 100 litres. Two grammes of sulphur were burned in this box, an amount which corresponds with 20 grammes per cubic metre. The following day a guinea-pig was inoculated with the disinfected virus. At the end of three months this animal remained in perfect health. Another guinea-pig, inoculated the same day with a second portion of the same virus preserved between two watch-glasses, and not disinfected, died at the end of two months with the characteristic lesions of glanders."

Additional experiments were made with the same virulent pus dried in the open air upon little squares of flannel. Inoculation with this material failed after exposure to sulphur dioxide generated by burning sulphur in the proportion of 15 grammes per cubic metre. But inoculation with the desiccated virus not exposed to a disinfecting agent also failed, and Vallin remarks that desiccation alone had perhaps sufficed to destroy the virus, as in the experiments of Galtier. Experiments were also made with pus obtained from a tuberculous abscess in a case of Pott's disease. This material was divided into two portions and placed in watch-glasses. One portion was subjected for twelve hours to the action of sulphur dioxide generated by burning sulphur in the proportion of 20 grammes per cubic metre. This pus, injected subcutaneously into a guinea-pig, produced no result. At the end of four months the animal remained in good health. The non-disinfected pus injected into another guinea-pig caused its death on the forty-eighth day. Its liver, spleen, lungs, and peritoneum, were filled with tubercle granules. Other experiments were made with pus obtained from two chancres "of doubtful nature." Inoculation with this material, after exposure to SO_2 (15 grammes of sulphur per cubic metre of space), gave no result, while the non-disinfected pus produced "characteristic pustules."

In the experiments thus far recorded the disinfecting power of the agent under consideration is fully established for certain kinds of material, and especially for vaccine virus. In my own experiments upon this material the results were extremely definite, and the conditions observed were such as to render them unimpeachable. Experiments upon original virus from various sources are especially valuable from a practical point of view, inasmuch as the results obtained are evidently reliable guides with reference to the destruction of infective virulence in the several kinds of material experimented upon, and this without regard to any theory as to the nature of the morbific agent. We know, however, that in several infectious diseases, at least, this agent is a living organism or germ. It is, therefore, a matter of importance to determine the exact germicide power of this and other agents which have been proved to be useful disinfectants, and numerous experiments have been made with this object in view. If the germ theory of disease is correct, as applied to all infectious diseases, there should be a correspondence between the results obtained in experiments with original virus and those made upon pure cultures of the

pathogenic organism to which such virus owes its infecting power. This is an interesting question in connection with the agent under consideration, inasmuch as Wernitz has shown that sulphurous acid promptly neutralizes the action of non-living ferments in comparatively small amounts, and there is therefore ground for the supposition that the specific disease poisons destroyed by this agent in the disinfection experiments above recorded were of this nature.

According to Wernitz,[1] the action of pepsine, of ptyaline, of invertine, and of diastase, is prevented by the presence of an aqueous solution of SO_2 of 1 : 1317 to 1 : 8600 (by weight); while the action of myrosine and of emulsine is neutralized by 1 : 21,000.

Wernich, of Breslau, experimenting in the Pathological Institute of Berlin, 1877, saturated strips of woollen or cotton goods with putrid liquids, and exposed them under a bell-jar containing a definite proportion of sulphurous acid gas. Then, with proper precautions, these strips were introduced into tubes containing Pasteur's culture solution, thoroughly sterilized. The development of bacteria in this fluid was taken as evidence that disinfection was not complete. The results obtained are summarized by Vallin[2] as follows:

When the strips of material were suspended for several hours under a bell-jar containing 3.3 volumes of sulphurous acid per 100 volumes of air, they were not disinfected. When the proportion of gas was increased to 7 per cent., or even to 4 per cent., the time of exposure being six hours, the strips of goods no longer fertilized culture liquids.

Schotte and Gärtner,[3] in 1880, experimented also upon the bacteria of putrefaction. In a chamber having a capacity of 40 cubic metres they placed, at various levels, shallow dishes containing culture liquids, into which putrefactive bacteria were introduced. Sulphur was burned in earthen vessels, placed about four feet above the level of the floor. When the amount burned was in the proportion of 15 grammes per cubic metre of space—an amount which gives one volume of SO_2 to 100 volumes of air—it was found that, at the end of six hours, the gas had escaped to such an extent that it was possible to enter and remain in the room, although during the entire time the doors and windows had been carefully closed. The result of the experiment was that the culture liquids exposed in the upper part of the chamber remained clear, while those placed upon the floor broke down at the end of twenty-four to thirty-six hours. When the amount of sulphur burned was increased to 28 grammes per cubic metre (about two volumes per cent. of SO_2), disinfection was complete. When the culture fluids were placed upon the shelves of a cupboard, "half-closed," and situated in the corner of the chamber, disinfection was only obtained by burning 92 grammes of sulphur per cubic metre of space.

[1] I. Wernitz, Ueber die Wirkung der antiseptica auf ungeformte Fermente, Dorpat, 1880.
[2] Op. cit., p. 254.
[3] Viertelj. f. Oeff. Gesund., 1880, l. xii. pp. 337–376.

We remark that the test of disinfection was not satisfactory in these experiments. A certain amount of SO_2 was, no doubt, absorbed by the exposed culture liquids, and these, in successful experiments, failed to break down, because of the antiseptic or restraining influence of this agent. But, to prove that the germs of putrefaction in these culture liquids were killed, it would have been necessary to inoculate fresh cultures with a small amount of this material which had been exposed to the action of a disinfectant.

Other experiments were made by the authors named, which we shall quote in the language of Vallin:[1]

"Strips of very thick woollen goods were soaked in culture liquids containing bacteria. These were dried, a proceeding which did not destroy the vitality of the bacteria, as proved by culture experiments. These strips were suspended from a cord stretched across the middle of the chamber at a level of about five feet above the floor. Half of the strips were left dry; the other half, after having been dried, were again moistened, so that they might be exposed in a moist condition to the sulphurous vapors. Our authors arrived at the following unexpected results: Even after having been exposed to the action of sulphur dioxide, produced by the combustion of 92 grammes of sulphur per cubic metre, the moistened strips caused culture liquids, in which they were placed, to break down at the end of three or four days. The dry strips exposed in the same way produced the same result somewhat sooner—*dez le je jour*. Gärtner and Schotte have concluded from this that the germs, or protorganisms, hidden in the deeper portions of the very thick woollen goods, resist strong fumigations with sulphurous acid gas, or, with other disinfectants. They arrive almost to the point of doubting the possibility of a certain and absolute disinfection, at least by the gases or vapors."

The limits of this paper admit only of a brief abstract of the elaborate experimental researches relating to the value of sulphur dioxide as a disinfectant, made by Koch[2] and by Wolffhügel,[3] under the auspices of the Imperial Board of Health of Germany, and published in the first volume of the *Mittheilungen aus dem Kaiserlichen Gesundheitsamte*.

The experiments of Wolffhügel relate to questions concerning the practical use of SO_2, the best methods of producing it, etc., while those of Koch are designed to fix its exact germicide value. In Koch's first experiments sulphur dioxide was generated by burning sulphur in a box having a capacity of 290 litres. Other experiments were made in a closed chamber. The amount of SO_2 present was estimated at the outset and at various intervals. Thus in his third experiment, in which the disinfection box was used, the amount of SO_2 was:

At first,	6.13 vol. per cent.
At the end of 24 hours,	4.88 " " "
At the end of 72 hours,	4.47 " " "
At the end of 96 hours,	3.3 " " "

In this experiment only spore-containing material was exposed in the disinfection box. This consisted of old dried miltzbrand (anthrax) blood, anthrax spores dried upon silk threads, spore-containing earth, and hay bacillus spores dried upon blotting

[1] Op. cit., p. 253.
[2] Op. cit., pp. 252–261.
[3] Ibid., pp. 188–233.

paper. The result was entirely negative, the developing power of the spores was not in any instance destroyed, even after ninety-six hours' exposure, and a mouse inoculated with the dried blood, exposed for this length of time, died promptly of anthrax.

The results obtained with material not containing spores, were more satisfactory; but still not of a nature to give confidence in this agent as a reliable disinfectant for the purposes and in the manner in which it is commonly applied. The experiments show, in the first place, that it is not safe to apply the data obtained by burning sulphur under a bell-jar, or in a tight box of small dimensions, to disinfection on a large scale, owing, principally, to the rapid loss of the gas which occurs in an ordinary apartment, with all apertures carefully closed. Thus in Koch's fifth experiment in a closed chamber, the rapid loss of SO_2 is shown by the following figures:

At the end of half an hour,	3.12	vol. per cent.
At the end of 2 hours,	1.25	" " "
At the end of 22 hours,	0.015	" " "

In Experiment No. 2, made in a box having a capacity of 290 litres, anthrax bacilli, without spores, from the spleen of a mouse recently dead, and dried upon silk thread, were destroyed by exposure for thirty minutes to SO_2 in the proportion of 1 vol. per cent.

In Experiment No. 7, also made in the box, the amount of SO_2 at the outset was 0.84; at the end of twenty-four hours, 0.55. An exposure of one hour in this experiment destroyed anthrax bacilli (still moist) upon silk thread. Four hours' exposure failed to destroy the vitality of *Micrococcus prodigiosus* growing upon potato, but twenty-four hours' exposure was successful. The same result was obtained with the bacteria of blue pus.

In Experiment No. 8, it was found that an aqueous solution of SO_2 of 11.436 per cent., by weight, did not destroy anthrax spores in twenty-four hours, but was successful in forty-eight hours. When the proportion of SO_2 was reduced to 5.718 per cent. disinfection was only accomplished after five days' immersion in the aqueous solution.

According to Arloing, Cornevin, and Thomas, sulphurous acid does not destroy the bacteria of symptomatic anthrax, which contain spores.

The Experimental results thus far recorded will perhaps prepare those who have heretofore had implicit faith in the disinfecting power of sulphurous acid, to accept without too much incredulity the following results obtained by the writer in recent experiments with this agent.

At the request of Dr. Wm. M. Smith, Health Officer of the Port of New York, I visited that city on the 9th of last January, for the purpose of applying biological tests in an experiment designed to ascertain whether it is practicable to disinfect rags in the bale. A manufacturing chemist of New York proposed to accomplish this by injecting sulphur dioxide into the interior of the bales through hollow tubes. The SO_2 had been compressed to the liquid form in copper cylinders, and being under a pressure of six atmospheres was expected to permeate the bale thoroughly when the valve was opened leading to the hollow and perforated screws introduced into it. The bale was to be placed in a closed chest of moderate dimensions, and disinfection was to be accomplished within a few minutes.

The experiment was made at the Baltic Stores, Brooklyn, in the presence of Dr. Smith, Health Officer of New York, Dr. Raymond, Commissioner of Health of the City of Brooklyn, and several other gentlemen belonging to the Health Department of New York and of Massachusetts.

The following material, which I had brought in sterilized tubes from the biological laboratory of Johns Hopkins University, Baltimore, was introduced into the bale through openings made with a pocket-knife. The depth of these openings was from two to four inches. The material to be disinfected was upon pledgets of cotton previously sterilized, which had been saturated with pure cultures of the various test-organisms. Some of these pledgets had been subsequently dried at a low temperature, others remained moist. The apertures in the bale were closed, after introducing these bits of cotton, by tamping in strips of old muslin. When these preparations had been made the bale of rags was placed in the disinfection chamber and the gas turned on. The time during which the gas was allowed to flow was three minutes and a half. The pressure, as shown by a gauge in connection with the copper cylinder, was eighty pounds at the commencement and seventy-five at the close of the experiment. The disinfection chamber was not tight, and all those in the vicinity were obliged to retire to a respectful distance to windward while the gas was flowing and for a considerable time afterward, owing to the abundant escape and stifling effect of the SO_2. It was only after an interval of twenty or thirty minutes that the disinfection chamber could be approached to withdraw the bale, and after it had remained in the open air for some time, I was almost suffocated while removing the pledgets of cotton containing the test organisms. These were at once placed, with sterilized forceps, in sterilized glass tubes, and each tube was at once plugged with sterilized cotton. In this way they were taken back to the laboratory in Baltimore, where the test of disinfection was completed by culture and inoculation experiments. The nature of the material and the result of the experiment are given in the accompanying table:

Other pledgets of cotton had been exposed in the bale, which had been saturated with tuberculous sputum, but this part of the experiment was not followed up, owing to the scarcity of rabbits for inoculation.

Soon after my return to Baltimore, I received from the manufacturer in New York, a copper cylinder, containing a liberal supply of SO_2 in liquid form. With this the following experiment was made, January 25, in a closet having a capacity of eight cubic yards. This closet, in the basement of the biological laboratory, had been constructed under the stairway as a refrigerating chamber. The walls were double and filled in with asbestos, and the door, made in the same way, was fitted to close as accurately as possible, and held closed by a strong clamp.

Number of tube containing cotton pledget.	Nature of material.	Test by cultivation.	Result.	Test by inoculation.	Result.
No. 1.	*Bacillus anthracis* containing spores (dry).	One culture tube.	Abundant development of anthrax filaments in twenty-four hours.	One rabbit inoculated subcutaneously.	Died of anthrax on third day.

No. 3.	*Bacillus anthracis* containing spores (moist).	Two culture tubes.	Abundant development in both.	One rabbit inoculated.	Survived the inoculation.
No. 4.	*Bacillus subtilis* spores (dry).	Two culture tubes.	Abundant development of *Bacillus subtilis* in both.		
No. 5.	*Bacillus subtilis* spores (moist).	Three culture tubes.	Abundant development of *Bacillus subtilis* in each.		

A sufficient quantity of the liquid SO_2 to produce ten volumes per cent., when volatilized in the closet described, was drawn from the copper cylinder into a large beaker, quickly placed upon the floor of the disinfection chamber, and the door closed. At the end of twelve hours the door was thrown open and the gas permitted to escape. The test-organisms were exposed upon little pledgets of absorbent cotton, which had been saturated with culture-fluids, containing the various microörganisms employed. Some of these pledgets of cotton had been dried at a low temperature in advance of the experiment, and others were exposed moist.

Some of the prepared bits of absorbent cotton were placed in glass tubes, open at one end and sealed at the other. Other pledgets were loosely folded in a single thickness of heavy muslin which had been sterilized by heat. The ends of these little packages were left open, so that the SO_2 might have free access to the interior. These packages properly labelled, were placed in the inside pockets of a coat, and this was suspended in the closed chamber used for the experiment. The glass tubes were placed in an open pasteboard box upon the floor of the disinfection chamber. Other pledgets of cotton, similarly prepared, were wrapped up in little bundles of cotton, weighing half an ounce each, and enveloped in a single layer of sterilized muslin. Still other pledgets were wrapped up in a woollen blanket, in such manner that they were in the centre of a compact bundle, eighteen inches long, and ten inches in diameter. The result as determined by cultivation experiments, was as follows:

Cotton pledgets exposed in glass tubes.

Micrococci from case of vaccinal erysipelas, moist, and dry. No development from the moist material, abundant development of micrococci from dry material.

Bacillus subtilis (spores), moist and dry. Abundant development of *B. subtilis* at end of twenty-four hours from both moist and dry material.

Bacillus anthracis (spores), dry. Abundant development of anthrax bacilli within twenty-four hours.

Cotton pledgets placed in coat pocket.

Micrococci from case of vacinal erysipelas, moist and dry. Two culture-tubes inoculated from each. Abundant development of same micrococci within twenty-four hours.

Bacillus anthracis (spores), moist and dry. Two tubes inoculated from each. Pure cultures of *B. anthracis* obtained in each within twenty-four hours.

Bacillus subtilis (spores), moist and dry. Two tubes inoculated from each. At the end of twenty-four hours a mycoderma of *B. subtilis* was found upon the surface of the culture liquid in each of these tubes.

The complete failure thus far made it useless to open the bundles of cotton and the rolled blanket, which were put aside for further experiments.

On the 1st of February a second experiment was made in the same disinfection chamber upon test-organisms prepared as before. In this experiment the conditions were changed by the introduction of steam into the chamber through a tube connected with a retort outside. Two litres of water were evaporated, and the steam passed into the chamber during the first four hours of the experiment. The amount of SO_2 in this experiment was increased to twenty volumes per cent.; the time of exposure was twelve hours; the result as follows:

Organisms exposed in coat-pocket.

Coat suspended from wall, and pledgets of cotton loosely folded in filter paper, with ends of packages open for free admission of gas.

B. subtilis (spores), moist and dry. Abundant development in twenty-four hours in culture fluids inoculated with the exposed spores.

B. anthracis (spores), moist and dry. Abundant development of anthrax filaments in culture-tubes inoculated with this material.

Micrococci—pure culture—from blood drawn from inflamed area in a case of erysipelas. Two dry and one moist pledget. Pure cultures of this micrococcus were obtained from all of these after exposure in coat-pocket as described.

Organisms exposed on pledgets of cotton in open tubes placed upon the floor of disinfection chamber.

B. subtilis (spores), dry and moist. Abundant development in culture fluids.

B. anthracis (spores), dry and moist. Pure cultures obtained from exposed material.

Micrococci, from erysipelas (same stock as above), two pledgets, dry. Pure cultures obtained from both.

The complete failure to destroy the test-organisms under the conditions mentioned induced me to try the following experiment:

February 2.—Pure SO_2 in liquid form was poured into a tube (experiment in duplicate) containing spores of *B. subtilis* on dry cotton. The rapid volatilization of the liquid, produced, of course, intense cold. As the tube was long and narrow, and volatilization was restrained by the low temperature, the time of contact with the SO_2 was at least ten minutes. The vitality of the spores thus brought in contact with liquid SO_2 was not impaired, as shown by culture experiments.

The experiment was repeated Feb. 5, with anthrax spores upon *moist* cotton. The result was the same. Anthrax filaments appeared in cultures inoculated with these spores at the end of forty-eight hours.

It was evidently useless to extend these experiments so far as spores are concerned; but the question remained as to the practicability of destroying pathogenic micrococci and bacilli without spores. As Koch has shown that the loss of sulphur dioxide is very rapid from a room which is carefully closed to prevent its escape, the following experiments were made in a gas-tight receptacle:

February 2.—The following named test-organisms were placed under a bell-jar, having a capacity of one gallon. The jar was sealed below by resting in a trough containing mercury. Enough liquid SO_2 to make twenty volumes per cent. was introduced into this jar, and was, of course, quickly volatilized. The time of exposure was eighteen hours; result as follows:

Micrococci (pure culture) obtained from a case of vaccinal erysipelas (culture started from drop of blood drawn from inflamed area). One moist and two dry pledgets of sterilized cotton, previously saturated with this culture, were exposed in glass tubes open at one end. Also a few drops of the culture fluid poured into a similar tube. Result negative; disinfection was complete, as proved by attempt to start cultures from the exposed organisms.

Micrococci (pure culture) from blood of woman with puerperal septicæmia (fatal case). Exposed one pledget of cotton, moist, in glass tube; and a few drops of culture fluid in the bottom of two other glass tubes; disinfection complete.

Micrococci (pure culture) from vaccine vesicle. Exposed two pledgets of cotton, moist, and one tube containing a few drops of a pure culture; disinfection complete.

Micrococcus ureæ (pure culture in beef tea). Exposed one pledget of cotton, moist, and one tube containing a few drops of culture; disinfection complete.

Having determined by this experiment that SO_2, even in the absence of moisture, may kill micrococci, a second experiment was made to ascertain whether the quantity of the disinfecting agent could be reduced, so as to bring it more nearly within practical limits.

Feb. 7.—SO_2 was introduced under bell-jar, as above described, and the following test-organisms exposed to its action for twenty hours:

Micrococci from vaccinal erysipelas.[1] Exposed two pledgets of cotton, dry, in glass tubes. From one of these, cultures of this micrococcus were obtained; cultures inoculated from the other remained sterile. Two pledgets of cotton moistened with a recent culture were also exposed. Cultures from these remained sterile. A few drops of a fresh culture placed in the bottom of a glass tube subsequently fertilized sterilized culture-fluids—failed to disinfect.

M. ureæ, exposed upon two pledgets of cotton, moist; disinfection complete.

In the above experiment the material to be disinfected, was placed near the bottom of the jar. In the following experiment a taller jar, having a capacity of five litres, was used; and the test-organisms were exposed upon a shelf near the centre of the jar. As before, liquid SO_2 was introduced in an open beaker, in a proper quantity to make four volumes per cent. The time of exposure was twenty hours.

Micrococci (pure culture) from vaccine vesicle, on cotton, moist; disinfection complete.

Micrococci, puerperal septicæmia, pure culture on cotton, moist; disinfection complete.

Micrococci, vaccinal erysipelas, pure culture on cotton, moist; failure to disinfect.

Micrococci, from vaccine vesicle, on cotton, dry, in duplicate; disinfection complete in one, failure in the other.

I have also tested the germicide power of an aqueous solution of SO_2 on the above mentioned micrococci, with the following results:

February 5.—Equal parts of a recent culture of micrococci from vaccine vesicle, micrococci from case of puerperal septicæmia, and *M. ureæ*, were added to a standard solution of SO_2 containing five per cent. by weight. The time of contact was two hours, after which two culture tubes were inoculated from each; no development occurred—disinfection complete.

7th.—The standard solution of SO_2 (five per cent.) diluted to 1 : 50 was added, in equal portions, to a pure culture of the micrococcus from vaccinal erysipelas (making the dilution 1 : 100=0.05 per cent. of SO_2 by weight, or 1 : 2000). Cultures inoculated after two hours' contact remained sterile. At the same time a solution of 1 : 100 was added to a culture of the micrococcus from a vaccine vesicle (*i. e.*, 1 : 4000 by weight); in this case disinfection failed.

10th.—The above experiment was repeated with the last-mentioned micrococcus with solutions containing 1 : 1000, 1 : 2000, and 1 : 4000, of SO_2 by weight (after admixture with the culture fluid).

The result corresponded with that previously obtained. Disinfection was accomplished by the solution of 1 : 1000 and 1 : 2000; but failed when the amount was reduced to 1 : 4000.

[1] The writer does not commit himself to the view that the micrococci from the various sources mentioned are specifically different, and the cause of the morbid phenomena in the individuals from whose blood the cultures were started; inasmuch as he has not been able to obtain any definite proof that such is the case. On the other hand, he admits that it is extremely probable that they are concerned in the development of these morbid phenomena, and are in fact pathogenic organisms.

11th.—The same result was obtained with a recent culture of the micrococcus from case of puerperal septicæmia—*i. e.*, the standard solution of five per cent., when diluted with forty-nine parts (1 : 50) of distilled water, in two hours' time destroyed the developing power of this micrococcus, while the same solution diluted to 1 : 100 (1 : 4000 of SO_2 by weight) failed to disinfect.

These results correspond with those reported by Jalan de la Croix, who found that one grain of SO_2 in 2000 of bouillon filled with growing bacteria, causes development to cease, and destroys the vitality of these bacteria. When spores were present, however, it was necessary to increase the amount to 1 : 135 (in how long a time?).

I may add, as a matter of interest, although not directly relating to our present object, that the same standard solution of five per cent. by weight, when added to culture fluids in the proportion of 1 : 250 (= 1 : 5000 of SO_2 by weight) prevents the development of all of the above-mentioned micrococci; while 1 : 500 (1 : 10,000 of SO_2) fails to prevent the development of the bacteria of putrefaction, or of the micrococcus from a vaccine vesicle, upon which organisms alone I have thus far tested the antiseptic power of this agent. These results also correspond closely with those of De la Croix, and show that sulphur dioxide ranks very high as an antiseptic.

In view of the experimental data recorded it is evident that the use of sulphur dioxide for the disinfection of spore-containing material must be abandoned. This is the conclusion of Wolffhügel[1] on the basis of Koch's biological tests, and his own experiments. He is therefore inclined to abandon entirely the use of this agent for disinfecting purposes. He says, with reference to the question of its use for material not containing spores, that the answer to this question has very little interest, from a practical point of view, as it is impossible to say in the present state of knowledge whether we have to deal with material free from spores or otherwise. Under the circumstances Wolffhügel thinks that we will do well to abandon sulphur dioxide, and to use only such methods of disinfection as will be effective without reference to the presence or absence of spores.

I am not ready to go to this length, and to recommend the abandonment of an agent which enjoys the confidence of practical sanitarians for the destruction of the infection of smallpox, of scarlet fever, of diphtheria, of cholera, and of yellow fever, upon the ground that it fails to destroy the spores of the anthrax bacillus, or of *B. subtilis*. For the truth of the germ theory has not yet been definitely established for any one of the diseases named, and Wernitz has shown the power of this agent to neutralize non-living ferments. Admitting, however, as I do, the great probability that the infectious agent in these diseases is a living germ, we have good reason for believing that spores are not formed in any one of these diseases. We must not then be too exacting with reference to this agent, until we are able to recommend something better in its place for the purposes to which it is commonly applied, viz., for the disinfection of apartments and ships.

My experiments show most conclusively that it does destroy the specific infecting power of vaccine virus dried upon ivory points, when present in the air of a disinfecting chamber in the proportion of one volume per cent., and that in aqueous solution it destroys the vitality of various micrococci in comparatively small amounts. It is even practicable to destroy these organisms dried upon pledgets of cotton by long exposure in gas-tight receptacles. But the conditions of success are such that it appears almost impracticable to conform with them in practice on a large scale, and it is evident that much of the so-called "disinfection" with this agent is a farce.

I am convinced that the percentage of SO_2 present in the disinfection chamber, above a certain limit, is of less moment than certain conditions relating to the material to be disinfected. Thus Koch succeeded in destroying the vitality of anthrax bacilli, still moist, from the spleen of a mouse, and attached to silk threads, by exposure for one hour to 0.48 volume per cent. of SO_2, in a disinfection chamber the atmosphere of which was loaded with moisture. In my own experiments with vaccine virus upon ivory points a still smaller amount (5 volumes per 1000) was effective in four hours time. Here the favorable conditions are without doubt the very thin stratum of material to be disinfected, and the fact that it is thoroughly moistened.

Admitting that, in the absence of spores, microorganisms suspended in the atmosphere, or attached to the surface of objects may be destroyed by sulphur dioxide, when generated in a sufficient quantity in a well-closed apartment, and in the presence of moisture, the question remains whether the same object may not be as well accomplished by thorough ventilation, and by washing all surfaces—walls, ceilings, floors, furniture, etc., with a 1 : 1000 solution of mercuric chloride, which we know to be promptly destructive of germs of all kinds.

DIPHTHERITIC CROUP—LIFE SAVED BY REMOVAL OF FALSE MEMBRANE FROM THE RIGHT BRONCHUS.

BY E. FLETCHER INGALS, M.D.,

PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE; AND PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMEN'S MEDICAL COLLEGE, CHICAGO;

AND

J. E. WHITE, M.D.

Patient A. A., aged five years and five months. First complained of his throat Friday, October 16, but until the following Wednesday night nothing serious was anticipated. That night the parents noticed croupy symptoms and the next morning Prof. Ingals was called and found small diphtheritic patches on the tonsils, with stridor in respiration and dyspnœa on any exertion. Bromide of potassium and ammonium with small doses of belladonna and opium every two hours were ordered to relieve the spasmodic tendency. One grain doses of calomel were given every hour to prevent further formation of false

membrane and two grains of quinine were ordered every fourth hour. Dr. Ingals was summoned again early the next morning, and fearing that an operation would be necessary, he asked Prof. D. W. Graham to accompany him. The child had passed a poor night but was then breathing better, and as there was no recession of the soft parts of the chest, an operation was not advised at that time. The child was given two grain doses of calomel every hour, and chloral was added to the antispasmodic mixture. The parents were warned of the danger and directed to telephone at once should greater dyspnœa occur.

Dr. Ignals was again summoned about noon, and at twelve o'clock, assisted by Doctors Graham and J. E. White, he opened the trachea. The patient rallied promptly after the operation and shortly afterward the pulse was found to be 130 and the temperature 102° F. The patient was left in charge of Dr. White. Breathing continued easy and there was no increase of temperature for about forty-eight hours, when a little more fever developed and some dyspnœa occurred, but it did not become severe until six or seven hours later. In the evening of the second day, about seven o'clock, Dr. Ingals was called hurriedly on account of sudden and severe dyspnœa. He found the patient gasping for breath and nearly suffocated.

The tubes had been removed by Dr. White and every effort made to clear the trachea, but nothing was found within reach of the ordinary tracheal forceps to account for the obstruction. After satisfying himself that the opening and the trachea were free, Dr. Ingals introduced a flexible tube throat forceps as low as the bifurcation of the trachea and finally into the right and left bronchi. At one time the septum between the two main bronchi was accidentally grasped, but the resistance felt enabled the operator to loosen his hold without injury to the part. Finally, when about despairing and when the patient's death seemed certain, a large plug of false membrane was drawn from the right bronchus, and the dyspnœa was immediately relieved. From that time until about two o'clock A.M. the patient did well, when dyspnœa again occurred, and again Dr. Ingals removed a plug from the right bronchus with the effect of giving immediate relief. Subsequently there was no dangerous dyspnœa. During the first two or three days after the operation, the mild chloride was given in diminished doses, and was then discontinued.

During the greater portion of the first week half a teaspoonful of alcohol was give in milk every two hours, and from eight to ten grains of quinine were given daily in two grain pills. A part of the time a stimulating expectorant was employed with decided benefit. For the first two days after the operation a steam atomizer charged with a solution of carbolic acid gr. xxx, glycerine ʒj, bicarb. sodæ ʒj to lime-water Oj, was kept running close to the bed about two-thirds of the time. Subsequently, for several days it was kept going constantly, and whenever the secretions seemed to be getting dry it was held close to the tube for a few minutes so that the steam was inhaled.

The diphtheritic membrane remained in the throat about a week. Eight days after the operation the child was still unable to breathe with the tube closed.

Two days later a smaller tube with a large fenestra was inserted, and the child was able to breathe when the tube was corked. Two days later, fourteen days after the operation, the tube was removed, and ten hours later the wound had contracted so that no air escaped. Healing speedily occurred, but the child's larynx remained sensitive to the slightest changes of temperature for many weeks.

In this case the operation was done promptly, and gave immediate relief, there being no membrane at the time below the opening into the trachea. The diphtheritic membrane, however, finally spread to the trachea and bronchi, and the time when such cases generally prove fatal—that is, between the forty-eighth and seventy second hour after the operation—this case would have been lost but for the removal of the plug of false membrane from the bronchus. Possibly many of the cases which are lost at this stage, might be saved by a similar procedure.

The indication for such procedure is severe dyspnœa, coming on rapidly or suddenly when the trachea is known to be free. Feeble respiration over one lung only might indicate the position of the false membrane.

STRANGULATED INGUINAL HERNIA. DURATION OF SYMPTOMS SIX DAYS. OPERATION: REMOVAL OF PORTION OF OMENTUM. RECOVERY.

BY WM. G. PORTER, M.D.,
SURGEON TO THE PRESBYTERIAN AND PHILADELPHIA HOSPITALS.

T. E. V., American, æt. 20, a brakeman, was admitted to the Presbyterian Hospital, in Philadelphia, on Tuesday, October 21, 1884, with a strangulated scrotal hernia of the right side, and gave the following history:

About five years ago he noticed a tumor about the size of a hickory-nut in the right groin. "It came and went," and he did not know that it was a hernia until about two years ago. He never wore a truss, and it never gave him any trouble. On the preceding Wednesday night, October 15th, while marching in a political procession, he was suddenly seized with the symptoms of strangulation. He had no movement of the bowels from the time of seizure, and had suffered with pain and obstinate vomiting, which had been of a stercoraceous character for some time previous to admission. His treatment before he came to the hospital had consisted of castor oil and morphia internally, ice locally, and taxis, all of which had failed. On admission his expression was anxious, his abdomen was tympanitic, his pulse 100, his temperature 100⅕°, his tongue was dry and covered with a yellowish fur; he was not suffering much pain, and he had vomited stercoraceous matter an hour before his admission. The symptoms having existed so long no effort at taxis was made, but the patient was at once etherized, and the operation for strangulated hernia performed. On opening the sac quite a mass of omentum and a small knuckle of intestine were found. The intestine was dark but otherwise sound, but the omentum was considerably bruised and largely

adherent to the sac. The adhesions were separated, the constriction relieved by the knife, and the bowel returned to the abdomen. A portion of omentum—about as large as an ordinary sized adult hand—which I feared would slough, was removed, and then the stump of the omentum, *including the sac*, was transfixed with a needle, armed with a double ligature, and securely tied just at its exit from the inguinal canal, the edges of the wound were brought together by a few interrupted sutures, a sufficient opening being left at its most dependent portion for drainage.

Shock was quite marked, and hypodermics of whisky were given with strong ammonia by inhalation and aromatic spirits of ammonia by the mouth as soon as he was able to swallow. The operation was performed at 5.30 P. M., and at 6.30 P. M. he had recovered from the ether and was complaining of great pain Morphia gr. ⅛ was given hypodermically, and this was repeated at 7 o'clock, and at 8.30 gr. ⅛ more was given by the mouth. The pain was now entirely relieved, and he went to sleep His pulse was 116, temperature 98°, and respiration 24. He retched somewhat after the ether, and belched wind that had a decidedly intestinal odor, but he did not vomit. The patient was kept fully under the influence of morphia. Small fragments of cracked ice were allowed and occasional hypodermics of whisky were given.

On the next day his temperature was 101°, and on the following day 102.° On the second day he passed some wind from the bowels; the only nourishment allowed was very small doses of lime-water and milk, equal parts, and he was kept fully under morphia. Warm fomentations were applied to the abdomen.

At 3 o'clock A. M., on the 24th, he had a liquid fecal movement per anum, another at 5 A. M., and another at 6 A. M. The wound gaped, and its edges sloughed somewhat; several bruised portions of skin were involved in the incision at the time of operation, these all sloughed. A charcoal poultice was applied.

The ligature from the stump of the omentum came away on the 28th, one week after the operation, the wound cleaned off and gradually granulated and cicatrized. The patient was allowed to get out of bed on the 15th of November, and was discharged cured, and left the hospital, wearing a light truss, on the 4th of December.

The points of interest about this case are the length of time which elapsed between the appearance of the symptoms of strangulation and the operation, with the recovery of the patient, the exceedingly small quantity of nourishment which is necessary to support life when the patient is kept under the influence of morphia, and the treatment of the omentum.

In regard to the first, the fact that the bowel was found in as good condition as it was after the long persistence of the strangulation, was largely due to the amount of omentum which was found in the sac, and which completely surrounded the bowel. In another case of strangulated hernia operated on a few days ago, in which the symptoms had persisted for five days previous to the operation, and in which very little omentum was found, the bowel was found to be perforated in two places.

In regard to the second point, while the symptoms of strangulation continued, and the patient was vomiting, of course little, if any, nourishment could have been absorbed, so that from the fifteenth to the twenty-first the patient was practically without food; during the night of the 21st whiskey f℥ij, milk f℥ij, and lime-water ℥j were mixed together, and a teaspoonful of the mixture given every two hours, and on the 24th of the month, nine days after the commencement of his symptoms, he was only taking in twenty-four hours twelve ounces of milk; this amount was very gradually increased, and solid food was not allowed for several weeks. The patient became very tired of his monotonous diet, but never complained of hunger during his treatment, although naturally he was a hearty eater.

In several cases in which I have adopted this method of treating the omentum, and in others in which I have seen it done, I have been much pleased with the results.

1223 Spruce Street, Phila.

MEDICAL PROGRESS.

A Rare Case of Purulent Peritoneal Exudation which Simulated Ascites; Cure by Puncture.—Dr. B. Pernice, in the *Gazetta degli Ospitali*, No. 33, 1884, records a rare case of purulent peritoneal exudation which simulated ascites. The patient was a man 25 years old. Three years previously he had fallen, and struck his belly on the right side, from which he experienced severe pain and cramp. Nevertheless in a few hours he was able to go home alone, though subsequently fever, pain in the abdomen, and vomiting followed, and he was compelled to keep his bed about a month. At the end of this time, he resumed his work, and considered himself perfectly well, inasmuch as all pain had disappeared, and his general nutrition was excellent. Shortly, however, the pain returned, and seriously interfered with his work by rendering respiration difficult. He was now compelled to enter a hospital. After remaining a month, he was discharged improved but not cured, and soon after the former symptoms returned with increased violence.

The patient's history was that of a perfectly healthy man until three years ago; since that time he had indulged freely in alcoholic drink. Examination showed a thoracic temperature of 98⅘° F. The belly was very voluminous, not painful but only slightly sensitive on deep pressure. Palpation revealed fluctuation over the whole belly, and percussion showed that nearly the whole cavity was filled with fluid, only a small zone in the umbilical region being tympanitic. Accurate deep examination was impossible owing to the tense condition of the abdominal walls, and the abundant collection of fluid. A line carried from the ensiform cartilage to the os pubis, measured 20 inches. The greatest (abdominal) circumference was 41 inches. The inferior border of the liver was not distinguishable, but the upper was normal. The spleen was also normal. Urine normal, with no trace of albumen. The fact that the man was a drunkard, rendered it probable that the fluid was ascitic. On the other hand, the traumatic origin of the disease together with the history of vomiting and fever, and the normal condition of the heart

and other organs, pointed to the existence of chronic peritonitis. Puncture was at length resorted to, and about 18 quarts of an opaque purulent fluid were evacuated, with the entire relief of the patient. The abdomen on examination was somewhat resistent, but no evidence of any abdominal neoplasm was discoverable, and the lower border of the liver was found to be normal.

Three months afterward, the patient again returned to the hospital, and 12 and 8 quarts of purulent fluid were again evacuated by puncture. He was detained some days after the operation in order to observe his condition, but there was no elevation of temperature, and he did not complain of abdominal pain.

The man shortly returned to his occupation, and, when seen some time later, had completely recovered. From the data furnished by this case, Dr. Pernice concludes that in similar conditions, puncture at an earlier stage of the disease is indicated.—*Centralbl. für die Gesammte Therapie*, February, 1885.

TREATMENT OF BROMIDROSIS OF THE FEET.—DR. J. S. STEWART, in the *Edinburgh Med. Journal* for March, 1885, recommends as the most satisfactory treatment, to have the feet thoroughly washed in hot water, then steeped for a few minutes in a solution of permanganate of potash of the strength of from 4 to 6 grains in the ounce of water. The feet are then dried, not to be again wetted until complete exfoliation of the tanned cuticle has taken place.

Hebra's lead plaster ointment is then thickly spread on strips of cloth about one inch and a half broad, and the foot covered from the toes back over the heel as high as the malleoli with these, arranged and applied like a scultetus bandage. Each toe should first be wrapped round with a strip of clean rag half an inch broad and thickly spread with the ointment. This dressing should be renewed every twelve hours with fresh rag and ointment, for a period varying from ten to sixteen days, according to the severity of the case and the thickness of the heel skin. In most cases the odor will be very much diminished by the end of the third day, and will not be perceptible by the ninth. The shedding of the skin takes place *pari passu* with the growth of the new cuticle, and may not be completed until the end of the third or even of the fourth week.

A NEW TEST FOR BILE ACIDS IN THE URINE.—DR. OLIVER, of Harrogate, has, during the past week, been demonstrating in several of the London hospitals what he believes to be a new test for the detection in the urine of the derivatives of the bile salts. It is in the form of a test solution, and also in that of test paper. The reaction of the test is founded on the physiological fact that when the bile mingles with the acid solution of peptones in the duodenum, the proteids are instantly and completely precipitated. The test solution is an acidulous antiseptic solution of peptone, and does not present to the urine a constituent extraneous to the organism. When brought into contact with a urine containing a bile-salt derivative, a precipitate resembling that of albumen when thrown down by nitric acid at once appears. By using a standard of opacity to represent the very delicate reaction induced in normal urine, Dr. Oliver showed how the quantity of the bile derivatives, as they appear in the marked deviations encountered in disease, can be readily gauged. He has, we learn, found bile acids plentifully present not only in the urine of jaundice and of other hepatic affections, but in that of several cases of anæmia (simple or idiopathic, leucocythæmic or malarial), and of other morbid conditions; and his observations generally appear to be of some clinical interest. We understand that Dr. Oliver is preparing for early publication the data he has collected.—*Lancet*, March 7, 1885.

ACTION OF THE ALKALOIDS OF QUEBRACHO.—DRS. E. HARNACK and H. HOFFMANN, in the *Zeitschrift für klin. Med.*, Bd. viii. Heft 6, 1884, give the following *résumé* of their researches on quebracho.

The bark contains four crystallizable alkaloids, *aspidospermine*, *quebrachine*, *quebrachamine*, and *aspidospermatine*, and also two amorphous alkaloids, *aspidosamine* and *hypoquebrachine*.

The writers have studied the action of these alkaloids upon frogs and mammals, and have arrived at the following conclusions:

All the alkaloids of quebracho exercise a paralyzing influence upon respiration in mammals as well as frogs, and in this respect quebrachine has a marked power of action. All the alkaloids excite a feeling of nausea; but aspidosamine alone causes vomiting. Hypoquebrachine and aspidosamine paralyze only the extremities of the motor nerves. They all paralyze directly the striated muscular fibres of frogs, but in mammals this effect is much less marked and even doubtful. In frogs the heart is rapidly paralyzed by these alkaloids, but in mammals this affect is less rapid, and usually the organ continues to beat after the complete cessation of respiration. Aspidosamine in its action upon frogs closely resembles apomorphia. This similarity in action does not obtain in man. Thus the emetic effect of apomorphia is shown after the administration of a much smaller dose than will produce vomiting with aspidosamine; and apomorphia causes violent excitement of the nervous centres, particularly the centre of respiration, whereas aspidosamine, on the contrary, quiets the respiration, and renders it superficial. The general effect which the alkaloids of quebracho have of lowering the excitability of the respiratory centre renders them of real therapeutic value, and in this respect ranks them along with morphine and hydrocyanic acid in therapeutic efficacy. They are indicated in dyspnœa depending upon disease of the circulatory apparatus to the exclusion of those originating in insufficient oxygenation or arterialization of the blood. Benefit, nevertheless, may be obtained from their use in dyspnœa due to asthma, chronic pneumonia, and intrathoracic effusions.

The alkaloids which may be best substituted for quebracho are quebrachine and aspidosamine. The latter is less energetic in its action, but is preferable on account of its special effect upon the respiration. However, it is less easily obtained pure than quebrachine, and besides has such marked emetic power, and is absorbed with so much difficulty that quebrachine or its salts is generally to be preferred.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, February 13, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 28, 1885.

PHYSIOLOGICAL EXERCISE.

"I AM no friend to violent exertion, myself," said the *Antiquary*,—"a walk in the garden once a day is exercise enough for any thinking being—none but a fool or a fox-hunter would require more."

We may not agree with Sir Walter's hero in his conception of physiological exercise; but we are equally remote from the present disposition to apotheosize the apostles of physical culture. The truth, as might be expected, lies between these extreme views. There must be a happy mean in which the balance is accurately adjusted, and exercise and repose are taken in proper measure to secure the highest efficiency of the human machine. The amount and character of the exercise best suited to produce and maintain this efficiency, are, then, the problems awaiting solution.

How far is the present enthusiasm—craze—for athletic sports, justified in human experience? The most casual inspection suffices to acquaint us with the fact that those who are required frequently to exert their utmost strength—as laborers and porters—and those fond of exhibiting their prowess as athletes, early exhaust the sources of power, and are short-lived, even if they escape the accidents due immediately to over-exertion. It is equally evident that those who reach the most advanced life are persons who have combined cheerful, continuous, even severe mental occupation with very moderate exertion of their physical powers—persons whose attention has been given to intellectual pursuits, and who have taken systematic exercise in a mild form.

Reduced to the last analysis, there are two objects to be subserved by exercise: to supply to the more rapidly circulating blood an adequate quantity of oxygen; to increase the activity of the nutritive processes, especially in the muscular system; and, as a necessary result of these, improved appetite and digestion wait upon a greater demand for aliment. It goes without saying that exercise increases the action of the heart and the frequency and depth of the respiratory movements. It is equally apparent that during active bodily movements the muscles receive and appropriate more material both for the evolution of force and the regeneration of their own structures, so that the physiological interchanges, of which they are the seat, become greatly more rapid and thorough. How much exercise, then, is needed to comply with the physiological requirements? Are athletic sports and exercises best adapted to accomplish the object in view, or will "a walk in the garden once a day" suffice? As it is evident that ordinary walking exercise will effect the results desired from the physiological standpoint, it becomes necessary to appeal to experience to decide the case of athletic games and sports.

As, indeed, the question of exercise can arise only in respect to the sedentary, and growing youths of both sexes, we have but to consider the effects of athletics on such subjects. In them the ill-results of violent physical exertion have unfortunately been too often observed not to be distinctly recognized. These results are, as all the world knows, cardiac troubles, aneurism, pulmonary emphysema, joint diseases, and other affections. The risk of such lesions is in direct ratio to the lack of preparation. Whilst it is true that graduated exercises may lead up to the most elaborate and severe feats, no amount of training suffices to obviate all the dangers of the necessary overexertion. Everybody is familiar with the history of Dr. Winship—Boston's strong man—who performed unparalleled feats of strength, but died in the thirties with some disease of the great vessels, produced by his tremendous exertions. If those who are trained in all athletic exercises experience such ill-results from their practice, what must be the consequences to the sedentary who suddenly takes on himself the performance of such violent feats. If athletics are to continue their hold on popular esteem, it is time that aptitude should be considered and a just appreciation of the dangers of overexertion should be made apparent.

For the great mass of the population, a true conception of a merely physiological exercise is of vastly greater importance than any training in athletics. It is in this direction that men and women need to turn to accomplish a higher physical development, rather than to dumb-bells, the crossbar, the trapeze, and all the paraphernalia of systematized movements. For these contrivances must, to most men and women, be either unsuited or injurious. The

present rage for athletics properly so-called, should, therefore, be discouraged, in that it leads the public mind away from physical training that may be universally employed. If special movements and contrivances therefor be accepted as the proper solution of the problem of exercise, the tendency will be, of course, to restrict such physical training to those who are in a position to avail themselves of such opportunities, whilst the mass of people will hold themselves absolved from attempting the unattainable. Within the hearing of the masses, a crusade should be preached to arouse them to the needs of an available physiological exercise. We may define this physiological exercise for children and youths of both sexes to consist in the unrestrained movements of the usual play and games, and for adults in walking, running, leaping, horseback riding, etc., within the limits imposed by the physical condition of each person.

An important element in the problem of physiological exercise is the time when it is to be undertaken. In the prescription of the physician, too often this necessary question is left to the decision of the patient; on the other hand, the advice given may be very unwise. We have known delicate valetudinarians, who had by choice, or habit, or necessity, taken a light supper in the early evening, directed to exercise before breakfast. It may be well in the case of those who have dined sumptuously at night to rid the organism of surplus and effete material, before partaking of the morning meal, but as a rule this is an inappropriate time for active exertion. To utilize the increased supply of oxygen which is the chief purpose of exercise, the best time to accomplish it is when the foods prepared by the primary assimilation, are pouring into the blood, for, then, this important agent is needed in full measure, to perfect the final changes, and to secure the elimination by the same agency—oxidation—of effete substances. If this physiological principle be truly grounded in the requirements of nature, the proper time for exercise is three or four hours after meals.

An application of the same principle may, with eminent propriety, be made to the question of work after eating. As the digestive functions require for their best performance all of the available surplus blood of the body, it is obvious that active exercise and work which divert this surplus blood to the muscles, must interfere with the proper disposition of the food, and either arrest its solution and absorption, or so interfere with these processes as to prepare only crude matters for entrance into the circulation. An application of the same principle should fix the hour for the most important meal at a time after the work of the day has been done. If, then, dinner be taken in the evening, as, for physiological reasons, seems most suitable, some active exercise is needed before retiring for the night.

An application of the same principle may equally be made to the needs of men of letters, for the work of the brain, as of the body, demands the utilization of all the available blood, since in the performance of this tidal function, now the digestive organs, again the muscles, and now the brain, require the transferable surplus for their best work, and only evil results when one function disputes with another the supply of necessary sustenance. These are trite observations, but this seems to be an occasion when their restatement is desirable.

PROPAGATION OF CHOLERA BY POLLUTED WATER.

It is now pretty generally conceded that the specific contagium of cholera is chiefly to be found in the bowel evacuations of persons suffering from this disease, and that the infecting matter must gain entrance into the intestinal canal to produce cholera in another. Infection may take place through the medium of air or food, but drinking-water is a very frequent and common means of dissemination. Since Dr. Snow first announced his views, in 1849, respecting the propagation of cholera by polluted water, founded on facts gathered at Horsleydown, Wandsworth, and other places, and subsequently confirmed by evidence in the famous and conclusive Broad Street pump case, other and abundant evidence of the most unequivocal character has been collected, which goes far to establish this opinion. Hence many of the former opponents of the theory, among them Pettenkofer, are forced to admit that this mode of conveyance of cholera does actually exist.

The evidence from India, the home of the disease, is, in the main, confirmatory of this view. Drs. Macnamara, Townsend, and Cleghorn, who have devoted special attention to the subject of cholera, have all furnished very strong proofs of the fact that the dissemination of this disease is largely dependent on the use of impure water. It is a matter of common observation in that country, that whenever the use of polluted water has been abandoned and a pure supply substituted, the disease has quickly abated. This was notably the case in Calcutta, which formerly procured its supply of drinking-water from open tanks, and, to some extent, from the Hoogly River, both of which sources were exposed to pollution. After an improved supply had been obtained, there was a marked diminution in the cases among all classes of the inhabitants.

The cities of Dantzig and Königsberg, in Germany, used to suffer equally from cholera whenever the disease made its appearance in Europe. Dantzig procured a supply of water from a new and unpolluted source and ceased to suffer from the disease, while Königsberg continued to use the old supply, and continued to suffer. During the prevalence of cholera in Holland in 1866, Dr. Ballot states that all those

towns in which rain-water alone was drunk, had either no cases of cholera or very few single cases, and these were supposed to have been imported; while, on the other hand, in those places where the water-supply was derived from the canals or wells, both highly polluted with sewage, the disease prevailed. The City of Amsterdam, which is supplied with rain-water carefully collected and distributed, had only 4 deaths per 1000, while other cities and towns supplied with water from the polders and canals had a rate of mortality of from 16.8 to 17.7 per 1000.

The outbreak of cholera mentioned by Prof. Chandler as occurring in a village near the Central Park, New York, in 1866, was traced to the polluted water of the village well. In the celebrated case of the Van Brunt Street well, Brooklyn, which was polluted by sewage, the disease spread among the fifty families supplied by it, until the use of the water was prohibited. Dr. Simon has shown, that in London, those houses supplied with polluted water from the river furnished a death-rate from cholera equal to 13 per 1000, while other houses situated under quite similar circumstances except that they were supplied with pure water, furnished a death-rate of only 3.7 per 1000. Similar examples are furnished by Frankland in the case of London, by Schifferdecker in the case of Königsberg, and by Parkes in the case of Berlin.

There is no proof that cholera may be produced by water uncontaminated by cholera evacuations, though it is probable that the use of water containing organic impurities, by causing a constant tendency to diarrhœa, and by lowering vitality, predisposes to this disease. As Dr. Wilson remarks, this much, however, appears certain, that whenever cholera evacuations make their way into drinking-water, we may expect to find the disease burst forth with the greatest virulence and fatality amongst those who use the water, and that, indeed, the endemic area will approximate with remarkable closeness to the limits of the district which it supplies.

Water specifically contaminated by cholera evacuations being the most common vehicle for the propagation of this disease, it may be stated with almost positive assurance that a town or community having a supply of pure water and a perfect system of drainage need have no dread of an invasion of cholera, even though the disease may have been brought into the place.

We have said this much with the view of calling attention to the necessity of strengthening these two prominent means of defence against the threatened invasion of cholera. We would especially caution the public against the use of water from wells in inhabited districts, which, as a rule, are grossly polluted by the soakage from cesspools and drains. The practice of obtaining a ready water-supply and a ready house-drainage in the same permeable strata is a common and most pernicious one, and it is particularly dangerous when a disease such as cholera invades a place. In many situations the only practicable method of obtaining a water-supply is by means of shallow or deep wells. In such cases the contamination of the soil by excretions should be most carefully guarded against. But in towns and cities provided with a public water-supply and a general sewerage system, pump-wells and cesspools are permitted side by side. It is an easy matter to force the abandonment of such wells, and the necessity for such action is particularly urgent at this time.

As cholera may be spread to a limited extent by other agencies, such as the air or food, it may not be out of place to remark that the most effectual means of prevention lies in the complete destruction of the infecting matter at its very issue from the body. For this purpose one drachm of corrosive sublimate with an equal quantity of common salt, dissolved in one gallon of water, is one of the most efficient disinfectants, and by its use we may prevent the infecting material from reaching the intestines of other persons, and prevent them from getting cholera.

CUNEIFORM TARSOTOMY FOR CLUBFOOT.

In the *Lancet* for February 14, 1885, may be found an abstract of a paper on the radical cure of clubfoot, read by Mr. Richard Davy before the Royal Medical and Chirurgical Society of London, in which the author records twenty-six cases of equinovarus, varus, and equinus, treated by Davies Colley's operation of excising a wedge-shaped portion of the bones composing the transverse tarsal joint. The results, briefly stated, were one death from septicæmia, or a mortality of less than four per cent.; a shortened symmetrical foot; dispensation with instruments; and locomotion on the sole. Antiseptics were not used, the open method of treating the wound having been practised, and the average stay in the hospital was seventy-seven days. Mr. Davy urged the operation in inveterate cases, and was inclined to plead for its adoption in young persons under certain circumstances.

In the discussion which followed the reading of the paper, the opinion seemed to be pretty general that Colley's operation was required in very rare cases, and that it was not indicated at all in young children. Although the procedure saves time, and tries the patience of the surgeon less than milder measures, the mortality must be far lower than four per cent. before it can obtain general recognition or replace the simpler, if more tedious, methods of treatment. Up to ten years of age, we believe, with Dr. Willard, of this city, that it is utterly unjustifiable. As Mr. R. W. Parker pointed out, the great obstacle to straightening talipedic feet is adapted

shortening of the ligaments upon the inner side and the sole of the foot. Hence, he recommends the subcutaneous division of these shortened bands in young persons, and for inveterate cases in the adult, before severer measures are adopted. In this city, where these deformities are most successfully treated, the common practice is to soften the structures of the foot for about ten days by the application of poultices, divide the plantar fascia, and then forcibly rupture the shortened ligaments by steadying the foot with the knee, grasping the limb above the ankle with the left hand, and making the necessary movements with the right hand grasping the anterior two-thirds of the foot. The limb is then placed for a few days in an immovable dressing, after which the mediotarsal joint is daily manipulated, and the limb returned to the splint. In the course of a few weeks, the varus distortion will be overcome, when the tendo Achillis is divided, through which the equinus portion of the deformity is relieved. The subsequent treatment consists in wearing the walking shoe.

There are, however, cases not only in the adult, but in older children as well, in which ordinary measures are insufficient for a cure. In such cases, cuneiform osteotomy of the tarsus more certainly overcomes the deformity than does excision of the astragalus or the cuboid bone, or of the many other operations that have been practised for that object. As shown by Lorenz, in a critical paper entitled "Die Operative Orthopädie des Klumpfusses," published in the *Wiener Klinik*, Hefte 5 and 6, 1884, the mean duration of treatment averages between six and seven weeks, and the results, so far as a useful foot is concerned, are far better than those attained by other operations. The mortality, too, is slight, since of the 91 cases which he has tabulated, only 3 died, the patient of Davy of septicæmia, that of Koeing of ulcerative endocarditis, and that of Rupprecht of diphtheria after the wound had healed, the last two being due to causes not connected with the procedure. Adding to the cases collected by Lorenz, the additional ones referred to in the discussion, by Davy, Rose, and Croft, 109 cases show only 1 death, or a mortality of less than one per cent.

FURTHER MEDICAL ADVERTISING.

Last week we called attention to the indelicacy and impropriety of a physician informing the public through the newspapers of the minute details of the progress and treatment of a case, which have been gained through his confidential relations as medical attendant. Recent developments appear to show that there is no exclusive right to this kind of newspaper notoriety.

So, doubtless, thinks the inventor of an electric osteotome, the performances of which are duly narrated in one of the issues of *The New York Tribune* of last week. We are gravely told that this is the only instrument of the kind, and that its inventor has hitherto "refrained from urging its claims on the profession until he had thoroughly demonstrated its utility," although he has "performed fifty-one distinct operations upon living subjects," with it. He, however has not refrained from giving the public the benefit of the new instrument, and to insure its due publication "a *Tribune* reporter called upon the inventor and obtained his permission to witness the operation," in which this "new instrument" was employed. As every detail of the operation is given with technical readiness, we may suppose that the reporter had friendly professional assistance. The number of the surgeon's office in New York being given, and his official positions mentioned with suitable prominence, the public are in this way invited to entrust such cases to the great inventor of the only electric osteotome.

We look now for a sharp rivalry to obtain this kind of distinction; in which it cannot be supposed that anyone will be permitted to enjoy a monopoly. As the daily newspaper, in the eager strife for sensations, is usurping the place of the medical journal, there must be a bitter contention to procure the choicest operations for the delectation of their readers, and hence every doctor who has a new instrument to describe, a bloody operation, or a loathsome case to narrate, will have his "special" at hand, and every morning we may look in the New York dailies for highly spiced professional details, furnished by the advanced apostles of "new code" ethics.

We are not justified in assuming that in every instance a physician who appears with professional details in the secular press has been privy to the publication. The ubiquitous reporter on the quest for novelties is not deterred by such a trivial consideration as medical ethics from utilizing any startling facts; but when a physician is often before the public in "locals," the impression naturally remains that he has directly contrived the publication, or has indirectly arranged to attract repertorial curiosity.

THE INDEX MEDICUS.

Last week we had the pleasure of stating that Mr. George S. Davis, of Detroit, with considerable liberality and enterprise, had undertaken to continue the publication of *The Index Medicus*, the announcement of the suspension of which, from a lack of a sufficient number of subscriptions, had been received by the profession with expressions of profound regret.

In undertaking this work, Mr. Davis incurs the

same responsibility which has resulted in an annual loss during the past six years to its former publisher, Mr. Leypoldt, but he feels that a publication which is of such inestimable value to the profession, and which is so highly appreciated by all who consult it, should not be allowed to cease, if further endeavor can make it self-supporting. In his public-spirited effort, Mr. Davis should receive the cordial encouragement and support of the profession throughout the world, for the value of *The Index Medicus* is not limited by geographical lines. We trust soon to learn that sufficient new subscriptions have been received to render its publication as permanent as it is indispensable.

THE ABORTIVE TREATMENT OF DIPHTHERIA.

In a brief communication to the *Berliner klin. Wochenschrift* for January 25, Dr. Coestes, of Biebrich, adds his testimony as regards the efficacy of the abortive treatment of diphtheria by calomel. He has recently treated five cases, including his own, by the administration of 15 grains of calomel, generally in three doses, closely repeated. Only one terminated fatally, and in that, the trachea was so much obstructed when he was called, that tracheotomy seemed inevitable. Succeeding the administration of calomel, however, with frictions of mercurial ointment and inhalations, the dyspnœa grew much less. Ultimately, however, the operation was performed, and the child died on the seventeenth day. The remaining cases all recovered, and Dr. Coestes justly says no one can take it amiss, if he, in consequence, has had his faith in the abortive treatment strengthened.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, March 16, 1885.

The President, Charles A. Leale, M.D., in the Chair.

Dr. John Shrady read a paper on

THE ETIOLOGY OF STILLBIRTHS.

In opening, he referred to a paper read by the late Prof. George T. Elliott, before the New York State Medical Society in 1867, in which the writer, after speaking of the case of the Princess Charlotte and the subsequent suicide of Sir Richard Croft, the attendant, remarked: "There is a mournful cadence in the simple word, stillbirths, which recalls many a blighted hope, many a professional regret." Statistical tables of health departments, he said, did not shed much light on the true causes of death. In the front rank of devitalizing causes, of course, syphilis was to be placed, and it had long been recognized as an agent of fœtal death, even by the oldest writers. Abortion, when this taint was present, usually took place from the fifth to the seventh month of utero-gestation. Dr. Shrady then related several very interesting cases occurring in his own practice. In one case the mother, although under active antisyphlitic treatment all through her pregnancy, expelled a putrid seven months' fœtus, and, strange to say, a very severe rupial eruption from which she was suffering, and which a gentleman well versed in dermatology pronounced incurable, entirely disappeared after the delivery. The recovery was a permanent one, and the query arose in connection with it, Was the cure coincident with the birth, or did the birth in a measure purge the maternal system?

In citing these cases, he said he desired to draw attention to the fact that the maternal system was thoroughly saturated with the syphilitic virus, and the fœtal inoculation was also necessarily complete. He believed that the female was more likely than the male to transmit syphilis to progeny. Again, without claiming too much for the iodide of potassium treatment, he could not pass over with justice the query of the late Dr. E. R. Peaslee, whether the success of ultimate maternity may not be due to the gradual wearing out of the syphilization, as manifested by the occurrence of abortions at necessarily longer intervals, say the third, fourth, and fifth months. He could recall an instance in point, that of a mother, who, after twelve expulsions of fœti of various degrees of development, crowned her hopes in her forty-fifth year by the birth of a healthy boy, at present beginning his education at a primary school. Others might, perhaps, have been saved, but for her strong opposition to the induction of premature labor. In this case chlorate of potash in combination with tincture of the chloride of iron was persistently employed during the last three months of utero-gestation.

Having alluded to other maternal dyscrasias which might be discusssed as factors in stillbirths, such as malarial and uræmic poisoning, the concurrence of eruptive fevers, the implication of vital organs, and the supervention of nervous shocks, he said that of all these, uræmia seemed to be the most prolific of danger to the fœtus. Yet even here the latter's vitality approached the marvellous. In his own experience, in cases of scarlet fever in the lying-in chamber the child born during the inoculative state of the maternal disease, finally escaped contagion entirely. Phthisis, as being essentially a devitalizing agent to the unborn, was to be doubted. On the contrary, the generative function expanded all its energies in saving the new and jeopardized life; though the child did not usually complete its first year.

Passing from the consideration of developmental to that of local causes, he said that it was proved that metritis held a prominent place as a disturber of nutrition. How this was possible could readily be seen, since the uterine mucous membrane was to the placenta what periosteum was to bone; and when metritis was chronic in form, the ovum was not likely to retain its vitality any number of months. Malformations of the uterus, although relatively rare, are likewise mentioned, he said, as productive agents in the blight of the ovum at any stage of development, but presumably at an early date. Dislocations and flexions of the womb also opened up a field of discussion, but for the present purpose had to be dismissed with a bare mention.

In considering what he termed the more debatable portions of the subject, he referred to the diseases of the placenta; quoting from Lusk that many authors dispute the very existence of such a thing, contending that the morbid changes hitherto referred to placentitis are simply due to retrogressive metamorphoses in extravasations, while others affirm its existence, assign to it etiological relations with metritis and endometritis, and describe its pathology under the heads of congestion, hepatization, and induration and suppuration. Chief among the frequently mentioned causes of stillbirths was fatty degeneration of the placenta. The term had undoubtedly been abused in the desire to offer the readiest explanation of many phenomena, or had sometimes been adopted to conceal ignorance. The question had been raised in the minds of some as to whether the fatty placenta were not a product of fœtal death, and whether it was not in accordance with the general law in all retrogrades from a higher to a lower organization, as in the case of cicatrices, where the reparative method falls away from the standard of the original structure. A certain amount of fatty degeneration was present in every placenta at about the eighth month of pregnancy, and was, in some respects, analogous to the process of involution in the uterus itself. The shadowy line dividing the *post hoc* from the *propter hoc* was yet definite enough to prevent agreement among disputants. Still, Dr. Charles A. Leale, in a paper entitled "Degenerations of the Placenta," read before the New York Academy of Medicine, had adduced some very striking instances which seemed to corroborate the affirmative side of the question. Dr. E. S. McKee read before the Cincinnati Academy of Medicine, January 19, 1885, the report of a case in which a woman had ten miscarriages, the cause of which was apparently fatty degeneration of the placenta. She was found to be again pregnant, and was placed on the chlorate of potassium, fifteen grains three times a day. A healthy boy was then born at full term. Some time afterwards she again became pregnant, and was for the second time placed upon this remedy, for a time taking as high as thirty grains three times a day. The chlorate of potassium was given constantly with tincture of chloride of iron, except when such remedies as tincture of nux vomica or bismuth were demanded on account of the gastric disturbances incident upon pregnancy. A healthy boy was again born at term.

Tubercle in the placenta, claimed as an occasional cause of fœtal death by some, was strenuously denied by Wilkes and Nixon. These joint authors claimed that those amorphous deposits which had done duty as tubercles were made up of altered blood. Among the other classified degenerations mentioned as causes were the calcareous, the fibrinous, and the waxy, as associated with leucocythæmia.

A certain class of cases are to be regarded as mechanical both in their origin and effect. To direct blows, falls, and the like many stillbirths had been attributed; but the number of mothers who escaped such a catastrophe was immensely large. Dr. Shrady said he was inclined to doubt the efficiency of these means in the production of stillbirths, certainly to such an extent as to qualify any direct testimony in a medico-legal examination. The mother, not always a passive agent in these matters, might have seized upon the coincidence as opportune; so that in accordance with the mercy of the law, which allows all doubts in favor of the accused, the real criminal might escape punishment. In these instances when the death *in utero* was deferred, occurring at length as a marasmus, perhaps a gradual detachment of the placenta by reason of an intervening blood-clot acted as much as a lethal factor as the somewhat untenable placentitis. Prolapsed funes have contributed their quota towards fœtal mortality; the usual history of the case being, that a gush of the amniotic fluid brought down the cord, with scarcely a warning pain, before the arrival of the medical attendant.

Thus far, he said, he had discussed the matter from the maternal side; but as the late Prof. Elliott intimated, there was a side to the question which had never claimed the attention it deserved, and that such could never be fully investigated except in the light of autopsies. The pathology of fœtal life was still obscure, and yet it would probably afford a clue to many a vexed question in that department of medical science. Except when a medico-legal question was raised, autopsies upon stillborn children were exceedingly rare, on account of the objections raised on the part of the family. Yet a case of suspected infanticide was on record in England in which an autopsy exonerated the accused mother by proving the existence of a diaphragmatic hernia; the small intestines being entirely lodged in the left side of the thorax, the left lung not larger than a shilling, while a hypertrophied heart compressed the right. Such autopsies, as a rule, had revealed unlooked-for conditions. Among these he referred to effusions into the serous cavities of the thorax and abdomen, endocarditis, overdistended bladder, fatty degeneration of the entire fœtus, suppuration of the thymous gland, the presence of meconium in the air-passages and stomach, atelectasis pulmonum, and umbilical hernia, containing within its sac the liver and a great part of the intestines. The condition of the brain, however, explained by far the greater number of cases, as there are liable to be met with intracranial effusions and apoplectic clots of all sizes. These cases tended to throw light upon those mysterious deaths loosely attributed to eclampsia occurring during the sleep of the mother. The subject of abnormal presentations and maladjusted diameters was purposely avoided.

DR. EDWARD G. JANEWAY said that he had not much to add to what was already known in regard to the etiology of stillbirths; but there was one condition to which he believed the author of the paper had not alluded, which might be added to the group of local causes described, viz., myxomatous degeneration of the placenta.

DR. T. H. MANLEY thought that Dr. Shrady's paper was very instructive, as far as it went; but the subject was one of such vast extent that it was utterly impossible to do justice to it in the limits of a single essay. Churchill spoke of two varieties of abortion only, the accidental and the habitual. Dr. Shrady had, he supposed, claimed as accidental those cases due to constitutional disease. There was one cause of stillbirths of which he believed no mention was made in the paper, which he thought was a very frequent one in this community, and that was the influence of malaria. In

his own practice he had seen a number of cases of abortion in which patients were suffering from various forms of malaria. It was a difficult matter to treat pregnant women affected with this poison because the very drug on which we had to rely principally in malaria was itself liable to produce abortion. He then mentioned a case of such a patient who consulted him when six months advanced in utero-gestation. He placed her on small doses of quinine, and she apparently became cured. But one month afterward he was called to see her and found that she had had an extremely violent chill, followed by high fever. Moreover, she told him that the same thing had occurred for five successive days previous. He found her very feeble and directed that her body should be sponged, and that she should be given quinine in full doses. He left her quite comfortable; but when he called the next morning he found that she had been delivered of a stillborn child. During the night, labor had set in, and, as he lived at a distance, another physician had been called in. The evening after the birth of the child the mother herself died. He related another case in which a patient suffering from malaria, miscarried at the fifth month. Becoming pregnant again, however, she was treated carefully with small doses of quinine, and this time went to full term in safety. In regard to the matter of habitual abortion, if a woman miscarried the first time she became pregnant after marriage, there was always great danger of a repetition of the occurrence.

Dr. William T. White said in regard to quinine as a cause of abortion that during a residence of more than eight years on the Isthmus of Panama, where, on account of the malarious climate, everybody was obliged to take quinine in large quantities, he had found that it was the practice to give it to pregnant women just as freely as to others, and he had never known of any bad effect to result. In New York also he was accustomed to using the drug freely in the case of pregnant women where it was indicated, and had never seen it produce premature delivery in a single instance. When asked by a member in what doses he employed it, Dr. White said that he sometimes gave it in doses of fifteen or twenty grains.

Dr. Samuel T. Hubbard related a number of cases in his practice in which syphilis had caused stillbirths. One was as follows: The disease was conveyed to the mother by nursing another woman's child at her breast. When she consulted him, she had a sore on the nipple which presented the appearances of a syphilitic ulcer, and on inquiry he found that the child which she had nursed, as well as its mother, was affected with syphilis. The patient was at once placed on vigorous antisyphilitic treatment, but, notwithstanding this, miscarried three times successively, the first time at three months, the second at five months, and the third at seven months. The treatment was continued, however, and she gave birth at term to a child, who soon died of syphilis; though ultimately she had two living and healthy children, born at full term. The husband never had syphilis.

Dr. Jacob Hartman related the case of a stillborn child in which there was considerable deficiency in the posterior portion of the cranium, which it appeared to him from certain discharges from the uterus afterward, was due to the mechanical pressure of organized blood-clots within the womb.

Dr. I. P. Oberndorfer related the case of a woman who, having in the meanwhile had several healthy children, fifteen years after acquiring syphilis gave birth, between the sixth and seventh month of pregnancy, to a stillborn child that was the subject of a well-marked bullous syphilide.

Dr. Alexander Buchanan related the case of a woman whom he was called to attend fifteen years ago. Her husband was the subject of syphilis, and she had had seven or eight abortions between the fifth and eighth month. He placed her upon the combined treatment, and after two or three years she gave birth to a healthy child at term. She afterwards left the city and about two years ago he heard that she had died of cancer of the uterus.

Dr. C. S. Wood thought that the question of malaria and of quinine in reference to abortion should have considerable discussion, and that there should be some concert of opinion in the profession as to whether quinine was really liable to give rise to this accident or not. In view of the prevalence of malarial influences in New York, it was a matter of no little importance to decide. When during his service as an army surgeon he had been stationed in a malarious district—Sacramento, he had found that the opinion of medical men there was, that while there was no other successful way of treating malaria except with quinine, the drug ought to be given in smaller doses to pregnant women. By repeating the dose every two or three hours the same quantity could be given in the twenty-four hours, as if it was administered in one or two larger doses. In his practice in New York he has seen doses of five grains of quinine bring on threatened labor pains, which would disappear when the remedy was withdrawn, and which were not reëxcited when smaller doses were given afterward. He had never seen a single instance in which anything of the kind was brought on by quinine in small doses. There was, on the whole, much less danger of causing abortion, he thought, by the use of quinine than to allow the patient to go on suffering from the devitalizing effects of malarial poisoning. The point to which he wished especially to direct attention was how to answer the question, Is quinine given in sufficient quantities to control malaria safe in the case of pregnant women, and if not, what efficient substitute have we for it?

Dr. J. R. McGregor said that he had practised for a number of years in a portion of the city which had a bad reputation on account of the malaria supposed to be ripe there, but he could not say that he had ever had any reason to believe that stillbirths were remarkably frequent in the upper part of the Island. He did not hesitate to use quinine in the case of pregnant women suffering from malaria, and he had never seen any bad results from it. The drug was eliminated so rapidly from the system that it seemed to him to be of little use to give it in small doses, and he was generally in the habit of employing fifteen or twenty grains a day, divided into two doses. The danger attributed to quinine he believed to be largely a scare, and he thought its origin could largely be traced to our homœopathic brethren, who had no substitute for it.

Dr. S. B. W. McLeod said that it seemed to him that if malaria was a recognized cause of abortion, quinine, which opposed its action, ought to be a successful preventive of abortion when malaria was present.

For his own part he never hesitated to use it freely, and so far from having met with any bad results from it, his confidence in its efficacy and safety was constantly increasing the more he employed it.

DR. JANEWAY said that he thought it would be well to call attention to the fact that a large number of stillbirths in this city resulted from a cause which had not as yet been alluded to, viz., the use of ergot by incompetent midwives. When connected with the Board of Health, he had made quite a careful investigation of this matter, and he had found that the use of ergot constituted a pretty large factor in the etiology of stillbirths in all cases attended by midwives. Another prominent factor was the fact that in difficult cases of labor the midwives usually waited too long before sending for medical assistance. These matters he considered important, in view of the fact that about one-third of all the cases of confinement in New York were attended by midwives.

THE PRESIDENT called attention to chronic obesity as a cause of stillbirths. Although the pelvic diameters might be ample, there might be such obstruction offered by the soft parts of the mother that the child could not be born alive. Several such instances had come under his observation, and in one case he had successfully delivered the patient of a living child by resorting to the induction of premature labor.

DR. SHRADY said that he had not intended to make his paper by any means an exhaustive one, and it would, perhaps, have been better to call it, "Some Points in the Etiology of Stillbirths." In regard to the matter of malaria, however, he would call Dr. Manley's attention to the fact that he had referred to it in the same part in which he spoke of uræmic poisoning. He simply mentioned it as one of the causes and did not dwell upon it, for the reason that, living as he did in a part of the city where malaria was prevalent, he might have been accused of laying too much stress on the matter. There were other causes that he might have spoken of, such as knots in the cord, the employment of instruments, careless use of the forceps, etc.; but it would have made his paper too extensive. As regards the correctness of the explanation given of the deficiency of the posterior part of the cranium in the case mentioned, he thought there might perhaps be some doubt, on account of the mobility of the fœtus in utero, and also the softness of the blood-clot in the uterus.

EXHIBITION OF A NEW AND SIMPLE APPARATUS FOR DETERMINING THE QUANTITY OF UREA IN THE URINE.

DR. CHARLES A. DOREMUS, Professor Adjunct to the Chair of Chemistry and Toxicology in Bellevue Hospital Medical College, presented a new ureometer which he had devised. It is a glass instrument consisting of a tube bent into two arms, a longer and a shorter one, at an angle of forty-five degrees to each other. The extremity of the longer arm, on which a graduated scale is marked, is closed, while that of the shorter one, which is provided with a bulb, is left open. The long arm is filled, by inclining it, with a hypobromite solution prepared according to the formula of Knap, by dissolving 100 grammes of sodium hydrate in 250 cubic centimetres of water. By means of a nipple pipette a measured volume of the urine (1 cubic centimetre) is injected slowly up the long arm by compressing the nipple. A rapid decomposition of the urea takes place, the bubbles of nitrogen rising in the long arm, while the displaced liquid flows into the bulb, which serves as a reservoir. With care the urine may be delivered at a rate that permits the decomposition to take place without loss of gas, and the graduation on the glass indicates the weight of urea in the urine used. Two forms of the apparatus were made, Dr. Doremus said: one graduated to real fractions of a gramme, the other to show grains of urea in the fluidounce of urine. The instruments were supplied by Messrs. Eisner and Amend, of Third Avenue and Eighteenth St., New York.

DR. A. FLINT, JR., said that he was glad to be able to make some remarks on the beautiful demonstration made by Prof. Doremus. It was a thing to rejoice in whenever any addition was made to the simple methods in our possession of obtaining important results, and he thought that no more important matter could be brought to the attention of the busy practitioner than such a one for determining the quantity of urea as Prof. Doremus had just presented to the Association. If looked at from a practical point, excessive accuracy in this procedure was not a matter of importance. It was useless, and worse than useless, to attempt to secure excessive accuracy in such manipulations. The important points which the practitioner usually required to know in regard to the urine of his patient were very few, and, thanks to the present achievement of Dr. Doremus, very simple means were now at his command for obtaining them all. In the first place, a ready test for sugar was afforded by the two solutions of Dr. Squibb. The method was absolutely perfect, and by means of it the absence of sugar, which was always a more delicate matter to determine than its presence, could be positively demonstrated. In the second place, no better tests for the detection of albumen were required than the cold nitric acid test, conjoined with heat, if care was taken to have the urine under proper conditions when making the examination. In this connection he mentioned an interesting case which had come under his observation as a life insurance examiner. There was some question as to whether there was albumen in the urine or not, and on the application of heat there was a slight, but distinct, precipitate. This was undoubtedly caused by phosphates, for when nitric acid was added it cleared up; but there then followed a slight precipitate which was due to albumen. With the cold nitric acid test there was, after the urine had been set aside for two or three minutes, the characteristic white zone between the nitric acid and the urine floating above it. In the third place, the question of the amount of urea arose. The practitioner wanted to know how much urea there was in the urine of his patient, so that he could judge whether the kidneys were doing their work properly in throwing off a sufficient quantity of excrementitious products. He had long felt the want of some easy way of determining this, and the apparatus which had just been exhibited seemed to him to meet the case precisely. He, therefore, regarded it as one of the most important contributions which had been presented to the profession on the subject. In conclusion, he said he should like to ask Dr. Doremus whether it was essential that the soda of the alkaline solution should be exactly in the proportion of six ounces to the pint of water.

Dr. Doremus replied that the caustic soda solution should always be in excess. The quantity of the alkali might be greater than this; but it was never to be below it. In regard to the quantity of bromine great accuracy was not necessary. The determination of the amount of urea, it was to be remembered, was only approximated by this method.

Dr. E. G. Janeway then presented two specimens which he said he thought would be of interest. The first one, which illustrated a point in doubt, was a case of

PERFORATING ULCER OF THE ŒSOPHAGUS.

It occurred in a child who, at the age of one year, was attacked with infantile paralysis, and who afterwards died of dysentery. The ulcer, which was round, and half an inch in diameter, was situated about one inch above the entrance of the œsophagus into the stomach, and not in the posterior wall, but the left lateral wall. The point of interest in connection with the case was the fact that the existence of such a peptic ulcer of the œsophagus before death had been denied; and in his recent work on diseases of the throat and nose, including those of the œsophagus, Morell Mackenzie stated that a case of his own which he had reported some time ago as "simple ulcer of the œsophagus," as well as one of Dr. Benson, was too incomplete to be relied on. Mackenzie thought they were open to the objection that the disease may have been of malignant nature, the ulcerated surface not having been submitted to the test of microscopic examination. This, however, he believed was a case of true peptic ulcer, such as was met with in the stomach, and due to the action of the gastric juice upon the mucous membrane. It was a difficult thing to prove just what changes occurred before death, and which were post mortem in a case of this kind; but the ulcer here in the œsophagus presented precisely the same appearances as those found in the stomach, which were acknowledged by all to give rise to perforation, peritonitis, and death. In the present instance there was inflammation not only of the connective tissue surrounding the œsophagus, but also of the pericardium and left pleura. Again, the odor of the parts was entirely different from the sour odor characteristic of post-mortem gastric digestion. During life, however, so far as could be ascertained, the child presented no signs of pericarditis, pleurisy, or perforating ulcer of the œsophagus.

SUDDEN DEATH IN A CASE OF TRACHEAL STENOSIS.

The other specimen, Dr. Janeway said, was from a case illustrating a rare method of sudden death. It was that of a child who had a mass of enlarged glands on the right side of the trachea, giving rise to tracheal stenosis, and died very suddenly from asphyxia. At the autopsy a cheesy gland was found at the bifurcation of the trachea, which had produced ulceration, while occluding the stenosed passage was a white mass which had undoubtedly become detached from this, but which was at first mistaken for coagulated milk. In addition, there was a fibroid induration of the upper lobe of the right lung, and a thickening around the bronchi. In connection with this case, Dr. Janeway remarked that this bronchial and tracheal stenosis was no uncommon thing, and that we should therefore be on the watch for it. Two physicians had expressed the opinion that this child had died of paralysis of the heart; but paralysis of the heart, like the term malaria, was often used merely as a convenient expression to conceal ignorance. What was believed to be paralysis could only be determined by an autopsy. When stridor was heard in connection with tracheal breathing it should always attract attention to the glands of the part. It was a fact, Dr. Janeway said in conclusion, that in childhood we could have the whole course of tuberculosis gone through with without any elevation of temperature whatever.

The President said that he had known of a case of sudden death in connection with enlargement of the thymus gland.

RHODE ISLAND MEDICAL SOCIETY.

Quarterly Meeting, held at Providence, March 19, 1885.

The President, Oliver C. Wiggin, M.D., in the Chair.

The Chair presented a communication from the American Association of Superintendents of Asylums for the Insane, asking the approval and coöperation of the different State medical societies in a proposed petition to the President and Congress of the United States for the enactment of laws to prevent the

IMMIGRATION OF THE SO-CALLED DEFECTIVE CLASSES

of foreigners,—hoping thereby to check the alarming increase of insanity in this country.

The Society voted its approval of the proposed enactments, etc.

Dr. Robert F. Noyes, of Providence, read a paper upon

ENTERIC FEVER OCCURRING IN PREGNANCY,

embracing a report of the following case:

Mrs. X., aged twenty years, between three and four months advanced in her first pregnancy, and thirteen days sick with typhoid fever, was admitted to the Rhode Island Hospital, August 19, 1883, with a temperature of 104.2°, and a pulse of 132. She was put in a private room of the hospital, and treatment by carbolic acid and tincture of iodine, with nourishment, stimulants, and sponging instituted. The next day, the fourteenth of the disease, the evening temperature was 104.8°; pulse 120.

Fifteenth day, evening temperature 104.3°; pulse 120.

Sixteenth day, evening temperature 104°; pulse 138. On this day uterine hemorrhage occurred, which threatened to be profuse, but was controlled by position and the use of ice, after which the vagina was tamponed. At this time the patient became delirious.

Seventeenth day, temperature 104.8°; pulse 140. During the day labor pains began, the tampon was removed, and at 8.15 P.M. delivery of the fœtus and placenta was accomplished, with very slight hemorrhage; the uterus contracting well. A warm, carbolized, vaginal douche was given, and the supporting and stimulating treatment continued. During the night the patient failed rapidly, her pulse became very rapid, and at times was imperceptible at the wrist. The stethoscope showed the pulse-rate to be 168 per minute. Syncope occurred several times, which was promptly treated by removing

the pillows, elevating the foot of the bed, and brandy hypodermetically.

Eighteenth day, temperature 104.4°; pulse 130. Still delirious. The carbolic acid and iodine were discontinued, and milk and brandy only were given by the rectum.

Nineteenth day, morning temperature 105.5°; pulse 144. Delirium, carphologia, subsultus tendinum, tympanites, and tracheal râles, which last-named continued for seventy-two hours, during which time the patient was nearly unconscious. As much milk and brandy were given by mouth and rectum as was possible, together with brandy hypodermetically, and opium by suppositories. Quin. sulph., grs. xl, was also given per rectum once in six hours. The tympanites was relieved somewhat by a turpentine enema, and stupes of the same on the abdomen.

Twentieth day, morning temperature 105.5°; pulse 144. Evening temperature 103.8°; pulse 140. Same treatment continued.

Twenty-first day, morning temperature 104.2°; pulse 140. Evening temperature 103°; pulse 140,

Patient sank gradually during the day. Brandy almost constantly by the mouth. Active delirium continued till midnight, when a suppository of sulph. morph., gr. ss, was given, which greatly relieved the symptoms.

Twenty-second day, morning temperature 105.2°; pulse 140. Evening temperature 102.4°; pulse 140. Condition unchanged. Same treatment.

Twenty-third day, morning temperature 104°; pulse 135. Evening temperature 102.5°; pulse 130. Condition slightly improved.

Twenty-fourth day, morning temperature 103°; pulse 138. Evening temperature 101°; pulse 138.

Tincture of digitalis, in moderate doses, was now added to the treatment.

From the twenty-fifth day, when the temperature was 99.4°, pulse 127, to November 15th, when Mrs. X. was discharged from the hospital *well*, there was a continuous but slow convalescence. Despite all precautions, a large sacral bedsore had developed, which went through its stages of sloughing, granulation, and complete cicatrization.

Dr. Noyes then quoted many authors who teach that abortion is to be expected in the vast majority of cases of enteric fever occurring in pregnancy, and gave the following opinions as to the cause of the miscarriage:

Schrœder believes that it is due to the death of the child in the uterus from excessive accumulation of heat.

Kaniesky says that a maternal temperature above 104° F. is very dangerous to the child, and Schweden coincides in this opinion; while another author considers the uterine hemorrhage which is prone to occur in typhoid fever, to be the cause of the abortion.

Returning to the case reported, Dr. Noyes remarked that his patient had a very rapid pulse. For twenty-one days it was seldom less than 130, and for seven days it was about 140, and upon one occasion it rose to 168. The delirium also was continuous for two weeks, while the temperature for eleven days was seldom below 104° F.,—the morning temperature upon three occasions going above 105°. Now, a pulse of 130, for any considerable time, with a high temperature and continuous delirium, renders the prognosis in typhoid fever very unfavorable.

Authors were again quoted as follows: Liebermeister observed 26 patients whose pulse rose above 140, and 21 of whom died. In 12 of these cases the pulse rose above 150, and of this number 11 were fatal.

Wünderlich states that death is almost certain after a morning temperature of 105.8°, and is sure to follow a morning temperature of 106.25°.

All the cases noted by Fiedler in which the morning temperature rose to 106.25°, proved fatal.

Dr. Mann, of Central Falls, reported one case of typhoid fever, the patient being five months pregnant. She aborted and recovered.

Dr. Hunt mentioned two cases one of which was fatal. In the other, the fever was very severe, but the woman recovered without aborting.

Dr. G. C. Wiggin said he had seen three of this class of cases in his practice. Two were mild, and the patients recovered, and went on to delivery at full term, In the third case the woman was delivered of a living child on the twelfth day of the fever without being conscious of her labor nor did she know that she had been delivered until several days afterwards. The child lived, and the mother recovered.

Dr. Briggs mentioned a case in which the fever ran high for three weeks, the temperature reaching 105° daily for six days. The fever subsided. Then there was a relapse with another week of fever. Labor then came on at the eighth month, and a living child was born, greatly emaciated, but it lived twelve days. The mother recovered.

Dr. A. Ballou could recall only two instances of enteric fever during pregnancy out of the four thousand confinements he had attended.

Dr. White spoke of a case that occurred at the Rhode Island Hospital. The woman was about five months pregnant, and the fever had been running several weeks, the patient seeming to have very little conciousness the greater part of the time. Suddenly a terrific intestinal hemorrhage occurred, saturating the bed and forming a large pool on the floor of the room. When the house physician, who was hastily called by the nurse, entered the room, he found the patient lying on the floor, dead. There had been no signs of abortion in the case. The child was thought to have died early in the course of the fever.

Dr. Wiggin remarked, on the general subject of typhoid fever, that he thought it was greatly to a patient's disadvantage to be moved after once prostrated by the disease, and that if he were to find himself down with typhoid fever, and in a barn, he would rather remain there and take his chances than be *transported* o a hospital or any other place.

Dr. George W. Porter of Providence, then read his

REPORT OF A CASE OF PYOSALPINX.

Mrs. T., aged twenty-seven years, was never very strong. She menstruated first when sixteen or seventeen years years old, but was never regular, the intervals being from six to eight weeks. She has been married six years, but has had no children. Has always had dysmenorrhœa, the pain being in her back, and across the lower part of the abdomen. For the last three years there has been a "burning pain" in both hips most of the time, intermittent, and coming on chiefly at night.

Five years ago she jumped several times from a

wagon body down to the ground, and at once began to have painful micturition which has been persistent ever since. She was unable to work for a year. She was first seen by Dr. Porter last October, who found slight retroversion of the uterus, and some thickening of the utero-sacral ligaments, resulting from old inflammation, for which she was treated for a short time.

Early in November, 1884, a pessary was placed, which was followed by cellulitis. In January last she began to notice pain in the left side, referred to the hip, and different from that previously experienced in the hips. It was attended by nocturnal exacerbations, but no chills. Soon after the right ovary was found to be prolapsed, and a mass existed on the left side of the uterus, which was very sensitive, and which increased rapidly in size, assuming the sausage-shape of a dilated and bent Fallopian tube.

Operation, February 14: An incision two inches long was made in the median line of the abdomen just above the pubes. Two fingers were inserted, and the left Fallopian tube drawn up. Some slight adhesions, holding the uterus and tube backwards, were broken up. As the ovary could not be found, the incision was slightly enlarged which revealed the ovary completely encircled by the distended tube which was everywhere very firmly adherent to the ovary.

A double ligature was passed through the broad ligament and tied firmly, on one side close to the horn of the uterus, and on the other, embracing the outer portion of the broad ligament. The tube and ovary were then cut away. A little pus escaped at the uterine end of the tube, but it was carefully kept from the peritoneum. There was no loss of blood except a slight oozing from the breaking up of the adhesions. The other ovary, slightly enlarged, was felt, prolapsed into Douglas's pouch. The right tube was not distended, and with its ovary was left undisturbed. The pelvis was carefully sponged out, and the abdominal wound closed by silver sutures, so placed as to bring into contact a considerable portion of peritoneum, on each side of the line of incision. The abdomen was covered with a thick layer of salicylated cotton, and firmly strapped with adhesive plaster. The spray was not used, but the hands, instruments, etc., were thoroughly carbolized. No apparent shock followed the operation. Menstruation, not due for six days, came on the second day after the operation, and continued five days. There was some pain on the right side, but none on the left. The catheter was used for a week. On the morning of the third day and on the evening of the fourth, the temperature was 100.2°, but at no other time did it exceed 100°. The pulse did not reach 100°. The wound healed by first intention. Some of the sutures were removed on the eighth day, but the deeper ones not so early, the last one remaining for two weeks. The patient returned to her home in three and a half weeks, with an excellent appetite, and gaining strength daily The operator's only regret was that he did not remove the right ovary also.

Dr. B. R. Lymonds read a paper on

RACHITIS.

The characteristic symptoms of the disease were said to be profuse sweats; a desire on the part of patients to be cool at night, causing them to throw off the bed clothes, etc; a general hyperæsthesia of the entire surface of the body; intestinal and bronchial catarrh; febrile movements; and a soft, blowing sound, synchronous with the first sound of the heart, heard over the anterior fontanelle if still enclosed. The etiology, anatomical changes, and treatment of the disease were given in detail.

DELEGATES TO THE NEXT MEETING OF THE AMERICAN MEDICAL ASSOCIATION

were elected as follows: Drs. H. Canfield, J. W. Sawyer, O. C. Wiggin, A. G. Browning, G. H. Eldredge, F. B. Fuller, Benjamin Greene, A. Ballou, George Kenyon, Job Kenyon, H. G. Miller, Charles O'Leary, G. A. Pierce, Anita E. Tyng, of Philadelphia, H. Terry, S. Hunt, W. E. Anthony, and W. J. Burge.

Dr. E. B. Smith reported a case of

CANCER OF THE INTESTINE.

The patient was a woman 44 years old, who had led a sedentary life and suffered from constipation, and attacks of intestinal colic. Toward the close of life the stomach became very irritable, and the abdomen so enormously distended by gas that the colon was punctured every other day by a fine aspirator needle. Cancer of the sigmoid flexure was diagnosticated. The intestine became wholly occupied by the disease, so that no alvine dejection occurred after November 30th, death, however, not occurring until the 12th of the following January. The autopsy revealed a hard, cancerous mass filling the region of the sigmoid flexure, and extending into the pelvic cavity five or six inches.

Dr. J. S. Hunt reported a

FATAL CASE OF EMBOLISM OF THE PULMONARY ARTERY

occurring the *thirty-ninth* day after confinement. The patient had had phlebitis with considerable tenderness in the left groin. The heart, on post-mortem examination, was found to be empty, and death was thought to have been caused by syncope

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 10, 1885.

The President, Robert F. Weir, M.D., in the Chair.

CARCINOMA OF THE TONGUE.

Dr. H. P. Sands presented a man to show the result of an operation performed three weeks ago for carcinoma of the tongue. The patient was fifty-eight years of age, formerly a colonel in the English army, of excellent constitution and in robust health until six years ago, when he fell, and soon afterwards developed symptoms of spinal trouble, supposed to be locomotor ataxia. These consisted of shooting pains in the limbs, difficulty in passing urine, and visual disturbances. Four years ago the patient, who had long been an immoderate smoker, noticed a crack on the left side of the tongue, near the tip, which afterward developed into an ulcer two years ago; the ulcer began to extend rapidly, and some local applications were made without arresting the progress of the disease. When Dr. Sands first saw the patient, about a month ago, in consultation with Dr. R. A. Caldwell, of this city, there was well-marked cancerous ulceration of the left side of the tongue. The disease ex-

tended from a point about three-quarters of an inch behind the tip to within an inch of the epiglottis. The ulceration did not extend beyond the median line, but hardened tissue could be felt beneath the surface on the right side. There was no enlargement of the submaxillary lymphatic glands. The man's general health seemed to be good, and as he suffered from severe pain, profuse salivation, and difficulty in articulation and mastication, he was desirous that an operation should be performed. The result was very gratifying, and showed how quickly patients sometimes recovered from an operation usually regarded as formidable. The procedure followed in this case was one which Dr. Sands believed to be best. When the disease is confined to the tongue both lingual arteries were tied, as a preliminary step; the tongue was then seized with a volsellum forceps, and removed with a scissors as far back as the epiglottis. The preliminary ligatures were applied to the lingual arteries in the usual way in the digastric triangle. On the left side a branch of the lingual artery was also tied,—probably the dorsalis linguæ. The effect of tying these vessels was to render the operation nearly bloodless, so far as the tongue itself was concerned. There was a little bleeding from small vessels at the floor of the mouth. But all oozing was pretty well checked by pressure within a short time after the operation. Iodoform gauze (Wölfler's), containing a little resin, to make it adhere to the surface, was applied to the surface of the wounds in the mouth. The wounds made for ligation of the lingual arteries were sutured, except where a soluble drainage-tube was inserted, and healed by first intention. The patient was nourished by enemata during the first twenty-four hours, and was afterward fed through a stomach-tube introduced three times a day for a week. The mouth was first irrigated every two hours during the day with a solution of permanganate of potassium, half a drachm to a quart. The temperature at no time rose above 99° F., and at the end of a week the external wounds were firmly united, and convalescence was established. At the present time, three weeks after the operation, the wound in the mouth was almost completely healed, the remaining granulating surface not exceeding half an inch in diameter. The patient, entirely relieved of pain and salivation, was able to swallow with ease, and, notwithstanding the loss of his tongue, could be understood in conversation.

RADICAL CURE OF A LARGE CONGENITAL OMENTAL HERNIA BY EXTIRPATION.

The President presented a man, aged thirty-three, from whom he had removed, in May last, a mass of omentum weighing a pound and a half, which occupied the left side of the scrotum. The tumor had existed from early infancy, and its development had given rise to but little inconvenience. Its size, however, subjected the patient greatly to annoyance and mortification. Several years since an epididymitis from a urethral trouble occurred. With this a considerable acute hydrocele developed, and as it was then thought that the hernia was of the usual variety, and separate from the cavity of the tunica vaginalis, the scrotum was punctured and the fluid withdrawn. The relief was marked, and no reaction followed the operation; but it was evident, during the removal of the hernial mass last spring, that the trocar had invaded the sac of the congenital hernia at the operation under spray. In May the ordinary longitudinal incision was made; the omental mass was tied off in two sections close up to the internal ring. One of the ligatures, partially slipping, threatened considerable hemorrhage; but this was obviated by a firm grasp with the forceps and another ligature. After careful dissection from the cord, the peritoneal prolongation was tied *en masse* and divided, a drainage-tube inserted, the wound closed, and sublimate dressings applied. The patient was about ten days after the operation, and had no subsequent trouble. As a precautionary measure, demanded by the companies in which he was insured, he for a time wore a truss, which has now for some time been abandoned. There is no disposition to fresh protrusion, and the parts are solidly closed. The hernial mass was the largest which Dr. Weir had any knowledge of being removed in this manner.

Dr. Halsted then read a paper entitled,

THE DESCENT OF FEMORAL HERNIA,

which will appear in full in a subsequent number of The Medical News.

NEWS ITEMS.

The Royal Medical and Chirurgical Society of London held its annual meeting on March 2d, and a very satisfactory balance-sheet was presented. The annual report showed a larger number of Fellows than in any previous year, namely, 741; and a larger number of attendances at the meetings of the Society. A larger proportion also of those who had attended had taken part in the discussion, namely, 145 out of 632. The library also had increased by 520 volumes, and 3421 books had been lent during the year.—*British Medical Journal*, March 7, 1885.

The Cartwright Prize.—Essays in competition for the Cartwright Prize must be handed in to some member of the Committee on or before April 1, 1885.

The Committee consists of Robert Abbe, M.D., 32 East 20th Street; Walter Mendelson M.D., 209 West 46th Street; and R. W. Amidon, M.D., Chairman, 18 West 21st Street.

Louisville Medical College.—The Annual Commencement of the Louisville Medical College was held February 26. Sixty-three graduates received the degree of M.D.

Professor Karl Bardleben, of Jena, has been unanimously chosen editor of *Die Zeitschrift für Medicine und Naturwissenschaften*, the organ of the Medico-Scientific Society.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MARCH 21, 1885.

Sawtelle, H. W., *Surgeon*.—Detailed as Chairman of Board for physical examination of officer of the Revenue Marine-Service, March 17, 1885.

Armstrong, S. T., *Passed Assistant Surgeon*.—Granted leave of absence for thirty days, March 16, 1885.

Ames, R. P. M., *Passed Assistant Surgeon*.—Detailed as Recorder of Board for physical examination of officer of the Revenue Marine-Service, March 17, 1885.

ORIGINAL LECTURES.

GULSTONIAN LECTURES.
ON MALIGNANT ENDOCARDITIS.

Delivered at the Royal College of Physicians, London, on Thursday, March 5, 1885.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA.

LECTURE III.

MR. PRESIDENT AND GENTLEMEN: Few diseases present greater difficulties in the way of *diagnosis* than malignant endocarditis, difficulties which in many cases are practically insurmountable. It is no disparagement to the many skilled physicians who have put their cases upon record to say that, in fully one-half of them the diagnosis was made *post mortem*. In spite, too, of able memoirs in the journals, the disease has not been much known, and it is only of late years that the text-books have contained chapters upon it. The protean character of the malady, the latency of the cardiac symptoms, and the close simulation of other disorders, combine to render the detection peculiarly difficult.

Diagnosis.—In the group of cardiac cases in which the disease attacks a patient the subject of chronic valvulitis, the matter is usually easy enough. The existence of fever of an irregular type, and the occurrence of embolism, generally suffice to make the case clear. It must be remembered that simple warty endocarditis not unfrequently attacks sclerotic valves, and may be accompanied by slight fever. Of course, in chronic heart disease, irregular pyrexia may arise from other causes—local suppuration, cellulitis, etc.—which must be excluded.

In rheumatic fever, a disease in which the heart is more systematically examined than in any other, if with the occurrence of a murmur the symptoms become aggravated, and assume a typhoid or pyæmic type, the recognition of the complication should be easy. The onset of severe head-symptoms in rheumatism—delirium, with high fever and coma—requires to be carefully distinguished. Fortunately, the simple endocarditis so common in this disease rarely, as I shall have occasion to show, passes into the grave form.

In pneumonia, a prolongation of the course, with the supervention of typhoid or septic symptoms, should lead to a very careful examination of the heart.

The greatest difficulty is met with in those acute cases resembling the malignant forms of the fevers; here the affection may simulate typhoid, typhus, cerebro-spinal meningitis, or even hemorrhagic smallpox. Even with the detection of a heart-murmur, the judgment may have to be suspended, and many cases die with the general symptoms of profound blood-poisoning, before the development of any special features upon which a diagnosis could be based.

From typhoid fever, with which the cases are most often confounded, the mode of onset, the pyrexia, and the abdominal symptoms offer the chief points for discrimination. The onset of severe endocarditis is more abrupt, not so often preceded by a period of failing health and progressive weakness. In a large number of cases, cardiac pain or oppression and shortness of breath are mentioned as early symptoms. The fever rarely presents, in the early days of the disease, the regularity of typhoid, and from the outset may be very high. A sudden fall to the normal, or even below, may occur; indeed, irregular pyrexia is one of the most important diagnostic signs. The combination of diarrhœa, abdominal distention, and a rose-colored eruption, points strongly to typhoid fever. The rash, when present, is usually petechial, a rare circumstance in typhoid fever. The development under observation of pronounced murmurs, particularly of aortic and regurgitant, is most suggestive of malignant endocarditis, and the occurrence of emboli would be a positive confirmation. Rigors rarely occur in typhoid fever, while they are common in endocarditis. It is well, however, to bear in mind that, in many of the most severe cases, death may occur, as in any of the infective disorders, without the development of the special symptoms necessary for a diagnosis.

Many of the cases present the clinical features of pyæmia, a condition which may actually exist, dependent upon the ulcerative lesions on the valves; and here the diagnosis lies between an ordinary septic infection from a wound, or auto-infection from a primary endocardial inflammation.

It is interesting to note the similarity of those cases of acute endocarditis in which death occurs in a few days, without the development of any other than the valvular lesion, with those instances of rapidly fatal acute periostitis and necrosis, and also with those cases of malignant septic infection from a slight external lesion.

It seems strange that difficulties should arise in the diagnosis between malaria and malignant endocarditis, but the records of cases plainly show that for weeks or months a condition of intermittent pyrexia may occur, simulating every type of ague. The paroxysms in regularity, in order of sequence, and in the accompanying general conditions, may fulfil every condition of a quotidian or tertian intermittent; and the development of cardiac symptoms, with breaking of the pyrexial type, may alone determine the nature of the case.

Etiology and Pathology.—With a view of obtaining data upon which to base statements regarding the etiological relations of malignant endocarditis, I have gone over the records of 209 cases. As before stated, 37 of these occurred in connection with pyæmia, traumatic or puerperal. Doubtless this number could have been very greatly increased had I examined files of special gynecological and surgical journals, but my investigation did not lie so much in these directions. In 45 cases, there was no record of any previous disease

which could be taken into account as possibly connected with the endocarditis. In 127 cases, there was a history of past or existing disease with which the cardiac trouble could, with a greater or less degree of probability, be associated.

One or two general considerations may first be mentioned. The period of middle life gives the greatest number of cases. Young children are rarely the victims; there were only three or four instances under 10 years of age, and not many more over 50. The cases occurring in connection with rheumatism presented an average younger age than the others; there were 36 instances under 30 years of age, out of 51 cases in which this point was mentioned.

Of 160 cases (exclusive of traumatic and puerperal), 99 were in males, and 61 in females.

Persons debilitated by exposure or other causes, or addicted to drink, seem particularly liable to be attacked; and in such subjects, during the course of an acute disorder, this complication is much more likely to arise.

As has been already referred to, the existence of sclerotic valvulitis is a very important factor in the etiology of severe endocarditis, a very considerable proportion of the cases occurring in individuals whose valves are thickened and crumpled from chronic inflammation.

The existence of a primary, protopathic endocarditis must, I think, be allowed. In 45 cases, no history could be obtained of rheumatism or other affections with which endocarditis is known to be associated. Many of these cases were of the most malignant type; in 10, death took place within a week. A specific statement of the absence of rheumatism was generally given. The onset was usually like that of a specific fever, headache, vomiting, rigors, pyrexia, and often early delirium and unconsciousness. The very acute cases resemble severe typhoid or typhus, but, when more prolonged, a pyæmic condition may develop. In a number of these cases the disease had attacked persons with chronic valve disease, some while under treatment, others in whom the compensation was complete and the old lesions only detected at the necropsy. In 5 instances, the ulcerative process attacked aortic valves, two of which were fused, and had undergone the fibroid changes always associated with this malformation.

In 127 of the cases, the endocarditis was associated with other diseases, some of the most important of which we shall now proceed to consider.

Rheumatism.—Since Bouillaud called special attention to the frequency of cardiac complications in this disease, its importance in the etiology of endocarditis has been universally recognized. And, as regards the simple form of endocarditis, the general statements are quite true, but, fortunately, the graver and fatal form is much less common, much less, I think, than is usually supposed. In 53 cases, there was a history of rheumatism, past or present. I included every case in which there had been the record of an attack, recent or remote. In only 24 did the symptoms of severe endocarditis arise during the progress of the acute or subacute disease. In 29 cases, there was simply a history of rheumatism, often years before, and no mention of the occurrence of joint troubles at the time of the development of the endocarditis. Dr. Ogle called attention to the fact that ulcerative endocarditis occurred very often in persons in whom no rheumatic history could be traced. Of 21 cases which he reported, some of which were probably atheromatous, in only 3 was rheumatism mentioned. In only 3 also of the Montreal cases was there any positive history of rheumatism, either before or during the attacks. The following case, under the care of Dr. Ross, is a good example of the mode of onset:

B. M., aged 22, a healthy girl until three weeks before her admission to hospital, on January 4th. At that time she was attacked with rheumatism of the wrists and ankles, not very severe, and she did not receive any treatment. A week from the beginning of the attack, she began to have chills, two or three a day, and she became feverish. During the next week she became worse, had occasional chills, not delirious; was brought to hospital on the 4th, in a very low state. On the 5th there was delirium and incoherence. Pulse 130; temperature 100°. Double murmur up and down sternum; joint-troubles not evident. On the 6th, 7th, and 8th, she remained in the same state, no chills; temperature ranged from 100° to 102°. On the 9th she was more restless. On the 11th a gray membrane was noticed on the fauces. On the 12th, the membrane in the throat had extended, and covered the soft palate. Temperature 103°. On the 13th she died suddenly. The necropsy revealed a large deep ulcer at the aortic ring, nearly destroying one segment, and penetrating deeply between the auricle and the left ventricle. There were small infarcts in the brain, extensive recent diphtheria of fauces.

In a larger number than in any other group, sclerotic valves were found, with the existence of which the past rheumatism could, in many instances, be connected. A primary rheumatic endocarditis was recognized by Latham, also by Graves and Stokes, and it is quite possible that some of the cases which I have grouped as protopathic represented instances of the kind in which, if life had been prolonged, joint-troubles might have supervened.

Cases of acute rheumatism sometimes occur in which there may be multiple miliary abscesses,[1] and a pyæmic condition similar to the case just narrated, but without the presence of endocarditis. Micrococci have been found in these abscesses, and the cases resemble those rare instances of idiopathic pyæmia. It is worthy of observation that a skin-eruption was most frequently noted in connection with the rheumatic cases, generally an erythema. In a case of Dr. Kirkes,[2] it was observed on both face and hands. The occasional presence of a scarlet rash in rheumatism[3], and in puerperal fever[4], has long been recognized.

In chorea, with which simple endocarditis is so often associated, the malignant form very rarely supervenes.

Pneumonia, as Bouillaud pointed out, is not unfrequently complicated with endocarditis, but the important part which it plays in the etiology of the malignant disease has not been generally recognized. In the cases I have reviewed, it stands at the head of the list of diseases in which secondary endocarditis of a severe

[4] Hicks, Obstetrical Society's Transactions, vol. xii.

nature develops, 54 instances having been noted, rather more than 25 per cent. of the total number of cases. For this I was quite prepared by our Montreal experience, for, in 11 of the 23 cases, the attack was associated with pneumonia. Of the occurrence of acute endocarditis in this disease, the statements are somewhat diverse. Bouillaud thought that, in a third or fourth of the cases in which there was left-sided pneumonia, there was inflammation of the serous membranes of the heart. Grisolle, in his classical work on pneumonia, states, on the contrary, that it is a rare complication, and this would certainly appear to be the conclusion of the Committee for Collective Investigation; for in the report upon 1000 cases, endocarditis is only once mentioned. My experience at the Montreal General Hospital is very different. I have notes of 103 necropsies of cases of lobar pneumonia, and the occurrence of acute endocarditis is noted in 16 cases, over 15 per cent. Of these cases, 11 were of the malignant form. An analysis of these shows that, in 6, the left lung was involved; in 5, the right; in 4, the upper lobe was affected; in 7, the lower. In 9 of the cases there was pericarditis; in 5 of the 11 cases, there was suppurative cortical meningitis. In the 54 cases which I have reviewed, in 36 the lung affected was mentioned, and in 26 the affection was on the right side, and in only 10 on the left; figures which are opposed to the statement of Bouillaud, that it is in left-sided pneumonia that endocardial complication most frequently supervenes. In 15 cases, acute meningitis is mentioned, and, in one instance, the meninges of the spinal cord were also affected. The aortic valves seem more often involved than the mitral. In 17 instances, there were old sclerotic changes in the valves.

The clinical features of several cases in which the endocarditis came on during pneumonia have already been given. In many of them, as in the girl, aged 29, referred to in the second lecture, the patients are brought to hospital unconscious, and die within a few few days, with symptoms of a grave cerebral disorder. In others, there is a history of ordinary pneumonia, and the case may pursue the usual course, and defervescence take place, when, in a day or so, fever of an irregular type recurs, and typhoid or pyæmic symptoms appear. The majority of the cases are of this kind. Again, some instances occur in connection with injuries, and the patient succumbs to a lobar pneumonia and endocarditis unconnected with any sepsis. Two of the Montreal cases were of this kind. In three or four cases, there were rheumatic symptoms preceding or accompanying the pneumonia, as in a case of Dr. Musser's, the remarkable temperature-chart of which is here shown.

Elderly persons were more often attacked than in the other groups. There were ten individuals over fifty years of age. In the Montreal cases three of the patients had had pneumonia before; in one it was the third attack, and in every one of them there was a history of either drinking habits or previous bad health. In some cases, the pneumonia had partially or entirely resolved at the time of death, in others there was red, or, more frequently, gray hepatization.

The relation of the meningitis to the pneumonia and the endocarditis is particularly interesting. The occasional occurrence of this complication in pneumonia has been referred to by many writers, particularly Grisolle, Huguenin,[1] and Greenfield.[2] In the 105 cases I met with it in eight instances, in five of which there was also endocarditis. The frequency of the association of these two conditions in pneumonia is illustrated by the figures already given; of twenty-five instances of meningitis in malignant endocarditis, fifteen cases occurred in pneumonia. In all the specimens I have examined, there were micrococci in the exudation, and in three cases many of the capillaries and small arteries were filled with them; and its seems natural, where the endocardium is involved, to attribute the process to embolism from the valves. But the occurrence of an identical cortical meningitis without any valvulitis shows that it may be due to other causes than the endocarditis. As Huguenin suggests, it may he dependent upon the presence in the blood of infective material derived from the infiltrated lung tissue.

In connection with these secondary or consecutive inflammations in pneumonia, it is interesting to call to mind the not unfrequent occurrence of pericarditis, and of croupous inflammation of the gastro-intestinal canal. Dr. Bristowe some years ago noted the frequent complication of croupous colitis; and, in 103 necropsies, I have met with this complication in five instances; and in one there was extensive croupous or membranous gastritis.

Diphtheria is rarely complicated with endocarditis, and I have been able to find only two or three instances in which severe symptoms were present; yet in some works endocarditis is stated to be not an uncommon sequence. Labadie-Lagrave[3] regards it as such; but it is probable that what he described as vegetations are only Albini's little nodules, the remnants of fœtal structures. In 108 necropsies in diphtheria Telamon[4] did not meet with a single case of endocarditis; and my experience has been the same in thirty post-mortem examinations, many of which were in adults.

In *dysentery* a few cases have occurred. Litten[5] has recorded an instance in which there was extensive ulceration of the aortic valves; and one of the Montreal cases occurred in connection with acute colitis.

In the *eruptive fevers* grave endocarditis occasionally develops—in typhoid, in scarlet fever, and in variola; but in the cases I have analyzed these diseases appear of very trivial etiological significance.

In *ague*, as Lancereaux[6] first pointed out, simple or severe endocarditis may develop. In some of these cases, as in the remarkable one reported by Dr. Bristowe, to which I referred in the second lecture, the paroxysms of true intermittent, and those of the ulcerative endocarditis, seem to run the one into the other.[7] In most of the cases there has been only a history of severe ague, and the endocarditis has followed repeated attacks. Dr. Greenhow[8] has reported a very instructive case of the kind.

[7] Dr. Bristowe informs me that, in the case referred to, he is inclined to regard the intermittent pyrexia as dependent from the outset upon the endocarditis, and not associated with malaria.

[8] Path. Soc. Transactions, vol. xxx.

Dr. Goodhart[1] makes the interesting suggestion that ulcerative endocarditis is more frequently met with at periods in which scarlet fever, erysipelas, pyæmia, and diphtheria prevail. The Guy's Hospital records certainly seem to show that the cases appear in groups pretty close together, and at a time when the diseases mentioned are epidemic. In Montreal we have had occasionally a "run" of cases together, but I have not noticed the connection referred to by Dr. Goodhart.

Pathology.—I approach a discussion of the pathology of malignant endocarditis with some trepidation, partly due to a sense of incompetency, and partly from a feeling that the time is scarcely ripe for a satisfactory presentation of the subject; and yet there are signs which make one hopeful; and it would not be rash to predict that the knowledge twenty-five years hence will be as much in advance of to-day as our information on the subject is of the time when Dr. Kirkes made his memorable investigations. A serious difficulty exists in the circumstance that we have not to deal with a single form of disease—an entity; but rather with a special manifestation in many affections—affections, too, the pathology of which is, in most instances, by no means clear. No one can doubt that the more severe cases of endocarditis present in a typical mode all the features of those diseases which we call infective, and believe to be caused by the absorption of some poison, the development of which in the blood and tissues profoundly disturbs, and finally annihilates, function.

Briefly stated, the theory of acute endocarditis which at present prevails, and the only one to which I shall refer, is, that it is in all its forms, an essentially mycotic process; the local and constitutional effects being produced by the growth on the valves, and the transference to distant parts of microbes, which vary in character with the disease in which it develops. This very attractive theory can be adjusted to meet every requirement of the case, though as yet lacking certain of those substantial data so necessary for full acceptance, but which, having been furnished of late years in other diseases, we may reasonably hope will in time also be forthcoming for this.

Let us see, first, what has been done, and how far the facts at our disposal seem favorable to this view. The constant presence of microörganisms seems undoubted; only, in the simple acute form, we need more careful observations with our improved methods. Some good observers have not been able to find them;[2] others declare them to be invariable constituents of the verrucose outgrowths.[3] The careful application of such a satisfactory mode of staining as recommended by Gramm should readily determine this question. A study of the endocarditis of puerperal and traumatic pyæmia will be most likely to yield important information, as here the conditions are simpler, and the relation of the microörganisms can more readily be determined. The cardiac complication in these cases is only part of a general process, excited by a local lesion, and is entirely secondary and subsidiary. Micrococci arranged in chaplets are constant constituents of the vegetations, and, in the case of puerperal fever, they have a close resemblance to those found in the peritoneal exudation. The well-known observations of Koch, Ogston, and others have shown the relation of microbes to pyæmia; and the recent culture-experiments of Rosenbach[1] go so far toward demonstration for man what Koch had previously done in the case of the pyæmia of the mouse. In these cases, a study of the modes of growth of the micrococci of the endocarditis, and of the effects of inoculations, and a comparison of these with similar observations in the organisms of the original lesion, or of the metastatic foci, should yield results of great value in the interpretation of the phenomena of secondary endocarditis.

In rheumatic fever, we are still too far from any accurate knowledge of its intimate pathology to dwell on the possible connection of any organism peculiar to it, and the endocarditis so common in its course. Klebs[2] distinguishes the microbes occurring in rheumatic cases from those of the septic forms.

In pneumonia, micrococci undoubtedly abound in the exudation of the air-cells, and their mode of growth in gelatine is peculiar, but the numerous experiments on artificial production are not yet conclusive. The evidence is accumulating which places pneumonia among the infective disorders; and it certainly is a seductive view to take of its pathology, to regard the local pulmonary lesion as excited by the growth of micrococci in the air-cells, and the various consecutive inflammations, the endocarditis and pericarditis, the pleurisy, the meningitis, the membranous gastritis or colitis, as due to the penetration of the organisms to deeper parts, and their local development under conditions dependent on the state of the tissues. The processes are all of the character described as croupous, and have as a common feature the presence of micrococci in a coaguable exudation. We have still, however, to settle the identity of the organisms of the air-cells with those of the consecutive inflammations; but we may reasonably hope ere long to have some positive data from investigations in this disease, which, more than any other, offers favorable opportunities for the solution of these problems.

In diphtheria, as we have seen, mycotic endocarditis rarely occurs; and, in a few instances, observed in association with scarlatina, variola, erysipelas, and other affections, we lack positive information with regard to the characters of the microörganisms.

In the way of experimental investigation of the properties of the micrococci, not much has been done of a satisfactory nature. Heiberg[3] placed bits of vegetations from a puerperal case beneath the skin and in the peritoneal cavity of a rabbit without effect. Eberth[4] and Birch-Hirschfeld[5] have produced panophthalmos in the rabbit by inoculating the cornea; and I was able to produce well-marked mycotic keratitis in the same animals with fresh material from the valves of two cases. H. Young, of Manchester, inoculated rabbits with pus from

[5] Archiv der Heilkunde, Bd. xvii.

an abscess in ulcerative endocarditis, and was able to detect micrococci in the blood.

No conclusive culture-experiments have yet been made. Grancher[1] has cultivated a microbe from the blood, taken during life with all necessary precautions, but apparently not in series, and no inoculations of animals were made. Cornil[2] has made cultures on gelatine, but apparently no special results have been reached.

How do the micrococci reach the valves? In cases of puerperal and traumatic septicæmia, the external lesion is undoubtedly the source of infection which is conveyed through the venous system; and, in these cases, it will be remembered that the right heart is most often affected. In other instances, where the skin is unbroken, we must suppose them to gain access by the lungs or intestines, most probably the former; and, in these instances, the left heart is the chief seat of the mycosis. Whether they reach the valve with the general blood-current, as Klebs supposes, or through the coronary arteries, as Köster holds, cannot be considered settled; but, from the position of the early vegetations in a non-vascular region of the valves, and from the fact already referred to, that colonies of micrococci can be seen directly upon the endocardium, it seems probable that Klebs's view is the correct one. He suggests, in explanation of the fact that the lines of closure of the valves are the usual seat of the process, that the micrococci, circulating with the blood, are here closely pressed into the endothelium by the firm apposition of the flaps. Whether or not in any given case endocarditis will arise, depends greatly on the condition of the valve tissue. In a case of pneumonia or other disease—such as pyæmia—in which we may suppose microbes circulating in the blood, the endothelium of normal valves may be able to resist their invasion, or, even if they do lodge and penetrate, the conditions may not be favorable for their growth; but, where an individual is debilitated, and the tissue-tone lowered, or if, as so often seems the case, the valves be diseased, then the micrococci find a suitable nidus, and excite, by their growth, an endocarditis which may be of a malignant type. As Dr. Goodhart suggests,[3] patients with chronic sclerotic valves are walking mushroom beds, in common times without spawn, but in periods of epidemics taking in germs by various channels, which fertilize in some cases into ulcerative endocarditis; in others, to suppurative processes. Certainly, on paper, so to speak, the view which I have thus imperfectly and hurriedly discussed seems plausible enough, and meets the requirements of the case fairly well; but let us, in conclusion, follow an important rule too much neglected, and get a definite outline for our ignorance. In the first place, we do not yet know, with sufficient accuracy, the frequency of the occurrence of microbes in simple endocarditis. Are they constantly present, or only in forms associated with special diseases? Secondly, we want ull information of the various forms of microörganisms occurring in secondary endocarditis, and of their relation to the microbes assumed to be the cause of the primary disease. And, thirdly, we are only at the threshold of inquiries relating to the culture of these organisms, to the macroscopic characters of their growth, and to the possible experimental production of endocarditis.

I cannot conclude without thanking my late colleagues at the Montreal General Hospital, by whose kindness I have had command, not only of the pathological, but also much of the clinical, material upon which these lectures were based; and lastly, sir, you will allow me to express my sincere regrets that my efforts have not been more worthy of such an intensely interesting subject, and of the distinguished audience which I have had the honor of addressing.

ORIGINAL ARTICLES.

SHOULD ARTIFICIAL ANUS BE FORMED WHEN A PORTION OF INTESTINE IS RESECTED FOR GUNSHOT WOUND?

By WILLIAM A. BYRD, M.D.,
of Quincy, Illinois.

In a letter which is published in The Medical News of February 28, 1885, "J. C. R." takes exception to the conclusions arrived at by The News in an editorial in its issue of February 21st, where the doctrine of closing the wounds in the intestine and then dropping into the abdomen is advocated. This editorial does not agree fully with the editorial in the issue of February 2, 1884, entitled "Radical Cure of Artificial Anus," in which the idea of making a Dupuytren's operation for the closure of artificial anus, instead of exsecting a portion of intestine and dropping it back into the abdominal cavity, is ably upheld. Now it may be very properly contended that excising a portion of intestine for gunshot wound and for the cure of artificial anus are two very different things. The gunshot wound is accompanied by great shock and extravasation of fecal matter in the peritoneal cavity, which causes an amount of irritation very liable to be followed by suppurative inflammation, even if the cavity is well cleaned out. These two conditions render the operation of closing the intestine for gunshot wound much more dangerous than the operation for curing artificial anus by excision. The very fact of the added complications and dangers should lead the surgeon to adopt the method fraught with the least danger, and that method, I believe to be the one where the artificial anus is formed. By that method the gases that form in the intestine have an opportunity to escape and not press upon the lungs and heart by upward distention as well as distend and tear out the stitches, permitting repetition of the extravasation. The ends of the bowel may be brought together in such a manner as to allow of spontaneous cure of the small artificial anus that is left to permit escape of the gas. For the method, I will refer the reader to my "Address on Surgery" delivered before the American Medical Association, in 1882, at the meeting in St. Paul, and to a paper by me on "The radical cure of artificial anus" which appeared in The News for April 12, 1884.

It matters not for what purpose a resection of intestine is made; to my mind, the same general

principles must govern the treatment. J. C. R. refers to a footnote in the *British Medical Journal* Jan. 24, 1885, p. 173, where Mr. W. Whitehead refers to a statement made by Sir Spencer Wells in his Inaugural Address upon the Revival of Ovariotomy "(*British Medical Journal*, November 15, 1884, p. 950), in which he states that, in a recent paper by Reichel, 121 cases of resection of intestine have been collected, the conclusions being. that the two ends of the bowel should not be united at the time of resection, but that an artificial anus should be established. The article to which the above is a note is entitled "Excision of the Cæcum for Epithelioma: Death on the Thirteenth Day." In the body of the article is this paragraph, of which the note is explanatory :

"The second point to decide was whether or not, after the removal of the growth, it was desirable to unite the divided ends of the bowel together. The desire to attempt the latter course was naturally great; but, the main object being kept strictly in view, it was not considered warrantable to subject the patient to such additional risk, especially in an operation which only holds a tentative position in surgery. Whilst admitting the wonderful success that has attended the operation of enterorrhaphy, it cannot at present be regarded as an established precedent free from objections and disadvantages. The danger of non-union, and the contingency, possibly remote, of future stricture, are risks which do not admit of being lightly passed over. Further, by bringing the two ends of the bowel outside, there always remained the opportunity, should it ever be considered desirable, of uniting them by a subsequent operation."

Sir Spencer Wells, in commenting upon Reichel's statistics, says: "This can be closed by a subsequent operation. You will probably soon see a report of a case, not yet published, where Mr. Jessop, of Leeds, cured a fecal fistula by separating the injured intestine from the abdominal wall, and uniting the upper and lower parts of the gut by suture." The two statements seem somewhat contradictory, but I am led to think he favors the formation of artificial anus in cases of resection of intestine.

Mr. Bryant's opinions, as given in the Harveian lectures, published in the *British Medical Journal*, in November and December, 1884, are rather indefinitely stated. But he expresses himself more positively in the report on "colectomy" published in the *Transactions of the Royal Medical and Chirurgical Society*, for 1882.

Mr. Bryant requested me when in London to explain to him my method for closing artificial anus. The operation is very simple to demonstrate but very hard to describe as to be easily understood, but I succeeded in making it clear to him on this occasion. He spoke of the frequency of stricture at the sigmoid flexure, and stated that the next case he had he would make colectomy with artifical anus, and he did so, as the report shows, in the early part of 1882. In the Harveian Lectures he has not changed his opinion, though I do not know whether or no he has gone further and adopted my method for the closure of the artificial anus after it has served its purpose of saving the life of the patient.

Mr. Frederick Treves, in a recent very excellent work on "Intestinal Obstruction," says:

"It may be that the operation of suturing the intestine immediately after the resection may be improved as surgery advances, but, as the matter at present stands, everything points in favor of the operation that demands the establishment of a temporary artificial anus.

"The comparative value of those two procedures has been fully discussed by Reichel in the monograph above alluded to, and this surgeon has shown clearly that the chief element of success in resection operations depends upon the formation of a temporary fecal fistula.

"It must be borne in mind that the patients who are subjects of resection operations are suffering from obstruction, and often from acute obstruction. Their lives are threatened by reason of this obstruction, and any operation performed should give immediate and entire relief to the distended bowel above the site of the occlusion. In the second of the two methods above described this relief is afforded. The engorged intestine can empty itself at its leisure. If, however, the divided ends of the bowel be at once united after the excision of the diseased segment, the distention, to a great extent, remains, the obstruction is but imperfectly relieved, the gut at the suture line is paralyzed, peristaltic movements must be interrupted at this point, and free circulation of the intestinal contents is thus rendered practically impossible. The fact must not be lost sight of, that in the resection operations the relief of an obstructed intestine is of more immediate moment as regards the patient's life than the removal of an epithelioma or neoplasm from the walls of the bowel.

"Then, again, the operation requiring immediate suturing of the intestine is long and tedious, and the state of the patient upon whom these operations are performed is usually such as to render a prolonged narcosis most undesirable and most dangerous. The procedure that postpones the suturing of the bowel to a future period is readily performed, and, indeed, is almost as simple as an ordinary enterotomy or colotomy.

"In all resection proceedings there is a great risk of death from fecal extravasation, and it is needless to point out that this risk is infinitely reduced by a perfect evacuation of the bowel above the obstruction.

"In many examples of resection, especially when undertaken for gangrene, the bowel is not in condition to insure sound and perfect healing. For the success of the primary suture operation this ready healing is essential, and it will be obvious that in excising the bowel, with this fact before him, the surgeon would be apt to remove too much.

"Owing to the disturbance of the mesentery the margins of the divided intestine are apt to slough a little. In the latter of the two procedures now under notice, this would prove a matter of no moment; in the former it would probably lead to fecal extravasation and death.

"It may be said, therefore, that in resecting the intestine a temporary artificial anus should always be established, and the suturing of the bowel left to a future period.

"To this rule one exception may be made. In cases of resection of small intestine high up in the jejunum, the divided ends should be at once brought together with sutures whenever the state of the intestine will permit. The mortality attending fecal fistulæ in the upper part of the jejunum is well known."

No apology is necessary for so lengthy a quotation, as the whole of it is applicable to the subject under consideration. There may be those who can

see no connection between excision of intestine for gangrene and for gunshot wound, but the ball in its passage injures the parts so as to cause gangrene to ensue at a more or less remote period from the receipt of the injury. And the bowel at the line of union would not be in fit condition for the passage through it of any thing like large masses of fecal matter. Any one who has had much experience with gunshot wounds knows well that the amount of shock, with paralysis of tissues in the immediate vicinity of the course of the bullet cannot well be known by sight. Tissue that has no appearance whatever of having been bruised frequently dies and sloughs out.

The pleasant experience of Drs. R. A. Kinloch and William T. Bull should not deter operators from viewing the other side. Then there are other cases of recovery from operations for excision of bowel for conditions somewhat analogous to those of gunshot wound. One of the most notable is the excision of two inches of intestine for wounds inflicted by a stab with a dull knife, the operator and reporter being Dr. Joseph Grindon of St. Louis. (*Courier of Medicine*, Oct. 1884, pp. 220, *et seq.*)

All who heard the Address on Surgery before the American Medical Association last year by Dr. Charles T. Parkes, of Chicago (Medical News, May 17, 1884, p. 563), must have been delighted with the care bestowed upon and the richness of the drawings used to illustrate the subject. He evidently believes in bringing the ends of the divided intestine together and then dropping it back into the abdominal cavity, as the following shows:

"Two cases of the series were subjected to the expectant treatment. These cases were chosen because their injuries did not seem very severe; the hemorrhage was not great and the prostration not extreme. Both died: the first in one day, the other lived five days. Post-mortem examination showed extensive extravasation of the contents of the bowel and septic peritonitis. In one case an attempt was made to establish an artificial anus. The wounded intestine was resected and the ends fastened to the edges of the abdominal incision. The animal died of septic peritonitis in three days. This trial was made early in the experimentation, before any definite plan of procedure had been settled upon. This is the only experiment that has given rise to any regret, for I feel satisfied that with a fair junction of the bowel and a clean abdomen, the animal would have been saved.

There is no reason given why this case should have been attacked with septic peritonitis, unless we are to infer that the abdomen was not clean, and I believe the trouble was in not having a sufficiently free opening in the abdominal wall, the intestine thus being left partially strictured at the point of exit. In making the artificial anus after resection of intestine, all the precautions should be taken that would characterize the same operation when the two ends of the divided bowel are united and dropped into the abdominal cavity. The abdomen should have the "*peritoneal toilette*" as carefully performed and every bleeding point should be just as assiduously looked after.

After a bullet has passed into the abdomen, no surgeon can know the extent of injury until the abdomen is laid open and the bowels are carefully examined. Small wounds may with safety be united at their edges, with the peritoneal surfaces brought in contact, providing the injury is not at the omental border, at which place Dr. Parkes has shown the greatest danger exists of ulceration, perforation, and attendant extravasation.

I have arrived at my conclusions as to the advisability of forming artificial anus more from my own experience than perhaps from what I have read, but the more I have read the more thoroughly am I convinced that it is a procedure that will receive more attention in the future. None of my cases have been of gunshot wound, but the same pathological condition obtains in all analogous operations in the abdominal cavity. Ephraim McDowell struck the keynote, which untouched, there would be no discussion now as to the proper mode of treating wounds of the intestine. We would still be trusting to the Lord entirely when a man got shot in the abdomen until the hidden trouble required his burial.

I have made artificial anus six times; twice for gangrenous strangulated hernia; in one I took off eight inches of intestine and a large piece of omentum, in the other three inches of intestine, and made an opening at a different point from the place of strangulation to bring the bowel out; in both foreign matter got into the abdomen, both got well, both were operated upon for the cure of the artificial anus, and both were cured and are yet living.

Twice I have formed artificial anus for adhesive obstruction; both got well of the trouble, one to die six or seven months after from albuminuria, and the other between two and three months after the operation from pneumonia.

Twice I have made artificial anus for congenital absence of the anus; in one, left lumbo-colotomy was performed, and the patient was killed by a foolish use of carbolic acid about three months afterwards for antiseptic purposes. The attending physician could not be induced to believe the rectum would absorb anything detrimental to health from a solution of carbolic acid. The other patient who had the coccyx excised, and the bowel completely detached and brought down into the opening, recovered, and is in excellent health.

Another case I saw July 5, 1879. A young man returning to his home in Mendon, Illinois, had gotten into a drunken row on the cars and had been stabbed in the side with a pocket-knife, the blade of which entered the ilium. Dr. C. J. Tibbets, a very intelligent dentist of this city being near him secured the cut bowel, and having seen John Loyns, the patient on whom I had exsected eight inches of intestine, fastened this cut end into the wound in his side with sutures, and left him off the train, at Mendon, in the care of Dr. Peter Young. He was doing very well when I saw him, except that there was a good deal of undigested food passing through the wound. He continued to do well for a day or so when he sank from dysentery, July 9th. Dr. Young informed me that there was no peritonitis; that the gut had become firmly attached to the wound in the side; and that he would certainly have recovered had it not been for the depressing effects of the intoxication and the dysentery. None of these

was a case of gunshot wound, but they were similar in that in all the ends of the intestine were freed from the surroundings and could have been dropped if it been thought best; that is all, but those of imperforate anus.

Besides these, I have operated three times for abscesses where they have communicated with the lumen of the bowel; in all these cases there was recovery complete and permanent.

The artificial anus can be readily cured by the method referred to in the issue of The News for April 12, 1884, page 414. I believe all the cases operated upon by that method have recovered—at least, all that I have heard of. The last case in which I used it was that of a man from Kansas who had come to St. Louis to consult my friend, Dr. Louis Bauer, who kindly invited me to operate upon him, which I did a few weeks ago at the Pius Sister's Hospital. From a letter received from Dr. Bauer, to-day, I learn that the patient is doing very well. At a future time I shall gather together the reports of this operation and publish them in a more extended form.

NOTES ON THE CLASSIFICATION, DIAGNOSIS AND TREATMENT OF THE STAGES OF CHRONIC NASAL INFLAMMATION.[1]

By JOHN N. MACKENZIE, M.D.,
of Baltimore, Maryland; Surgeon to the Baltimore Eye, Ear, and Throat Charity Hospital.

I propose to ask attention to a classification of chronic nasal inflammation, which is based on personal anatomical investigation and clinical experience, and which, I venture to think, will prove of practical value in the diagnosis and rational treatment of this affection.

The leading anatomical characteristic of chronic nasal inflammation resides in certain changes which the erectile bodies undergo. In the earlier stages of catarrhal inflammation there exists a peculiar excitability of these structures which causes sudden obstruction of one or both nostrils; later on is found a permanent swollen or puffy (dilated) condition of the erectile tissue, due to a subparalytic state of the intercellular walls with consequent dilatation of the erectile spaces. As the disease advances, there is a metamorphosis of the intercellular walls into dense fibrous tissue, which in contracting gradually obliterates these spaces, and causes finally atrophy of the erectile bodies.[2]

These changes in the erectile structures furnish the anatomical ground for the classification which I present for your consideration.

Classification of the Stages of Chronic Nasal Inflammation.

I. Simple Inflammatory (Rhinitis Simplex); divisible into periods of—

a. Irritability of erectile tissue.

β. Permanent dilatation of erectile tissue.

II. Hypertrophic (Rhinitis Hypertrophica); divisible into periods of—

a. Dilatation with hypertrophy.

β. Complete hypertrophy.

III. Atrophic (Rhinitis Cirrhotica); divisible in periods of—

a. Commencing atrophy.

β. Complete atrophy.

I. The first or *simple inflammatory stage* consists of two periods, the one characterized by *abnormal irritability* of the cavernous tissue, the other by *permanent dilatation* of the same.

a. *Period of irritability:* Characterized by increased irritability of the mucous surfaces, expressing itself chiefly in abnormal excitability of the erectile tissue, leading to sudden obstruction of one or both nostrils in the presence of changeable atmospheric conditions, when the individual assumes the recumbent position, as at night, or when under the influence of certain forms of excitement, and in some women at the menstrual period; in fine, when the individual is exposed to any of the exciting causes of coryza.

β. *Period of dilatation or permanent puffiness* of the erectile tissues (chronic coryza). As the result of the repeated erection of the cavernous tissues which occurs in the first stage, a paralytic or subparalytic state of the resilient and contractile elements of the walls of the erectile cells develops, leading to their permanent dilatation, recognizable by the eye as an engorged or *puffy* condition of the turbinated tissues, which may be distinguished from true hypertrophy by its collapsing under the probe, by the readiness with which it can be pressed against the external wall of the nostril, and by its diminution in bulk under various measures which produce reflex contraction, or emptying or depletion of the erectile spaces, such as the sudden application of cold, the use of cocaine, etc.

It is this subparalytic condition of the tissue, represented by the puffy character of the swelling, which is the *connecting link between the simple and hypertrophic stages.*

II. *The second or hypertrophic stage* is divisible into two periods, characterized respectively by *hypertrophy with dilatation*, and by *complete hypertrophy.*

a. *Period of hypertrophy with dilatation:* Characterized by commencing hypertrophy of intercellular connective-tissue walls of the erectile bodies with uniform puffiness of the tissue not especially involved in the fibrous process.

β. *Period of complete hypertrophy:* Characterized by more or less complete conversion of the affected portion of the tissue into a fibrous mass; swelling generally uniform, unyielding. This complete hypertrophy is most commonly met with on the posterior extremity of the inferior turbinated body, while its anterior extremity is generally puffy, dilated, doubtless from *collateral engorgement.*

III. *The third or atrophic stage* is separable into two periods, one of *commencing atrophy* and one of *complete disappearance of the erectile tissue.*

a. *Period of commencing atrophy:* Characterized by pronounced contraction of the newly formed

[1] Read Feb. 20, 1885, at the Clinical Society of Maryland.

[2] For further particulars concerning these changes, see article by the writer in The Medical News of Oct. 4, 1884, entitled, "Some Notes on the Pathology of Intranasal Inflammation."

fibrous bands, leading to irregular, nodular condition of the tissue more prominent in the posterior part of the inferior turbinated body and along its inferior border. This uneven appearance of the diseased portion not infrequently assumes the appearance of fibrous or papillomatous excrescences which may become detached, the process of detachment constituting one step in the future and complete atrophy of the tissue. The erectile spaces are inconspicuous and, in some places, entirely gone.

β. Period of complete atrophy (turbinated cirrhosis): Characterized by a rudimentary condition of the turbinated bodies, due to more or less complete disappearance of the erectile tissue.

II. In the natural state, the lumen of the nostril, or that space which exists between the turbinated bodies and the septum, is indicated by a slit, narrow and pointed above, and broader and more triangular below, which may be roughly compared to the slit in the sounding-board of a violin. When the turbinated tissues are made to contract artificially, obliteration of this slit occurs, the middle and inferior meatuses are represented by a broader, more pyramidal passage, and the middle and deeper portions of the nostrils come into view. The opening of the posterior nares into the retro-nasal cavity is then seen as a dark, clearly cut perpendicular line. In some persons, especially in those whose nasal chambers are naturally capacious, this linear opening may be seen without artificial contraction of the turbinated bodies.

The position of the turbinated bodies also varies within certain limits in the normal condition. When the inferior turbinated bone is "depressed," its anterior end appears as a rounded or, in some instances, bluntly pointed protuberance jutting out from the external anterior wall of the nostril, and closely in contact with the floor of the inferior meatus, from which it seemingly springs. When the bone is "elevated," there is a distinct, sometimes very broad, space between its inferior border and the nasal floor, the curve and dip of its anterior extremity is generally well defined, so that a *comma-shaped space* is left between it and the external wall. The inferior surface of the bone is not visible except in cases in which the long axis of the bone is directed upward and forward.[1] In some families, the inferior turbinated bone of one side is unusually developed without giving rise to serious inconvenience,[2] a fact which it is well to bear in mind in coming to a conclusion in diagnosis.

The rounded, bulging middle turbinated bone occupies the upper and outer portion of the anterior rhinoscopic picture. In the anterior portion of the nostril the space between it and the inferior varies greatly within the limits of health. Usually it presents a more or less pear, or inverted, comma-shaped appearance, with or without a comma-shaped space between it and the outer nasal wall.

It is only in very exceptional cases that the superior bone can be seen.

In the posterior rhinoscopic image the floor of the nostril is not visible in health, being hidden by the bulge of the palatal muscles, and the inferior edge of the lower turbinated bone is only visible in exceptional cases of the "elevated" form. Generally only the upper portion of its posterior extremity is visible. The posterior border of the septum is almost invariably straight, but just anterior to it, and within the nostril there is a slight bulging or cushion which represents the cavernous body located there.

The middle turbinated body generally projects inward as a pear shaped protuberance, whilst the superior is either scarcely visible, or appears as a rudimentary-looking tubercle or projection.

Only a small portion of the inferior meatus is visible as a small, dark, and three-cornered space. That portion of the middle meatus which is included between the turbinated bones is seen in the mirror as either a half moon or imperfectly defined S-shaped slit. The irregular spaces between the bones are continuous with the space common to the three meatuses, and which appears as a dark chamber in the rhinoscopic image.

The color of the mucous membrane in different individuals and in the same individual at different periods varies within the limits of perfect health. It may be said, in general, that it is of a pale reddish hue, more pronounced in the area covered by erectile tissue. In the posterior rhinoscopic picture, the color of the membrane appears of a darker hue, the parts being thrown more or less into shadow.

The mucous membrane is closely adherent to the anterior portion of the septum and walls of the vestibule, whilst over the posterior part of the septum and turbinated bodies it is looser, and separated from the periosteum by the erectile body which becomes a thin layer as the anterior extremity of the bone is reached.

In the anterior portions of the nostril, therefore, the turbinated bodies are more compact and closely adherent than the posterior segments of the nasal chamber.

I have dwelt upon the above anatomical considerations because I have found them invaluable guides in diagnosis. In anterior rhinoscopy the amount of swelling may be very conveniently measured by the changes in breadth and direction of the S-shaped slit, and the degree of obliteration of the comma-shaped space, whilst the amount of posterior hypertrophy is most accurately determined by the anatomical facts detailed above. The amount of swelling on the septum may also be determined in a similar manner.

The amount of swelling or hypertrophy, and the implication of the bone in the process, may furthermore be measured by the hard and incompressible or the soft yielding character communicated to the finger by the probe, whilst hypertrophy may be differentiated from mere puffiness by the ease with which the erectile bodies may be emptied or compressed by mechanical causes or artificial contraction. In the latter case the rapidity of contraction is often a measure of the amount of mere puffiness. In using cocaine, for example, if the swelling be due to mere

[1] In a case suffering from mental disease, I observed the inferior turbinated bone so elevated that it occupied the position usually assumed by the middle, and its obliquity was such that more than half of its inferior surface was distinctly visible.

[2] I have observed this condition twice.

puffiness, acute or transitory engorgement, it subsides very rapidly, almost instantly, while if hypertrophy coexists the tissues collapse much more slowly and less completely.

In making the diagnosis of incipient rhinitis, it should be borne in mind[1] that the disease not infrequently has its starting point in the erectile bodies, and occasionally in the periosteum. In such cases, the first evidence of its existence is a more or less engorged state of the area occupied by cavernous tissue. A stimulus, too, which in the normal state would exert little or no impression, is usually sufficient to provoke more or less erection of this tissue with, it may be, the evolution of reflex phenomena. In all cases the cavernous structure becomes sooner or later involved. Abnormal irritability of the area covered by this tissue, with slight puffiness of the same, are, therefore, invaluable guides in the early recognition of chronic intranasal inflammation. It should be borne in mind, at the same time, that this condition of the erectile bodies is not always the forerunner of rhinitis, but may be due to other and physiological causes. The swelling of the mucus membrane of the vestibule and anterior portion of the septum (cartilaginous septum) is always inconsiderable, except in the latter portion of the hypertrophic stage, when it is often excessive.

In their perfect physiological condition, the nasal passages are moistened by a scarcely perceptible halitus which varies in amount according to the condition of the surrounding atmosphere and other external and internal causes. The existence of mucus must be regarded as pathological, and therefore incompatible with a perfectly healthy condition of the nasal passages. While the secretion of mucus may be due to temporary causes (local or systemic irritation), it is always present in greater or less amount in the earlier stages of rhinitis. The more or less constant presence of mucous secretion within the nostril is therefore indicative of commencing inflammation.

III. *General Rules of Treatment.*—The general principles governing the rational treatment of the different stages, may be summed up tersely in the following propositions:

In the early part of the first stage, the treatment is mainly hygienic (hardening the skin, acclimatizing the nasal passages, attention to general health, protection of nasal passages from direct or indirect sources of irritation, removal, if possible, to an equable climate, etc.), and consists in many cases simply in the search for, and removal of, the cause (local or reflex irritation, general systemic disease, vices of constitution from various causes, excesses, surroundings of patient, etc.). At this period local treatment is often unnecessary, and in some cases harmful. In other cases, great benefit is derived from the judicious use of detergent, alterative, and astringent preparations, applied, as far as possible, to the diseased surfaces alone, in the form of solution or mixture with some such substance as cosmoline, glycerine, vaseline, etc., or these substances may be advantageously used unmedicated. In a certain proportion of subjects, the administration of remedies to control reflex excitability of the nerve centres is productive of good.

The treatment of the second period of this stage must be carried out on the same general principles as above. Remembering the condition of the contractile elements of the intercellular walls, measures should be taken to restore their loss of power (strychnia and electricity occasionally useful). Failing in simpler means, resort may be had to the galvanocautery or to electrolysis.

In the above periods, medicines in solid form (*e. g.*, powders) are absolutely contraindicated, as tending to increase the irritation and to hasten the coming of the hypertrophic stage.

The management of the first period of the hypertrophic stage consists in a combination of the above methods. Here surgical procedures are more justifiable. In the second period of this stage, the treatment is essentially surgical, and consists in the removal of the obstruction, in procuring thorough cleanliness of the nasal passages, and attention to the general principles indicated above. Solids are contraindicated. The general treatment of the third stage is tonic and hygienic; the local, is palliative, and consists in keeping the parts scrupulously clean and lubricated.

[1] See article referred to above.

RAPID ANÆSTHESIA BY ETHER.

BY A. F. MÜLLER, M.D.,

ATTENDING PHYSICIAN, GERMANTOWN HOSPITAL; MEMBER OF THE PATHOLOGICAL SOCIETY OF PHILADELPHIA, ETC.

THE following method of rapid anæsthesia by ether was suggested to me seven or eight years ago by a thought that the great length of time often consumed in etherizing patients was due to the fact of the frequent interruptions necessary to replenish the cone or towel used for the purpose, and the consequent partial recovery of the patient. To obviate the difficulty and obtain a continuous flow of pure ether vapor, I had made an apparatus, consisting of the two valves of a rubber foot-ball; sewed together at the edges and connected by a tube with a bottle containing ether, which is plunged into a bucket of hot water. Ether boils at 98°, and vapor passes over steadily and rapidly, and is inhaled by the patient, whose face is covered by the inhaler, protected by a clean towel.

The result has been surprising, as will be seen by the following cases, all etherized by this method within the last three months at the Germantown Hospital. In none of the cases was there nausea previous to anæsthesia; one at least came to the house the morning of the operation having eaten a hearty breakfast. In most cases no struggling, and if so, only slight; no stage of excitement. In cases that require only a few moments for operation, the patient wakes up nearly as quickly as after nitrous oxide. After the patient is etherized, the amount passing over can be regulated by a stopcock at the bottle end of the tube.

The apparatus I have used is very crude, made only for the purpose of experiment, and I am having an improved one made, which I hope will be more satisfactory in some of its details.

The quantity of ether used to produce complete insensibility in no case exceeded three ounces; in some it was less than an ounce and a half.

Case 1.—D. E., epithelioma of eyelid; plastic operation: unconscious in thirty seconds.

Case 2.—K. McF., peritomy: unconscious in one minute twenty seconds.

Case 3.—K. McF., peritomy: unconscious in one minute eleven seconds.

Case 4.—M. P., paronychia and palmar abscess: forty-five seconds.

Case 5.—Mrs. B., lacerated cervix: one minute twenty seconds.

Case 6.—Mrs. B., lacerated cervix: one minute fifteen seconds.

Case 7.—Bilateral lithotomy: one minute fourteen seconds.

Case 8.—Miss M., dilatation of cervix: one minute forty seconds.

Case 9.—Mrs. T., laceration of cervix: one minute twenty-four seconds.

Case 10.—Mrs. S., fracture of anatomical neck of humerus: one minute seventeen seconds.

Case 11.—Mrs. M., fracture of tibia and fibula: forty seconds.

Case 12.—Mrs. M., fracture of tibia and fibula: one minute forty-five seconds.

Case 13.—Mrs. B., fracture of tibia and fibula: two minutes.

Case 14.—Cataract: one minute fifteen seconds. This man when operated upon in the Germantown Hospital for cataract in the other eye about a year ago, took a large quantity of ether, and required an hour to put him under its influence.

Case 15.—Mrs. D., amputation of forearm: one minute thirty seconds.

Case 16.—McLane, hypopyon: one minute twenty seconds.

Case 17.—Mrs. S., lacerated cervix operation: one minute thirty seconds.

Case 18.—Cleaver, sarcoma of iris: one minute twenty seconds.

A CASE OF ARCUS SENILIS IN A BOY THREE AND A HALF YEARS OF AGE.

By H. F. HANSELL, A.M., M.D.,
Chief of Clinic of Eye Department of Polyclinic, Ophthalmic and Aural Surgeon to Southwestern Hospital etc, Philadelphia.

Recently at The Southwestern Hospital was presented the following case which, as far as I am able to learn, is unique: A mulatto boy three and a half years of age with distinctly marked and unmistakable arcus senilis in each cornea. "Circulus" senilis would be the more accurate designation, since the ring is complete on each cornea, though not quite so fully developed below as above, and on the sides. It appeared on each eye simultaneously in the upper segments of the cornea, about one year ago while the boy was convalescing from an attack of measles, and slowly advanced until the arc was made into a ring. I could obtain no history of inflammation or ulceration, and the mother positively asserts that the child's eyes "never had anything the matter with them, except the white rings."

These rings of fatty degeneration are in nowise dissimilar to the arcus senilis of adult life or old age. There is a margin of clear cornea between them and the sclerotic border, and they are sharply bounded toward the centre by clear corneal tissue which shows no trace of previous inflammation.

The influence of heredity, which can usually be traced where the arcus appears in the very young, in our case is negative. The mother and several brothers and sisters are free from the affection. The boy has no other abnormalities, and his health is perfect.

Edwin Canton, in his monograph on Arcus Senilis, says: "The arcus is said to have been seen at birth. I doubt the correctness of this assertion, and as I have already remarked, believe that an arciform opacity, the result of ulceration, was mistaken for it." The youngest case he mentions occurred in a boy of 12, in whose father, aged 56, mother, aged 53, and two brothers, aged 16 and 20, the arcus was very distinct. Middlemore says, it occurs as early as 40, Laurence between 30 and 40, Sybel saw it in a man of 32, Dixon in a girl of 18. Gross, in his *Pathology*, says: "The earliest age at which it usually occurs is 50, although it has been observed in a few instances in young children."

254 South Sixteenth Street.

MEDICAL PROGRESS.

Abortive Treatment of Typhoid Fever by Mercurial Inunctions.—Dr. Kalb, of Thalmässing, in the *Berliner klin. Woch.*, No 3, 1885, reports that he has treated one hundred cases in this way. Mercury is no new medicament—it is only applied in a new way in this fever. Six grammes of the ointment (in children four) are rubbed in for half an hour each time daily for six times in all—1st, on the belly; 2d, on the inner side of the right thigh; 3d, the left, and then beginning with the abdomen again. The ointment is preferable when a little rancid; it causes less eczema than when fresh. Internally at first a few pills of calomel and opium are given, even when diarrhœa is present. No other medication is resorted to, save methodical use of alcohol (sp. oryzæ), colored with cochineal. The course of the disease under this treatment was mostly as follows: On the eighth day, consequently on the second after the inunctions ended, the temperature fell to normal or thereabout, and remained so. The pulse remains for a few days over 100 or 120, yet it falls with the temperature to normal, or even 60. With the fall of temperature an abundant sweating almost always sets in, and the body is covered with miliary vesicles. The spleen remains enlarged and palpable for ten to fourteen days after this. Dr. Kalb did not fail to make comparative experiments, and found that the inunction treatment caused an evident shortening of the course of the disease. Eighty per cent. of his cases so treated were free from fever in ten days from its beginning. But to be successful, treatment must be begun before the ninth day of the fever, consequently before rose-spots are visible. No stomatitis worth mentioning has ever resulted, and patients recovering so soon must be carefully watched for a fort-

night and dietetic errors avoided, so that relapses may be prevented. The charts adhibited show the cases to have been of some severity, as temperatures of 40° and 41° C. (= 104° to 105°.8) are registered.—*Edinburgh Med. Journal*, March, 1885.

Treatment of Vaginitis.—Sigmund recommends the following solution for the treatment of vaginitis:

Iodine	gr. 1¼
Potassium iodide	gr. 6 to 12
Glycerine, pure	ʒv.

Dissolve and apply to the walls of the vagina, or introduce tampons wet with the solution for the treatment of blenorrhagic vaginitis with granulations.—*L'Union Médicale*, February 12, 1885.

Retention of a Dead Fœtus to the Normal End of Pregnancy.—Dr. Pelzer reports the following case of retention of the dead fœtus during several months. The case was under observation at Rabenau's Polyclinic, and is of interest on account of its rarity.

The woman was fifty years old and had menstruated regularly since the age of sixteen. She had borne two children, and fifteen months previously to her appearance at the polyclinic had aborted at three months. She gave no history of syphilis, and had always been in good health.

On the 6th of November, 1884, the woman appeared at the clinic—giving the history of not having menstruated since the 12th of February. She had none of the subjective symptoms of pregnancy.

The uterus lay in normal position, was somewhat soft, and indicated the fourth month of pregnancy. The neck of the uterus was thick, soft, and showed by the speculum a bluish color. The os uteri was rather large.

The breasts were well developed, but on pressure no milk appeared. The examination caused no pain. Further examination was made about one week after her first appearance at the clinic, and had the effect of exciting uterine contractions, inasmuch as two days later the woman returned, giving a history of profuse bleeding since her preceding visit. Examination revealed the presence of the membranes in the cervical canal. The product of conception was therefore extracted—during which the membranes were broken and a quantity of amniotic fluid, clear, but of bad odor, escaped. The placenta, which was slightly adherent, was then delivered, and afterward the uterus was thoroughly washed out with a solution of corrosive sublimate (1:4000).

The fœtus was well preserved. The umbilical cord was long and entirely free from knots. The placenta was of ordinary form and structure. The further progress of the case was normal, a slight retroflexion only being present, which arose, no doubt, from the lack of care the woman exercised. The malposition was corrected by a pessary, and, January 26, the uterus showed a measurement of three and one-fifth inches.—*Centralbl. für Gynäklogie*, Feb. 28, 1885.

Extraction of Hard Cataract.—At the January meeting of the *Congrès de la Société Française d'Ophthalmologie*, Galezowski's method for extraction of hard cataract, which, according to that operator's statistics, has given such brilliant results, was discussed at length.

The method of operation is as follows:

1. The eyelids are separated with the articulated blepharostat, and the globe seized below the cornea with forceps to render it steady.

2. With a very delicate Graefe knife he punctures at the junction of the transparent cornea with the sclerotic, about one-eighth inch above the horizontal diameter.

3. He then introduces the point of the knife below the pupil and incises the capsule from below upward in a semicircle. He then makes counter-puncture on the side opposite the corneal border, an eighth of an inch above the horizontal diameter.

4. He then incises the cornea one-twelfth of an inch from the sclerotic border.

5. The blepharostat and forceps are then removed, and the eye permitted to rest.

6. The upper eyelid is then elevated with the little finger at the right hand, and at the same time the curette is applied to the sclerotic border of the wound.

7. With the thumb of the left hand he then presses upon the lower border of the cornea. The crystalline lens is engaged and escapes without difficulty.

8. The iris frequently returns of itself; if not, he replaces it with a fine silver stylet.

9. A collyrium of eserine is next applied to the eye.

10. Carbolic acid spray is directed upon the wound for one or two minutes, and antiseptic carbolic dressing applied.

M. Galezowski considers the use of the carbolic spray as very important for the cure of the corneal wound.—*Gazette Médicale de Paris*, March 7, 1885.

Cannabis Indica in the Opium Habit.—Dr. J. B. Mattison, in the *Canada Medical Record* of Jan. 1885, recommends the fluid extract of cannabis Indica in the treatment of the opium habit where the characteristic restlessness or insomnia is manifested after the withdrawal of the opium. Full doses are given and repeated every hour, second hour, or less often as may be required. Squibb's fluid extract is used, and 60 minims given at a dose, no unpleasant symptoms having ever been noticed, and Dr. Mattison considers that the small doses recommended in the books are useless.

Treatment of Zona.—Dr. Fabre recommends the following treatment of zona: In the beginning of the disease, mild purgatives may be necessary. These should be followed by general sedatives, such as opium, belladonna, and ether, to diminish the pain. Locally, anodyne liniments may be applied and the diseased parts dusted with subnitrate of bismuth or oxide of zinc. If the vesicles are fresh and transparent, they may be aborted by covering them with collodion; but if they have been present four or five days, application of collodion will have no good effect; but, on the contrary, they will suppurate beneath it. The neuralgia which persists after the cure of the eruption should be treated by hypodermic injection of morphine or atropine, and arsenious acid in doses of from $\frac{1}{50}$th to $\frac{1}{8}$th of a grain be administered internally.—*L'Union Médicale*, Feb. 26, 1885.

Sciatica Cured by Chloride of Methyl.—At a meeting of the Société des Hôpitaux, held February 13th, M. Desnos read a communication from Dr. Almagran, of Orleans, concerning a patient suffering from severe and persistent sciatica. The disease had resisted all treatment and gradually became worse, and after application of the cautery the pain was intolerable. After two applications of chloride of methyl all along the course of the sciatic nerve, progressive improvement resulted, within three days the pain had entirely disappeared, and at the end of three months had not returned.—*Revue Médicale*, Feb. 21, 1885.

Laparotomy Repeated for Intestinal Occlusion.—Dr. Alfred Obalinski, in the *Wien. Med. Presse*, Nos. 48–50, 1884, gave the history of a laparotomy performed by him for intestinal occlusion. Ten days after its performance, the patient was sent home cured, September 29, 1884. January 16th of the present year, the patient returned to Dr. Obalinski, again seeking relief and complaining of the same pain as existed four months previously. Examination revealed the fact that about the 8th of January he began the second time to suffer intestinal pain which progressively increased in intensity. Seeking the advice of his family physician, he was directed to use purges and enemata, but these were without effect, and laparotomy was suggested as the only means of relief.

After careful examination, owing to the existence of meteorism, constipation, pain, etc., Dr. Obalinski was convinced that he again had to deal with a case of volvulus. Accordingly, a long incision was made in the abdomen about half an inch to the left of the cicatrix of the former wound. The peritoneum was found to be entirely normal, pale or slightly reddish. In it was a clear but dark-colored effusion, after the removal of which the intestine was found strangulated in the mesentery. The same difficulties presenting themselves as in the former operation, Dr. Obalinski punctured the small intestine with a probe trocar, but the perforation thus made refused to close, and accordingly sutures were introduced to insure thorough closing of the intestine. After the operation, there was movement of the bowels twice during the night, and the condition of the patient for two days succeeding the operation was very favorable. The pulse was strong at 80, the temperature about 100° F., and no abdominal pain was experienced. At the end of this time, however, severe abdominal symptoms were manifested and these were followed by collapse, great tympanites, and small thready pulse. Notwithstanding all efforts to sustain the patient, death resulted. The opinion was held that peritonitis had been caused by a failure of the catgut sutures to close the perforations in the intestine, and the consequent escape of the contents of the bowel into the peritoneal cavity. Post-mortem examination, however, showed this view to be incorrect.

In the peritoneal cavity was found about a quart of yellow feculent fluid. Further search revealed the presence of an opening in the ileum about one inch long and a fifth of an inch wide, with fatty edges. Further examination showed the colon to be the seat of numerous infiltrated spots, about twenty in number, the size of a *kreutzer*. The neighboring lymphatics were also markedly infiltrated, and the spleen was double the normal size and soft.

The case is especially of interest, as showing that the patient probably would have recovered from the second operation had it not been for the diseased condition of the bowel, due to a degeneration produced by typhoid fever, whose previous occurrence had not even been suspected.—*Wiener Med. Presse*, Feb. 15, 1885.

Artificial Fluid Tympanic Membrane: A New Mode of Treatment of Chronic Otorrhœa.—Michael, having noticed an improvement in the hearing of persons with perforated tympanic membrane when fluid was contained in the ear, conceived the idea of introducing into the ear an artificial fluid tympanic membrane instead of the pledget of wadding ordinarily used.

The method he proposes is the following: By means of a dropper he introduces glycerine into the ear until testing of the hearing, made after the introduction of each drop, shows an increased power of audition. If a drop too much is introduced, it is removed by a little wadding. He then introduces a few drops of elastic collodion, which does not unite with the glycerine, but forms a pellicle on the top of it. It is necessary at certain intervals to renew the collodion, as after a time the pellicle formed by it is destroyed.

When purulent otorrhœa is to be treated, Michael uses, in the place of pure glycerine, glycerine and alum or tannic acid.

Michael specially remarks that there is no danger in purulent otitis of confining the pus behind the collodion. The double advantage of this mode of treatment is protection of the ear from the air and the application of an astringent solution to its mucous membrane.—*Revue de Thérapeutique*, March 1, 1885.

Diabetic Neuralgia.—Dr. Florain, in the *Gazette Médicale de Paris* of Feb. 28, 1885, after discussing a typical case of diabetic neuralgia which came under his notice, concludes the pathogeny of the disease not to be well established. It is, however, easily recognized by its appearance concomitantly with diabetes, its intensely nocturnal exacerbations, and symmetry.

The appearance of the attacks before pregnancy, while the patient is in relatively good health, when there is no anæmia, sets aside at once the possibility of an anæmic origin. Moreover, gestation itself can no longer be reckoned as an exciting cause, inasmuch as the attacks may recur three months after confinement, and after a metro-peritonitis followed by abundant hemorrhage.

In the treatment of the disease, electricity seems to be efficient, faradization being very certainly followed by beneficial results.

Dr. Florain explains the good effect of electricity by supposing that the increased muscular action excited by the current, results in the formation of lactic acid at the expense of the inosite of the muscular tissue and of the hydrocarbons accumulated in the blood.

A Case of Floating Liver.—Dr. J. Maack, in the *St. Petersburger med. Wochenschrift*, 1884, No. 40, reports a case of floating liver in an unmarried woman

aged 35. Eleven years ago a swelling was observed under the border of the right ribs, and was pronounced a hydatid tumor of the liver. The swelling gradually increased in size, and produced but little disturbance until May, 1884, when nervous symptoms of such intensity manifested themselves that she again submitted herself for examination. The liver was out of its normal position, and a hemispherical smooth, stationary mass was present in the right ileo-cæcal region, overlying the right os ilei. The liver was not enlarged, but contraction had probably taken place

Floating liver previously has only been observed in women who have been especially prolific, and to relieve the symptoms produced thereby only the application of a bandage is necessary. In the preceding case, however, all attempts to produce pressure by a bandage were followed by pain, oppression, and fainting.

The case is, moreover, a very unusual one, in which the cause of dislocation of the liver was not relaxation of the abdominal wall, but stretching of the suspensory ligament of the liver, due to hydatid tumor, which in the meanwhile had decreased in size.—*Centralblatt für Chirurgie*, Jan. 24, 1885.

Physiological Action of Cocaine.—At a meeting of the French Academy of Sciences, M. Vulpian read a paper on the physiological action of cocaine, by MM. Grasset and Jeannel. The conclusions reached are the following:

1. Cocaine produces in the ape violent convulsive attacks.

2. Chloral is antagonistic to cocaine as an excito-motor as well as in its thermic effects.

3. The thermic action of cocaine does not appear to be identical in the ape and dog.

4. Antipyrin does not appear to be antagonistic to cocaine in thermic effects.—*L'Abeille Médicale*, Feb. 23, 1885.

Hysterical Fever.—M. Debove, at a meeting of the Société Médicale des Hôpitaux, recently held, read a paper upon hysterical fever. The existence of this disease, though admitted by ancient authors, has been disputed for the most part by modern writers. In supporting the view of the entity of the affection, M. Debove cited the case of a woman, aged 24 years, and who has been under his care for five years. The woman has the various hysterical manifestations, and about three years ago first experienced marked febrile disturbance, and has ever since had a temperature above 102⅖° F. At very irregular intervals violent exacerbations take place in the febrile symptoms, more or less resembling attacks of intermittent fever, and accompanied by a temperature of from 102⅗° F. to 104° F. These attacks were at first thought to be malarial, but the small size of the spleen and the absence of all cachexia, and the failure of quinine to influence the disease, showed this conclusion to be erroneous.

Latent tuberculosis was also excluded, and a diagnosis made of hysterical fever. Shortly after the hysterical origin of the fever was decided upon, the patient experienced a renewal of the febrile symptoms of great intensity. The temperature reached 105⅘° F., and the pulse was 130.

Sulphate of quinia had no influence whatever upon the attack, which persisted fourteen days. On the thirteenth day, 75 grains of antipyrin reduced the temperature below 100⅖° F., and her general condition was much improved. M. Debove has also observed other cases analogous to that just cited, not so clearly defined, but which support the conclusions he has reached as to the reality of hysterical fever. In the somnambulistic state, M. Debove has observed the temperature to rise from 1° F. to 2° F. by mere suggestion. Lowering of temperature by the same means has been less certainly obtained, the central temperature remaining invariable or even rising. Under these circumstances, M. Debove is of the opinion that the central thermic elevation is due to the contraction of the peripheral vessels under the influence of the suggestion of cold and to the consequent diminution of the loss of heat from the surface of the skin.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, Feb. 20, 1885.

Treatment of Tetanus.—Prof. Verneuil (*Revue de Médecine de Toulouse*), in the treatment of tetanus, adopts the following as fulfilling the indications most necessary to combat the disease:

1. *Complete immobility*, best obtained by Bonnet's apparatus.

2. *Constant and elevated temperature*, obtained by enveloping the entire body in a thick covering of wadding.

3. *Uninterrupted sleep*—chloral coma continued about twenty days.

When tonic contraction of the heart or bronchial muscles threatens the life of the patient, the continued current or tracheotomy must be resorted to. If there is danger of death from starvation, owing to dysphagia, or if the œsophageal sound is repelled, gastrostomy may be a final resort.—*Revue Médicale*, Feb. 28, 1885.

Twenty-three Tæniæ Expelled in One Day.—A. Laveran, Professor at d'École du Val-de-Grace, reports the following remarkable case of the expulsion of twenty-three tæniæ in one day. The patient was a lieutenant in the French army, and entered the hospital of Val-de-Grace in December, 1884, and soon after his admission passed segments of tænia. Previous to his admission to the hospital, he had been treated with various drugs, among which were santonine, pumpkin-seed, and castor oil, none of which was satisfactory. December 23, trial was made of the ethereal oil of male fern. The day preceding its administration, the patient partook of no food save milk. On the morning of December 24, examination of the stools which had been passed the preceding day revealed the presence of twenty-three tæniæ, all but one of which were complete—the head of this one being absent, or at least not found. The tæniæ measured together about 177 feet. The macroscopic appearances were those of the unarmed tapeworm, and examination by the microscope confirmed this opinion.

Prof. Laveran concludes his report with an interesting bibliography of the cases in which multiple tæniæ have been found to exist, and justly remarks that the term *solitary*, usually applied to this parasite, is not always correct.—*Archives de Médecine et de Pharmacie Militaires*, March, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 4, 1885.

THE TREATMENT OF ILEUS.

ALTHOUGH laparotomy has come to be recognized as one of the justifiable measures in the treatment of intestinal obstruction, it is a resource which, on account of its radical character, will probably always be the last adopted. It is gratifying, therefore, to be able to add one more remedy to those already existing, which may, without any risk of harming the patient, possibly avert the necessity for so formidable an operation. Such a resource has been recently brought forward by KUSSMAUL and CAHN, in the *Berliner klin. Wochenschrift*, Nos. 42 and 43, 1884, and still more recently by DR. C. HASENCLEVER, in a paper read before the Berlin Medical Society, and published in the same journal, No. 5, 1885. It consists in washing out the stomach. Hasenclever reports six cases, in all of which marked relief was afforded, and although only two recovered, the autopsies in the remainder revealed other serious lesions which necessarily rendered any treatment futile. Cahn reports three cases from Kussmaul's clinic, of which two recovered.

Still more recently, DR. J. T. WHITTAKER read a paper on this subject before the Cincinnati Academy of Medicine, an abstract of which, together with the discussion which followed, is published in the current issue of this Journal. Two cases are referred to by Dr. Whittaker as occurring in his own practice, one by Dr. J. L. Cleveland, and another by Dr. William Judkins. The cases of Whittaker and Cleveland, although relieved, died, but that of Judkins recovered. It would seem also from Dr. Whittaker's paper that the primary suggestion of this treatment came, not from Germany, but from Cincinnati, and from Dr. Cleveland.

As soon as the diagnosis of obstruction is made, the stomach should be washed out once or even twice a day. In this way often large quantities of fecal matter, mucus, and gas, are removed, while the singultus and stercoraceous vomiting cease, and the patient experiences marked relief. Spontaneous fecal evacuations also sometimes follow. The irrigation is practised until the patient is completely relieved, or the procedure is shown to be useless. The washing is continued until the fluid comes away clear.

The rationale of this treatment cannot be definitely stated, but from the standpoint of relief to vomiting, its use is as much indicated as that of opium and ice, which, while they often relieve this symptom, nevertheless fail to remove the cause. Whether the vomiting be explained as the result of a reversed peristalsis, or be regarded as simply mechanical, the opium merely obtunds the excitability of the nervous system, and thus averts, for a time, the reflex act of vomiting, while the intestinal contents continue to accumulate. By the irrigation, one element of the trouble is at least removed—the distention of the stomach and upper part of the intestine, because, as was shown by Oser, in the *Wiener Med. Blätter*, 1884, No. 41, the operation not only cleans out the stomach, but the small intestine as well; and this, too, as effectually, where there is insufficiency of the pylorus, as in acute and chronic intestinal obstruction.

As to the curative action of this treatment, where there is no insuperable obstacle against the re-establishment of the natural evacuations, Kussmaul suggests the following explanation: 1. By removing the large accumulation of fluid in the intestine, more space in the abdomen is provided, and the enormous distention of certain parts at the expense of others is avoided. 2. The peristaltic movements of the intestine, above the point of obstruction, previously violent and irregular, become more quiet and regular. 3. It is only possible to remove a remediable obstruction, such as a bend or an invagination. Hasenclever suggests that the great distention of the stomach and intestine, in addition to the presence of unusually irritating contents, may produce strong irritation of the splanchnic fibres, and a consequent inhibition of peristalsis, with paralysis of the bowel. It frequently happens in ileus, that, succeeding a period of violent, painful peristaltic motion, there follows a long period of absolute rest, in which the activity of the intestine appears to be paralyzed, and one can easily understand that after the removal of any irritating matters, the inhibition grows less, so that the forces regulating peristalsis again acquire the ascendency, and produce fecal evacuations.

In the course of the discussion upon Dr. Hasenclever's paper, Senator having mentioned the use

of castor oil and croton oil in ileus, Ewald took exception to the use of purgatives, and especially of drastics, as calculated to produce serious mischief in breaking up the adhesions, pretty sure to be excited by hardened and adhering feces, whether the obstruction be due to a twist or an invagination.

Senator thought that patients admitted to hospitals for this affection had usually already taken purgatives, either of their own accord or at the suggestion of a physician, and they sought the hospital because they had failed to receive relief from them. No fair conclusion, therefore, can be drawn in hospital practice as to the action of purgatives. On the other hand, experience in private practice had taught him in many instances of ileus, that purgatives had been very useful; not only in simple fecal obstruction, but also in stenosis of the intestine, the result of tumors. In all such cases in which there was no strangulated hernia or an evident invagination, or some other contraindication, as peritonitis, he had been in the habit of using, in the beginning of the treatment, cathartics, and drastic ones at that, The theoretical objections to the use of cathartics have as little to sustain them in practice, as those against the use of opium given with a view to *quiet* peristalsis, while irritating enemata and ice water injections are simultaneously given to *excite* peristalsis—apparently opposing measures which he and other physicians had nevertheless found of signal service.

Among the other purposes for which Kussmaul's procedure has been suggested, is biliary colic, due to impacted gall stones. At a recent meeting of the Berlin Medical Society, Rosenthal reported two cases treated in this manner. One was that of a woman of 33, who had been six months under his care with successive attacks of biliary colic, for which all the usual measures had been resorted to, morphine alone giving her relief. He then washed out the stomach, with a view to obtaining the sedative effect to which attention had already been called by Senator. As an apparent consequence, the vomiting, which had been troublesome, ceased. She returned almost daily to have the operation repeated, and on the fourteenth day she brought with her two gall stones, each about as large as a hazelnut. Since then she has had no recurrence of the symptoms.

The second case was also that of a woman who suffered from very severe attacks of hepatic colic with obstinate vomiting, and after washing out her stomach for a few days, not only did the vomiting cease, but the stones were also passed.

Rosenthal did not undertake to explain the rationale of this treatment.

ARTHRECTOMY AT THE KNEE.

Practical surgeons need scarcely be reminded of the bad functional results which follow resection of the knee for tubercular disease. In adults and subjects who have almost completed their growth, the limb is always shortened, while in children not only is there a suspension of growth, but angular deformity and contraction of the muscles are commonly met with, especially in those of the lower classes, who, after their discharge from the hospital, are usually neglected, and the limb becomes a positive incumbrance.

In the *Centralblatt für Chirurgie*, No. 9, 1885, Professor Volkmann, of Halle, calls attention to the important facts, first, that tuberculosis of the knee-joint of adults is, as a rule, primary, commencing in the synovial membrane and rarely extending to the bones, or if the latter be secondarily involved, the disease is quite superficial; and, secondly, that in children the disease usually begins in the bone, as a very small deposit varying in size from a pea to a hazelnut and that the cartilage is entirely or in greater part intact. Hence, he concludes that removal of the joint surfaces of the bones is not called for in adults, and that the old typical resection or removal of the epiphyses may be avoided in the majority of cases occurring in children.

Actuated by his conclusions, he has for some time, in cases of fungous gonitis, both of adults and children, practised with the best results, what he terms synovial arthrectomy, that is to say, the total excision of the degenerated capsule, leaving the bones and cartilages as far as possible intact. In advanced cases, arthrectomy is preceded by certain preparatory procedures. Thus, contraction of the joint is remedied by extension with weights, or by manual reduction, followed by an immovable bandage; large abscesses are freely opened, carefully scraped, and the walls sutured; and the fungous masses of sinuses and undermined skin removed with the spoon, and the parts dressed with antiseptic agents.

The joint is partially opened by a transverse incision, when, if after digital exploration and inspection of the parts, total extirpation of the capsule is indicated, the incision is enlarged, and the patella divided with a saw. Should the disease extend high up, converting the bursa beneath the quadriceps extensor tendon into a tumor with thick walls, a flap is raised, of which the base corresponds to the interarticular line, and the apex is on a level with the upper end of the bursa. The joint having been freely exposed, the entire capsule, including the synovial membrane and its processes, the remnants of the semilunar cartilages, and the ligaments are removed with scissors and scalpel until sound tissues are reached. Should the subquadricipital bursa be involved, it is first attacked, through which the femur is exposed to the extent ot two and a half or three inches. The cartilaginous surfaces of the bones are frequently left intact, but, in other cases, superficial or thick layers require excision. Tuberculous foci in the bones, should they

exist, are spooned or chiselled out. When indicated, partial resection of the joint ends is practised, but all sound bone and cartilage are scrupulously spared.

The preparatory straightening of the joint makes it possible to bring the limb in a straight or slightly flexed position. The epiphyses are kept in close contact, the divided patella is united with catgut sutures, and the tendon of the quadriceps or the patellar ligament, should they have been divided, are again united to the patella. The wound is, finally, carefully closed with sutures, with the exception of openings for the drainage tubes. During the operation the large surface is frequently irrigated with the sublimate solution, and, at its completion, antiseptic dressings are applied, and the limb supported on a splint.

The wound, with the exception of the openings for the drains, heals by primary union, and the operation is absolutely without danger, provided, in the case of children, too much blood be not lost, and the anæsthesia be not too deep and prolonged. The final results show a normally formed, not shortened, but stiff limb, the anchylosis of which is far more firm than after ordinary resection. The only subsequent precaution to be observed is the wearing of proper apparatus for a long time to overcome the tendency exhibited by the flexors to contract.

The paper of Volkmann is not supported by the details of cases, but a special article, prepared by one of his pupils, will appear in the course of the year, in which the comparative merits of arthrotomy, or incision and drainage, partial and total arthrectomy, and resection for fungous gonitis will be fully discussed. In the meanwhile his practice, which is most rational, will, we trust, be generally adopted.

It is interesting to note that in a paper, entitled Conservative Operations in Articular Tuberculosis, read at the Copenhagen Medical Congress, and published in the *Révue de Chirurgie*, No. 3, 1885, Professor Ollier, of Lyons, agrees in the main with Volkmann. Thus, he says that in children tubercle generally begins in the bone, while it starts in the synovial membrane in adults; and he declares that in only one case of a child below the age of ten has he been obliged to practise a formal resection of the knee. In this class of subjects, he opens the joint freely, excises and destroys fungosities with the hot iron, and scoops out tubercular foci. In adults, on the other hand, he prefers resection or amputation, since less radical measures rarely suffice to effect riddance of the disease.

THE THYROID GLAND AND MYXŒDEMA.

Professor Horsley has begun his labors at the Brown Institution, London, by a most important contribution to the physiology of the thyroid gland and its relation to the remarkable cretinoid condition which has, in some instances, followed its removal in man, and to the pathological state described by Ord as myxœdema. It has long been taught that the thyroid gland has no important influence on the bodily functions, and surgeons, acting on this assumption, have, in scores of instances, successfully removed it for various growths and degenerations. Kocher, however, has shown that in many cases a most serious disturbance of nutrition is apt to follow the operation, resulting in a condition which he calls cachexia strumipriva, a condition closely resembling, if not identical, with myxœdema and some forms of cretinism. Mr. Horsley has found that the removal of the gland in monkeys has a similar effect, but leads more rapidly to a fatal result. After complete removal the animal shows no change for five or six days, then the appetite fails, but afterwards becomes voracious. Fibrillar tremors of the muscles become general, and the animals get thin, pale, and languid. The eyelids and face become puffy, the neck thick, the abdomen distended, the salivary glands swollen, and the skin hypertrophied. The temperature gradually falls, the tremors cease and coma supervenes, with death in from six to seven weeks from the date of the operation. After death, the spleen is found enlarged, and the omentum hypertrophied, but the most remarkable changes are in the connective tissue elements, which are everywhere swollen by a mucoid transformation of the ground substance, with which is associated a wasting of the fat. The analysis shows a great increase in mucin, three or four-fold in the case of the subcutaneous connective tissue and tendon. Mucin is also found in the blood.

It seems reasonable to attribute these various conditions—cretinism, myxœdema (in which also the thyroid has been found atrophied or diseased), and cachexia strumipriva—to disturbance or arrest of the functions of this gland, and the possibility of the supervention of this state will make the operation of thyroidectomy almost unjustifiable. It would be interesting to ascertain the subsequent histories of cases operated upon in this country. Green, of Portland, Fenwick, of Montreal, and others, have had a large number of cases, many of which should be available for such an inquiry.

THE OPERATIVE TREATMENT OF PYOSALPINX.

Extirpation of the appendages, incision of the sac with drainage, and aspiration through the vagina, are the operations which have hitherto been practised for the relief of suppuration of the Fallopian tubes. Ovariosalpingectomy, in the hands of experienced surgeons like Tait, shows a mortality of 5 per cent.. and the formation of a hæmatocele in about 7 per cent. of the survivors. Hence the operation is not

a very lethal one; but when the sac has contracted firm adhesions to the surrounding parts, especially to the posterior layer of the broad ligament, and the bottom of the pouch of Douglas, it is not only very difficult of execution, but the distended tube is liable to be lacerated, thereby endangering life from peritonitis. Salpingotomy, or incision of the sac with suture of its walls to the abdominal wound, and subsequent drainage, is rendered almost impracticable when there are firm adhesions between the swelling and the pelvis, on account of which the sac is not easily drawn forward, and the sutures are exposed to the dangers of rapidly cutting their way out, thereby leaving openings for the escape of the pus into the peritoneal cavity. Puncture or aspiration through the vagina is attended with the disadvantage of having to be frequently repeated, and the risk of the escape of some of the contents of the sac into the peritoneal cavity, should the adhesions in the pouch of Douglas be incomplete.

In the *Centralblatt für Gynækologie*, No. 10, 1885, Wiedow, of Freiburg, calls attention to other methods of treatment which he believes will be found to fulfil the indications. When the distended cyst lies deep in the pelvic cavity, and is fixed by firm adhesions, a sagittal incision should be made through the vagina into Douglas's cul-de-sac, and the cyst be freely opened. Should exploration with the finger, however, indicate the absence of adhesions, the wound is plugged with iodoform gauze to excite adhesions, when incision is practised. When the cyst, on the other hand, lies in front of the broad ligament, and extends for some distance up the anterior wall of the belly, it may be reached by an incision, about two inches and a half long, carried through the wall of the abdomen, about an inch and a half above Poupart's ligament. If it be then found that the sac is adherent, it is at once opened; but should there be no adhesions, the case is managed as in the previous instance, before the abscess is cut into.

Since experience with pelvic abscesses has shown that they are best drained through two openings, Wiedow concludes that it will be wise to deal with pyosalpinx by incisions carried both through the pouch of Douglas and through the abdominal wall. In any event, irrigation with antiseptic solutions must be practised with great care, lest rupture of recent adhesions results. In an illustrative case, treated by Hegar by through and through drainage, recovery was complete in one month; but it will require very extended observation to determine whether the method possesses any real advantages over the removal of the appendages. If, after an exploratory laparotomy, extensive adhesions be met with, thereby imperilling the success of the operation, we do not doubt that the suggestion of Wiedow would be eminently proper.

GENERAL GRANT'S CONDITION.

The condition of General Grant, after a fortnight of comparative well-being and slight improvement, has undergone a marked change for the worse. Two weeks ago there was first noticed upon the back of the pharynx a vertical strip of discoloration and slight elevation, the nature of which could not then be determined; it was half an inch broad, and extended out of sight behind the palate and base of the tongue. It remained without much change for more than a week, but on Sunday had apparently become a phagedænic ulcer, and at the same time the ulceration of the tongue extended and the palate became œdematous.

During the nights of the 28th and 29th he suffered great distress from a feeling of obstruction in the pharynx, which was relieved by the local application of cocaine and twenty minims of Magendie's solution hypodermically. During the attack he was somewhat dazed, and on the following day there were evidences of cardiac failure, with intermittence of the pulse. The distressing sensations were apparently due to œdema of the pharynx, but, fortunately, the œdema did not involve the glottis. The marked increase of the area of ulceration, and the uncertainty as to the distance to which it has extended downward behind the tongue, cause much solicitude, and his condition, as we go to press, must be deemed extremely critical.

It should be borne in mind that the disease throughout has been rather of the pharynx than of the tongue, and has closely resembled in its course and lesions the soft form of epithelioma of the œsophagus, in which induration due to epithelial proliferation is slight and the ulceration is coextensive with its area. While to this fact may be due the absence of the pain which so commonly and distressingly complicates epithelioma of the tongue, this exemption is gained only at the price of a more rapid extension of the disease, and greater exposure to the secondary consequences of the ichorous discharge.

THE INHALATION OF DEFIBRINATED BLOOD.

In view of the bad results which follow the ordinary methods of transfusion of blood, and of the great tolerance of the respiratory organs to foreign fluids, and the rapid absorption of the latter, Professor Fabrini, of Palermo, calls attention, in the *Centralblatt für die Medicinische Wissenschaften*, No. 9, 1885, to what may be termed pulmonary transfusion. The fluid employed consists of twenty parts of bullock's blood, and eighty parts of a three-fourths per cent. watery solution of chloride of sodium, in which the red corpuscles preserve their normal properties for a long time. Inhalations of about three ounces and a half of the mixture, through the medium of an ordi-

nary spray apparatus, do not excite coughing, nor do they bring about any perceptible alterations in the circulation, respiration, or the temperature, and auscultation shows that the mixture is rapidly absorbed.

Fabrini has resorted to this novel method of transfusion in cases of oligæmia with the best results, as indicated not only by the improvement in the general condition of the patient, but also by the increase in the relative number of the red corpuscles, and in the quantity of hæmoglobin. These results are stated in a general way, and not supported by details of cases. Hence, more extended trials will have to determine the value of the method.

REVIEWS.

A System of Practical Medicine by American Authors. Edited by William Pepper, M.D., LL.D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, assisted by Louis Starr, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania. Volume I. Pathology and General Diseases. 8vo. pp. 1094. Philadelphia: Lea Brothers & Co., 1885.

Both Editor and Publishers are to be congratulated at having reached this stage in their great undertaking, and we may venture to estimate from this volume the general prospects of the work, and judge how far the time was ripe for "the presentation of the whole field of Medicine as it is actually taught and practised by its best representatives in America." The aim of an encyclopædic work such as this, should be the presentation of a mass of reliable information on the various medical topics, arranged in such an orderly manner that the reader, seeking for details on any subject, can obtain therein a digest and summary of the facts relating to it. From a careful review of this volume we should say that these conditions have been fairly well fulfilled. The articles, on the whole, represent the position of existing knowledge regarding the subjects of which they treat, and not viewed simply in the light of the personal experience of the writers, but broadly dealt with, embodying the collective experience of the profession.

The articles contained in this volume are contributed by twenty-one authors in various parts of the country.

The important introductory section on General Morbid Processes is by Professor Fitz, of Harvard, who presents an able summary of the facts relating to inflammation, the degenerations, tumors etc., rather too Teutonic in tone; but perhaps that is unavoidable in dealing with subjects in which our German colleagues are such masters.

The article on General Etiology and Diagnosis is from the pen of Dr. Henry Hartshorne.

On the subjects of Hygiene, Drainage, and Sewerage, the Editor has been, indeed, fortunate in obtaining the coöperation of the greatest living authorities, Dr. Billings and Mr. George Waring, Jr., whose articles, of a most practical and useful character, will be very highly appreciated.

Typhoid and Typhus Fevers are dealt with by Dr. James H. Hutchinson, of Philadelphia. One hundred pages are occupied in the consideration of the former disease, and the author has brought to his task a large personal experience, wide and extensive reading, and sound critical judgment, and the article is certainly one of the most important contributions to the volume.

The exhaustive and able paper on Relapsing Fever, by the Editor, is the outcome of one of the few careful studies of this interesting disease which have been made in this country.

The Variolous Affections are considered by Dr. Hyde, of Chicago; Scarlet Fever, by Dr. J. Lewis Smith, of New York; and Diphtheria by Dr. Jacobi, of New York, The names of these authors guarantee the character of the articles.

The late Dr. Bemiss, of New Orleans, contributed the papers on Malarial Fevers and Yellow Fever.

The article on Cholera, by Dr. Stillé, will be read with much interest in view of its possible visitation this year. The recent investigations of Koch are incorporated, but the author is non-committal on the subject. He is clear enough, however, in the question of the importance of quarantine, on which there is at present so much difference of opinion.

Professor Law, of Cornell, has written upon Rabies, Glanders, and Anthrax; Dr. Lusk, of New York, on Puerperal Fever; Dr. J. C. White, of Boston, on Leprosy; Dr. J. C. Wilson, of Philadelphia, on the Plague and Influenza; Dr. Keating, on Mumps and Whooping-cough; Dr. Watson, of Jersey City, on Pyæmia and Septicæmia; and there are articles by Hardaway, of St. Louis; F. P. Foster, of New York; Schmidt, of New Orleans; and Simmonds, of Yokohama.

Although the issue of this volume has been somewhat delayed, most of the articles are well up to date, and contain references to the most recent researches. The concluding article on Beri-Beri seems stale, and it is a pity there is no reference to the observations of Scheube and others. No mention either, is made of the occurrence of the disease in the Sandwich Islands, commercially so closely connected with this country.

It could not be expected that the articles should be of equal value, but on the whole the work has been well done, and if the succeeding volumes maintain the same standard they will greatly enhance the reputation of American Medicine.

It seems particularly appropriate that this great work, perhaps the most important American medical publication ever undertaken, should appear during the centennial year of the existence of the publishing house of Lea Brothers & Co.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, March 9, 1885.

The President, Samuel Nickles, M.D., in the Chair.

Dr. J. T. Whittaker opened a discussion on

ILEUS TREATED BY WASHING OUT OF THE STOMACH,

by remarking that ileus is not a very rare disease, as is shown by the fact that it is so often the subject of dis-

cussion in medical societies. Leichtenstein says that one death in every three to five hundred is from obstruction of the bowels, and Treves states that two thousand people die of it every year in England. The intense suffering which its victims endure makes it a subject of interest to the profession, and makes welcome any contribution to its therapy. Yet the speaker saw a case recently in which the suffering was not of marked severity, although it proved fatal. About three weeks ago, he was called to a village in the vicinity to see an individual suffering from constipation. He had, however, been in the habit of becoming constipated at frequent intervals for a year and a half. He had also been a victim of dysentery. From this history the speaker concluded that the case was one of stricture. He was a robust man forty years of age; he had no fever and but little pain. He suffered rather from an uneasiness which led him to get in and out of bed almost constantly, and to make efforts every half hour or hour to evacuate the bowel. There was some jaundice present; but not marked emaciation. The most prominent symptom was vomiting. Every fifteen or twenty minutes he discharged a quantity (usually two or three ounces) of a dark fluid which was glutinous, but had no stercoraceous odor. The abdomen was perfectly flaccid, so that the anterior wall could be pressed down upon the vertebral column without difficulty.

Examination of the rectum revealed nothing in the nature of a stricture, even when the hand was partially introduced. An attempt was then made to wash out the bowel, when it was found that only about a pint and a half of fluid could be injected, and that this returned without bringing along with it any fecal matter. This had been done before his arrival by Dr. Highland, the attending physician, with the same result, and mild laxatives had been administered without result. Having seen great benefit in these cases from the washing out of the stomach, the speaker had taken a stomach-pump with him. He introduced it, and just as the slight constriction at the cardiac orifice of the stomach was overcome, there was a gush of a pint or a pint and a half of the dark brown fluid to which he had referred, coming up beside the tube. He got no fluid through the pump, and proceeded to wash out the stomach. The patient was greatly relieved, the vomiting ceased and on the next day he had an operation. Two days after, however, the speaker was again called and found the patient in about the same condition as at his former visit. He again washed out the stomach. During the preceding day, a severe hiccough had developed, for which the physician in attendance had given opium in small doses without succeeding in allaying the difficulty. The dose of opium was now increased, with the effect of putting a stop to the hiccough. In order to make more certain the relief of the constipation, the patient was now placed upon his hands and knees, and the rectal tube was again introduced. About eight inches from the anus there was encountered a feeble constriction which was easily overcome. Three or four pints of fluid were easily injected, but when the tube was removed only a half pint of it came away. The end of the tube was coated with a little rose-colored mucus. After this procedure, everybody was hopeful, and the patient became cheerful in the belief that the stricture had been overcome. The speaker did not see the patient again, but a few days after his visit he observed in a daily paper a notice of his death. He had not been informed of the immediate cause of death, but was of the opinion that it had been due to a perforation of the intestine, probably at the site of an ulceration.

It is not usually difficult to recognize in these cases the character of the obstruction. It would be very extraordinary, in the first place, to find an invagination in a man forty years of age. This is rather a disease of childhood. Brinton has shown us that of 100 cases of bowel-obstruction, 43 are due to intussusception, 27 to strangulation, and 17 to stricture. There is not in most cases much difficulty in determining the seat of the stricture, where that is present. An internal strangulation is not so easy to recognize. Generally, however, we come upon the localization of stricture without much difficulty. In the case reported the stricture was recognized by the introduction of the tube, and that is the manner in which it can be reached in most cases. Brinton's statistics show that in 100 cases, 4 are in the cæcum, 10 are in the ascending colon, 11 in the transverse colon, 14 in the descending colon, 30 in the sigmoid flexure, and 30 in the rectum.

After making the diagnosis of stricture, it is customary to attempt to relieve it first by the administration of mild laxatives, then we try opium. Opium has been said to be the best cathartic in obstruction of the bowels. By it we put the bowel at rest and allow natural peristalsis to overcome the constriction. Every one knows the danger of administering drastic cathartics. Opium, however, only obtunds and subdues the violent impression upon the nervous system. After everything has failed, we try operative procedure, but we are all aware of the great danger of this operation. We do not, in reality know the exact mortality of the operation, because the majority of the cases are not published. The speaker had been cognizant of several fatal cases that were never reported, and if the truth could be known, he thought that the mortality would reach above 63 per cent., as given by Treves. After opium has failed, we are left, he believed, with a disease for which there is no remedy.

Kussmaul, has recently reported four cases treated by what he termed a new method, namely, by washing out the stomach. Two of these cases were necessarily fatal, one being cancer, the other tuberculosis. Kussmaul, in his treatment, introduced the stomach-tube, then poured water in through a funnel, applying the treatment every day. He found that with each washing a large quantity of matter is evacuated, the patient at once ceases to vomit, and the collapse is greatly relieved. In some cases a cure has been obtained. Since his report, in November, 1884, cases have been reported by Cahn, Rosenthal, Fraenkel, Senator, and others. Senator, of Berlin, reported a case in which recovery was obtained after collapse had come on. He had been treating the case with opium, and seeing the report of Kussmaul, concluded to try that method of treatment. The individual at once improved and progressed favorably until the tenth day, when there was a relapse; the patient sank into a gradual collapse and died.

It was found upon autopsy that tuberculosis had been the cause of death. This case was reported to the Berlin Academy, and a discussion held upon it. Fraen-

kel's case recovered after obstipation of seventeen days. Rosenthal reported a case where three years before, a woman had been treated for gall-stone colic, by washing out the stomach, the first relief having come on after spontaneous vomiting. Rosenthal also reported a precisely similar case, since treated in the same manner. Since that time other cases of obstruction have been reported. No cause has been reported in which palliation of the symptoms was not obtained. Many cases did not recover because in some of them recovery would have been an impossibility. The practice is becoming established, and in the opinion of the speaker there was no doubt that other successes would follow.

In regard to the *modus operandi* of the method, he said a number of explanations had been made, none of which was quite satisfactory to the gentlemen who had propounded them. The first explanation is that by the emptying of the stomach of large quantities of fluid and gas, room is given in the abdomen for the movement of the intestines. In most cases the abdomen is distended with gas, so that there is no opportunity for the occluded gut to move about. The second explanation is that when we pump out the stomach we not only evacuate the contents of the stomach, but also of the intestinal canal.

The investigations of Oser in 1879, show that there is pyloric incontinence in these cases. The stercoraceous vomiting would also prove the truth of this. Oser proved it by experiments on dogs. In relieving the intestine of its great distention we give it an opportunity to unlock itself. Further, in chronic cases good is done by washing out the stomach because it allows the food to be absorbed and thus to increase the nutrition of the patient. The main advantage, however, according to Kussmaul, is that by removing the irritating matter from the stomach and intestine we substitute natural gentle peristalsis, for tetanus and spasm, and thus allow natural motions to take place.

Senator and Ewald were not satisfied with this explanation, however, the speaker continued, and appealed in their theory to the nervous system. The intestines are supplied, they said, with two sets of nerves, the excitant and inhibitory. Senator thinks that when we remove the contents of the stomach we cause the excitant to get control of the inhibitory nerve centres, and permit them to act in a normal manner. The ominous calm which supervenes upon the tetanus before death shows the predominant control of the inhibitory nerves. In the two cases in which the speaker had tried the remedy, he had found it of great benefit although both were fatal cases. In one case he knew that recovery was impossible, because there was a firm compression of the ileum, and an erosion of the intestinal wall.

The speaker then quoted briefly from the report of the session of the Academy published in the *Cincinnati Clinic*, April 28, 1880, in which it was recorded that he had reported a case treated by this method. In that case he had used the stomach-pump two or three times, and brought the case before the Academy to exhibit what he thought was a triumph in the treatment of ileus. The patient however, died very suddenly from the shock of strangulation, and the speaker was made the subject of considerable comment, having even been charged by a wise newspaper editor with having caused a death by the use of the stomach-pump. He was pleased, however, with the recollection that there were members of the Academy who supported the treatment at the time. One member, he saw by a review of the report, had, commended the treatment, and had even credited him with the originality of its introduction. This however, though he thought it true until lately, he must now disclaim, for in the same report he found recorded the remarks of another member of the Academy, Dr. J. L. Cleveland, who had instituted the same practice in a case of obstruction from perityphlitis treated by him four years before the meeting. Whatever credit is due to this method does not belong to Germany, or any part of it, but to our own country and city, and to members of this Academy.

Dr. J. L. Cleveland remarked that while cases of ileus are not of very frequent occurrence, they are of a character when they occur that tasks the ingenuity of the physician to the utmost. There is no class of cases, he said, in which the physician feels more helpless than in these. If the point of obstruction can be found, it can generally be relieved; but if this cannot be found, we are utterly helpless. We know further, that if the obstruction cannot be relieved the patient will die, and that in the utmost agony, hence the value of any contribution which will enable us to save these patients.

The method proposed, with the explanation given, the speaker thought, had the merit of being at least rational. He had a vivid recollection of the case to which the reporter had referred in the conclusion of his remarks, in which he had made use of this method of washing out the stomach, and had found it of great benefit to the patient. His reason for resorting to the procedure at the time, he said, was the fact that the patient was suffering greatly from distention of the abdomen and from vomiting. The relief which he obtained from it far exceeded what he had anticipated.

Dr. William Judkins reported that, less than thirty days ago, he had made use of the method of treatment under consideration, being led to do so from the recollection of the favorable report of it made to the Academy five years ago. The patient upon whom he used it had not had a stool for five days, and was suffering severe pain in the abdomen. He first gave him hypodermic injections of morphine, which relieved the pain. The next morning, finding the condition about the same as on the previous day, he washed out the stomach. The patient at once vomited a quantity of mucus and fluid upon the introduction of the tube. This was again done in the evening at the request of the patient, on account of the relief it afforded him. Soon after a natural evacuation occurred, and the difficulty ceased.

Dr. G. S. Mitchell expressed surprise at the statement of the reporter, that the abdominal walls were so flaccid in the case he had reported as to permit of their being pressed back against the vertebral column. Tympanites is the rule; and furthermore, in a case of tympanites, there would be more applicability of the explanations given as to the method by which washing out of the stomach could overcome the difficulty. The speaker believed that almost as much good could be done in most cases by introducing the tube into the rectum, and allowing the gaseous contents of the bowel to escape. Washing out the stomach, he added, while frequently prasticed, is not unattended with danger; neither is

the introduction of the tube in all cases free from difficulty.

The speaker then reported the case of a barkeeper who had for a long time suffered from dysentery, when an obstinate constipation set in. When seen by him the individual had been without an operation for only two days, but was suffering intense pain and incessant vomiting. The temperature was 100.5°, and there was slight dyspnœa. He gave him small doses of Rochelle salts. The vomiting was controlled by plain soda water. The laxatives did no good, and he resorted to the subcutaneous administration of morphia. He then introduced an œsophageal tube fourteen inches into the rectum, and introduced two quarts of water. The tube was allowed to remain, and in a short time gas began to escape, and finally the abdomen was reduced to its natural flaccid condition. When the water came away it was accompanied by a small amount of fecal matter. The next day the patient was much worse. His temperature was 101°, and the abdomen was very tympanitic. Collapse soon supervened, and he died in a few hours. The autopsy revealed three constrictions in the colon, above one of which was an ulcer that had perforated into the peritoneal cavity. A small quantity of pus, but no fecal matter, was found in the peritoneal cavity.

Dr. Philip Zenner thought that the difficulty of introducing the stomach-tube and the difficulty of getting water to pass through after its insertion had been overestimated by the last speaker. The patient must assist the operator by the act of swallowing, and when that is done there is no difficulty in its introduction. He had never seen any difficulty in the introduction of water simply by the weight of a column a few feet in height. He thought that the tube could not have been properly inserted if there was any difficulty in getting water to pass through it.

In regard to the comparative value of the introduction of the tube into the stomach, and its introduction into the rectum, the speaker thought that the danger of the latter procedure was much more to be feared than that of the former. Some of the fatal results following that method of treatment, he feared, were due more to the remedy than to the disease. Another danger of popularizing this treatment lay in the fact that by its use other methods of really greater value were lost sight of in the strong hope of recovery based upon the marked amelioration of symptoms which followed its use. The method will be of greater value when we shall have discovered by more thorough investigation in just what cases it is most applicable. In his opinion, the treatment would be most applicable to chronic cases, in which the disease would gradually, but inevitably, lead to a fatal termination. One of the cases of Kussmaul was chronic in character. There are certainly acute cases in which the treatment could be of no benefit at all. He has known cases which terminated fatally within two days after the inception of the attack. In such cases the speaker could see no reason for anticipating any benefit from this method of treatment. While we have in it a method of unquestionable power, it is our duty to endeavor to determine in just what cases it will most advantageously exert that power.

Dr. Thad. A. Reamy stated that he had seen a case of ileus in which the only obstruction was due to an inflammatory band that had run across from the intestine to the pelvic peritoneum low down, and had constricted the bowel in that way. It was in a child that had received an injury six or seven weeks prior to that time. From the injury a circumscribed peritonitis had developed and given rise to the adhesive band. The peritonitis had almost subsided, however, when the obstruction manifested itself. Death occurred one day after its appearance. That was a case, the speaker continued, in which, if its character had been known, surgery would have unquestionably afforded relief. But in such a case there could be no hope for relief from the method under consideration. Still, in a great many cases this treatment will be of benefit. While he thanked the reporter for bringing the subject before the Academy, he thought it was not proper to allow the subject to drop with the impression that had been made with regard to the mortality following operative procedure. If the cases were placed under surgical treatment at an early period, he thought there was no question that the mortality would fall far short of 63 per cent. Washing out the stomach was doubtless highly proper in chronic cases; but in acute cases, in which ordinary methods had failed, a resort to surgical procedure would unquestionably reduce the mortality below 50 per cent. in the present advanced state of abdominal surgery. We need not wait for the statistics, he continued, but we should make the statistics by opening the peritoneal cavity and relieving the obstruction. If, then, the mortality of the operation would not prove much less than it now is, we must assume that there is something in the female peritoneal cavity that gives a tolerance to operative interference that is not found in the male. The operation should be made early, and with the same care as would be exercised in the removal of an ovary.

Dr. Joseph Ransohoff agreed heartily with the last speaker, that the method advanced by Dr. Whittaker would answer in some cases very admirably. He thought it worthy of consideration, however, whether the case reported was one of stricture or simply one of obstruction. He had once been called to see a case which closely simulated one of obstruction, but in which there was nothing but an impaction of gall-stones. Two weeks ago he had been called to see a little boy suffering from constipation, pain, vomiting, tympanites, and a tumor in the groin. The diagnosis of strangulation of the intestine had been made, and the attending physician had made preparations to operate. It was found that it was a case of retained testicle, and the large tumor was due to a hydrocele that had formed around it. After the hydrocele was tapped the testicle descended, the bowels moved, and all the symptoms were relieved.

In reference to the case reported this evening the speaker did not think it nearly so conclusive as the one reported five years ago. That case began with a narraton of the clinical history and terminated with an account of the post-mortem section. The specimen was also presented to the Society showing the occlusion of the gut. In this case these were all wanting. The symptoms would indicate that there was an obstruction of the bowel; the only positive evidence of this, however, was that a slight constriction was met at a point about ten or twelve inches within the rectum. The speaker stated further that he had made the experiment of passing a tube into the rectum a great many times both on the

living subject and in the dissecting-room, and that while in some cases he had succeeded very well, in a large number of cases the tube had failed to pass the sigmoid flexure. A soft tube is particularly apt to bend and remain in the rectum, but a tube that is a little more firm is apt to get caught and remain in the folds of the intestine. When a stricture is to be found in the bowel, there are physical signs that are usually well marked. A stricture does not develop suddenly, but is usually several years in developing. By careful examination of the abdomen by careful palpation there can usually be found a tumor. The diagnosis of stricture in those cases in which none of these symptoms has been detected, must be taken with some doubt. In well-marked cases of constriction the speaker had no faith in the use of the stomach-tube, and, under ordinary circumstances, he had little more faith in the use of the rectal tube.

The speaker further thought the use of the rectal tube was attended with considerable danger, and, in the case reported by a previous speaker, he had been led to inquire whether the finding of pus in the peritoneal cavity might not have been due to the use of the rectal tube. Had fecal matter been also found, such an explanation would have received pretty strong support. In cases in which the symptoms were well marked, he could not comprehend how the use of the stomach-tube could be more than palliative in its character. While its use for the relief of annoying symptoms is proper, he thought that when these symptoms return such methods would be abandoned, and an abdominal section made. If this is made early, he could see no reason why the mortality should be more than 25 or 30 per cent.

Dr. Whittaker, in concluding the discussion, remarked that he did not think the last speaker drew a sufficiently distinct line between acute and chronic, and complete and incomplete strictures. It is not always an easy matter to detect the location of occlusions. In proof of this he called attention to a case he had reported five years ago, in which, although a strangulation was found post-mortem, it could not be discovered by the most careful palpation previous to the fatal issue. Nor could the last speaker, who made the post-mortem, detect it until the abdomen had been opened and the intestine searched. As in the majority of cases, so in this, the failure was due to the presence of a thick layer of adipose tissue in the abdominal walls. He strongly objected to the ground just taken, that the use of the stomach-tube could be only palliative, inasmuch as some of the cases that have been reported have been unquestionably cured. That a case should be cured by removing the liquid and gaseous contents of the stomach and intestine is not a matter of surprise when we reflect that some cases are relieved simply by puncturing the intestine through the abdominal wall. The point of most value, however, is the comparative innocuousness of the stomach-tube; on this the speaker wished the more to insist, because one of the members had spoken of the dangers attending its use. There is, it is true, danger in the use of the rectal tube; but thus far there has not been reported a case in which damage was done by the stomach-tube, unless in cases of ulcer. The reports of Haenisch show that the tube causes but a slight abrasion of the mucous membrane, which quickly heals. The speaker agreed with the member who had stated that there is sometimes difficulty in the introduction of the stomach-tube. He had experienced this in some cases, particularly with the soft tube. In these cases he thought it better to use the firmer tube belonging to the stomach-pump. When this is warmed and carefully introduced, there is usually no difficulty. He had, however, never found any difficulty in getting water to enter after the tube was inserted. In regard to the more acute cases he said that the treatment he had proposed would be of as much avail in them as in the more chronic. There are cases which terminate fatally within eight hours, under the so-called shock of strangulation. In these cases opium would be a necessary adjunct. The first benefit of washing out the stomach is in relieving the vomiting. In this regard its effect is marvellous. The effect is shown even in the countenances and comments of those who witness the treatment; but the effect on the patients themselves is almost beyond words. There is nothing so horrible as a case of acute ileus,—in fact it entirely deserves its ancient name, "miserere."

CINCINNATI MEDICAL SOCIETY.

Stated Meeting, March 3, 1885.

The President W. H. McReynolds, M.D., in the Chair.

Dr. F. O. Marsh reported the following

UNUSUAL CASE OF SKIN DISEASE.

Mrs. S., German, æt. 47, has resided in America thirty years, is married, and has one son who is a deaf-mute. Patient possesses average intelligence; always enjoyed good health, except an attack of acute rheumatism twenty years ago; gives no history or evidence of syphilis. About two years ago, the present trouble began with pains in the limbs, which were believed to have been of rheumatic origin. About the same time, she noticed spots about the knees, ankles, fingers, and toes, which according to her description were areas o inflammation, at first covered with scales, which were loose at the commencement of the trouble, but subsequently became firmly adherent, forming a horny epithelial deposit, which subsequently scaled off, leaving a raw surface. This process has been repeated on all parts of the body, forming projecting circumscribed accumulations of horny epithelium. The affection has invaded the scalp, again disappearing without leaving any trace of cicatrization or destruction of hair.

At present two or three of the accumulations are to be seen on the inside of the knee, resembling the crusts of rupia. The most remarkable feature, at present, is the condition of the fingers and toes, which have been affected for a year, having become successively involved, the last invasion taking place about nine months ago; all except the thumb and index finger of one hand are affected. The distal phalanges, especially on the dorsal aspect, are capped with an irregular horny deposit, the nails being much elongated and distorted, or hooked. The little finger of one hand is capped down to the middle of the proximal phalanx with a stiff, thick, and parchment-like covering, resembling the finger of a tightly fitting glove. The zone of tissue immediately behind the glove-finger is considerably elevated above its edge and congested, giving the whole the appearance of a tightly fitting finger-stall of parchment cutting into the flesh. The thumb had been similarly affected,

but the patient had pulled off the cap about three months previously. This relic, which she had preserved with considerable pride, I am permitted to present to you this evening. It will be observed that the formation is much more regular than the above description of the other digits would indicate. The cap is about one-twelfth of an inch in thickness, hard and horny, and the body of the nail which has also been desquamated in its normal position is quite regular. A new nail has been formed, though more irregular than the first, showing that the matrix had not been destroyed. The thumb itself, though free from the peculiar deposit, is somewhat constricted in all its dimensions.

There is no pain at present, but the onset of the affection was attended with pain, which, according to the patient's account, must have been excruciating, and lasting for over a week. Circulation in the extremities is very defective, the patient complaining much of the cold. Otherwise the general health seems not to be much impaired, being disturbed by feelings of apprehension and troubled dreams, though the general disposition while awake is cheerful. Almost simultaneously with the skin affection and the rheumatic pains above alluded to, the ankle-joint became affected by an arthritis. At present the knee-joint is swollen and painful, and sleep is disturbed by muscular twitchings of the affected limb. The wrist-joint is also much enlarged, but not painful. The enlargement seems to affect the articular ends of the bones. The skin-covering of each of these affected joints was at the outset the seat of the epithelial affection in a very marked degree. On the palm of the hand where one of the characteristic excrescences had recently been removed could be seen the hypertrophied papillæ of the corium. Close inspection shows the structures laminated, and microscopic examination reveals the growths composed of flattened epithelial cells closely packed. Cleaned with caustic potash and stained with methylene-blue no microörganisms could be seen except the living bacteria of the water used in mounting, Cornu cutaneum I am unable to find described as occurring on the phalanges and affecting the nails, or as being painful. Neither does it seem to correspond in these respects with the usual descriptions of ichthyosis.

DR. DRURY was much interested in the case, though he confessed the disease seemed to him obscure. The history appeared to indicate that the case was one of ichthyosis, though it was certainly a remarkable and unusual manifestation of the disease.

DR. JOHN L. DAVIS said that this case was interesting from the difficulty and uncertainty of diagnosis. At first sight there is the appearance of an obscure or irregular ichthyosis. The scaly nodules in several parts of the body point to this. Though we have here a striking local disease, the speaker regarded it as the outcome of a constitutional malnutrition, the vulnerable point revealing itself in the trophic nerves of the epithelium. While the term onychoptosis or piplonychia is sometimes used to designate a rare affection consisting in a shedding of the nails, it is in reality only a symptom occurring oftenest in the course of certain severe acute diseases, as scarlatina, typhoid fever, pneumonia, etc.; very rarely does it occur as the leading manifestation of disease. He recommended principally constitutional treatment by means of tonics and arsenic.

DR. RAVOLGI thought this case must be regarded as one of ichthyosis. From the report, it would seem that there were two varieties or rather perhaps two degrees of the affection on the fingers—first the parchment-like condition, *ichthyosis macrée*, and the still more intense condition of *ichthyosis cornea* or *I. hystrix*, representing the most exalted condition of the disease.

A remarkable feature in this case is the late period at which the disease appeared.

Authorities are divided on the question of heredity. In most cases the disease develops itself a few years after birth in the form of I. furfuracea subsequently passing through the form of *I. macrée*, and only at a comparatively late period reaching the condition of I. cornea. The epidermis in this affection seems to possess an unusual capacity for keeping up its nutrition; it is not desquamated at the usual period of its life history, but remains adherent, forming at last horny plates which finally fall off, leaving the underlying surface red and heavily pigmented, which may afterward become again covered with the epidermic masses.

There could hardly be any congenital or hereditary element in the etiology of this case, inasmuch as there was no family history of any such affection and the disease had appeared at a very late period. The general history of partial ichthyosis, moreover, generally seemed to indicate that it arose without reference to heredity.

The neuralgic pains which accompanied the affection would indicate that the trouble was of nervous origin, there probably being some accompanying disturbance of the vaso-motor filaments governing the nutrition of the histological elements.

From the studies of Filesius, Simon Bärensprung, and recently of Esoffit, it seems that in this disease the papillæ are enlarged and elongated, and the sebaceous and sudoriferous glands somewhat atrophied and at times cystic.

Ichthyosis has generally an unfavorable prognosis, though the acquired form is more amenable to treatment than the hereditary.

The treatment should consist of, first, the removal of the epidermic plates, which could be facilitated by maceration in alkaline solutions or soap. The use of Vleminckx's solution, containing flowers of sulphur and chloride of lime, might improve the condition of the skin, and prevent the reformation of the scales. Fowler's solution would prove a valuable systemic remedy.

DR. MARSH was inclined to concur in the diagnosis of ichthyosis, but thought some of the conditions were quite unusual, such as the accompanying arthritis, the severe neuralgia, and the affection of the nails, as well as the regularity in form of some of the formations, as in the cast from the thumb. The joint affection, he thought, could hardly be a spinal arthropathy, as there were pain and all the symptoms of a genuine arthritis of a chronic nature. He thought the continued proliferation of epithelium within the firm shell or case of unyielding epithelium first formed would account satisfactorily for the constriction or compressed appearance of the thumb after the cast had been shed. The same constriction would account for the hyperæmic or congested zone at the base of the glove-finger on the little finger, as the venous return was probably obstructed.

The shedding of the nails might throw light on the

pathology of the disease, as such a condition could hardly be due to a glandular affection of the skin alone, as some authorities had claimed ichthyosis to be.

CORRESPONDENCE.

A NEW UREOMETER.

To the Editor of The Medical News.

Sir: In the report of the meeting of the New York County Medical Society, published in your issue of the 28th, is a description of a new ureometer, by Dr. Chas. A. Doremus. Excepting that it has no base, the apparatus described is essentially the same as that devised by myself, and described with figure in the *Comptes rendus*, vol. xcvii. page 1142, November, 1883. The description was republished in the *Zeitschrift für analyt. Chemie*. and in several other German journals, as well as in the *Philadelphia Medical Times*, vol. xiv. page 277, and figures also in the last edition of Da Costa's *Diagnosis*. It has been manufactured and sold by Greiner & Friedrichs, of Stützerbach, since January, 1884, and has been favorably received in Germany.

In October, 1884, I brought it to the notice of the Philadelphia County Medical Society, and described as a modification that might be home-made, the identical tube apparatus without base, now claimed by Dr. Doremus. Either Dr. Doremus has knowingly claimed as his own an apparatus, to the invention of which I am entitled to unquestionable priority, or he has betrayed ignorance of the literature of urine analysis. I highly appreciate Dr. Flint's kind remarks as to the utility of my ureometer.

Very truly yours,

Wm. H. Greene.

3225 Sansom Street, Philadelphia,
March 30, 1885.

NEW INVENTIONS.

AN IMPROVED PALATE-HOOK.

By H. M. Wilson, Jr., M.D.,

physician to the throat and chest department of the baltimore general dispensary.

It is the intention of this simple device to combine traction with the support of the uvula in a more efficient manner then is done in the palate-hook of Voltolini. It consists of a strip of German silver an inch in length by seven-sixteenths of an inch in width, bent five-sixteenths of an inch from its extremity at an angle of about ninety-five degrees. At the distal end of the shorter arm of the angle, on either side, is a short upright an eighth of an inch wide, leaving a deep sulcus between it and the longer arm, the top of which is bent backwards and rounded at the edges to prevent discomfort to the patient. The whole is firmly soldered to a German silver rod and secured to a suitable handle. The hook is easily adjusted and as easily removed, and its shallowness, its relatively higher sides, and the angular relation of its several parts render it more compact and with outward curve of its point, better fulfils the required condition than its prototype. This hook, which is at once recognized as a modification of Voltolini's, causes little inconvenience to the patient and is tolerated wherever the mirror itself is. The instrument is made by Wilms & Co., of this city.

NEWS ITEMS.

NEW ORLEANS.

(*From our Special Correspondent.*)

The Meeting of the American Medical Association.—The local Committee of Arrangements, of which Dr. Samuel Logan is Chairman, is actively engaged in making preparations for the coming meeting of the American Medical Association. This Committee is divided into the following sub-committees:

Committee on Finance: Dr. A. B. Miles, House Surgeon Charity Hospital, Chairman.

Committee on Registration: Dr. S. E. Chaillé, University Building, corner of Common and Baronne Streets.

Committee on Reception and Arrangements: Dr. G. J. Friedrichs, Girod and St. Charles Streets.

The Committee on Finance are making good progress, and hope to raise all the funds required.

The Committee on Registration propose to adopt a new plan for registering physicians and thereby to avoid the delay and confusion, which afforded annoyance at the last meeting. Five or more desks will be provided, and to each will be assigned so many letters of the alphabet, and every physician will be notified by printed posters in hotels and elsewhere, of the location of the desks and where his name must be registered.

The Committee on Reception and Arrangements have not yet selected the hall, but will do so in ample time. The Exposition Authorities offered one of their halls, but after due consideration it was thought best to decline, since there would be no rooms for the Sections to meet in. The distance too would be a formidable obstacle, to say nothing of the danger, that the surrounding attractions might prove damaging to the success of the meeting. In all probability there will be a Physicians' Day at the Exposition, immediately succeeding the session.

The programme is not yet prepared, but will be ready for publication twenty days before the opening day. To this end, those expecting to read papers are urged to forward them at once to Dr. Samuel Logan, corner of Common and Baronne Streets. Quite a number of papers have already been received.

Mr. Ernest Hart, editor of the *British Medical Journal*, was expected to be here and was invited to address the Association but will not be able to be present. The propriety of giving any excursions is questioned, since it is supposed that the Exposition will absorb the spare time and attention of the visiting members. This, however, will not prevent receptions and private entertainments, of which several are already announced. Visiting members will be fortunate in one respect, there can be no trouble as to reduction of rates. No better terms could be obtained than those now offered to visitors to the Exposition and there will be no necessity of obtaining certificates of membership, every physician can get his ticket at his own city at the reduced rates of one cent per mile and be spared all the trouble heretofore experienced.

The Sanitary Council of the Mississippi Valley recently closed its annual session. It was apparently a very harmonious one and every body was of a repentant and forgiving turn of mind.

Dr. Joseph Holt, President of the Louisiana Board of Health, in his address of welcome, plainly stated that the policy of the Board was to be in full accord with all other health organizations, and acknowledging the right of the interior States to have a voice in matters pertaining to quarantine and infectious diseases of the Mississippi Valley.

The Health of New Orleans.—New Orleans was never healthier than at present and the outlook is favorable for a continuance during the summer, for all our health organizations are in accord and working well together. It has had one disadvantage that citizens do not think it is so necessary to supply the Auxiliary Sanitary Association with funds since the Board of Health has been reorganized. A scientific quarantine is to be tried this summer; if it works well, it will solve a great problem and enhance Dr. Holt's reputation a hundredfold.

MONTREAL.

(From our Special Correspondent.)

Preparing for Cholera.—A meeting of the Medical and Hygienic Societies was held on 18th of March, for the purpose of drafting resolutions to be sent to the Federal and Provincial Governments relative to cholera. The following resolutions were passed:

That cholera is an infectious disease introduced into the country from foreign parts.

That in the opinion of medical men of experience the present shipping and quarantine regulations are insufficient to prevent its introduction.

It was further adopted that the Federal Government be urged:

1. To adopt and enforce with the utmost stringency the British Medical Shipping Act and such regulations as may be considered requisite concerning emigration and quarantine.

2. To appoint government health officers on board all ocean vessels carrying passengers, who shall be held responsible for the sanitary condition of such vessels and the health of all on board.

The following resolution was also adopted for presentation to the Provincial Government:

That the Provincial Government be urged to adopt a comprehensive measure dealing with public health, which will arm cities and municipalities of the province of Quebec with ample powers to prevent the introduction and spread of contagious and infectious diseases, and that the draft of the bill concerning public health already prepared and in possession of the health office be forwarded to the Government with suggestions for the preparation of such enactment.

A committee was formed to prepare memorials to the Government, composed of Drs. Hingston, Ross, Cameron, Larocque, Godfrey and Mr. J. L. Archambault. The members of the deputation will be appointed at a subsequent meeting.

The International Medical Congress, Washington, 1887.—The following rules and provisional lists of officers of the Ninth International Medical Congress, to be held in Washington, in 1887, are published by order of the Executive Committee.

Rules.—1. The Congress will be composed of members of the regular medical profession, and of such persons as may be specially designated by the Executive Committee, who shall have inscribed their names on the Register of the Congress, and shall have taken out their tickets of admission. As regards foreign members, the above conditions are the only ones which it seems, at present, expedient to impose.

The American members of the Congress shall be appointed by the American Medical Association, by regularly organized State and local medical societies, and also by such general organizations relating to special departments and purposes, as the American Academy of Medicine, the American Surgical Association, the American Gynecological, Ophthalmological, Otological, Laryngological, Neurological, and Dermatological Societies, and the American Public Health Association; each of the foregoing Societies being entitled to appoint one delegate for every ten of their members.

All Societies entitled to representation are requested to elect their Delegates at their last regular meeting preceding the meeting of the Congress, and to furnish the Secretary-General with a certified list of the Delegates so appointed.

2. The work of the Congress is divided into nineteen Sections.

3. The general meetings will be reserved for the transaction of the general business of the Congress, and for addresses or communications of scientific interest more general than those given in the Sections.

4. Questions which have been agreed upon for discussion in the Sections shall be introduced by members previously nominated by the Officers of the Section. The members who open discussions shall present, in advance, a statement of the conclusions which they have formed as a basis for debate.

5. Notices of papers to be read in any of the Sections, together with abstracts of the same, must be sent to the Secretary of that Section before April 30, 1887. These abstracts will be regarded as confidential communications, and will not be published until the meeting of the Congress. Papers relating to questions not included in the list of subjects suggested by the Officers of the various Sections will be received. Any member, after April 30, wishing to bring forward a subject not upon the programme, must give notice of his intention to the Secretary-General at least twenty-one days before the opening of the Congress. The Officers of each Section shall decide as to the acceptance of any communication offered to their Section, and shall fix the time of its presentation. No communication will be received which has been already published, or read before a Society.

6. All addresses and papers, read either at General Meetings or in the Sections, are to be immediately handed to the Secretaries. The Executive Committee, after the conclusion of the Congress, shall proceed with the publication of the Transactions, and shall have full power to decide which papers shall be published, and whether in whole or in part.

7. The official languages are English, French, and German.

In the Sections no speaker will be allowed more than ten minutes, with the exception of readers of papers and those who introduce debates, who may occupy twenty minutes.

8. The Rules, Programmes, and Abstracts of Papers will be published in English, French, and German.

9. The Officers of the General Committee on Organization are a President, such number of Vice-Presidents as may hereafter be determined on, a Secretary-General, and a Treasurer, and those elected to these positions will be nominated by the General Committee to hold the same offices in the Congress. All vacancies in these offices shall be filled by election.

10. There shall be an Executive Committee, to be composed of the President, Secretary-General, and Treasurer of the General Committee, the Chairman of the Finance Committee, and of four other members to be elected by the General Committee. The duties of the Executive Committee shall be to carry out the directions of the General Committee, to authorize such expenditures as may be necessary, and to act for the General Committee during the intervals of its sessions.

11. There shall be a Standing Committee on Finance, to be appointed by the President, subject to the approval of the Executive Committee. The Chairman of the Finance Committee shall be *ex-officio* one of the Vice-Presidents of the Congress, and also a member of the General and Executive Committees. The Treasurer shall be *ex-officio* a member of the Finance Committee.

12. Presidents of the Sections shall be *ex-officio* members of the General Committee.

13. The Committee on Organization of each Section shall be composed of a President, such number of Vice-Presidents as may be deemed expedient, of one or more Secretaries, and of members forming a Council.

The preliminary organization is as follows:

President, Austin Flint, Sr., M.D., of New York.

Vice-Presidents: Henry I. Bowditch, M.D., of Boston; Henry F. Campbell, M.D., of Augusta, Ga.; Nathan S. Davis, M.D., LL.D., of Chicago; R. Palmer Howard, M.D., of Montreal; Levi C. Lane, M.D., of San Francisco; Tobias G. Richardson, M.D., of New Orleans; Alfred Stillé, M.D., LL.D., of Philadelphia; The Chairman of the Committee on Finance; The President of the American Medical Association; The Surgeon-General of the United States Army; The Surgeon-General of the United States Navy.

Secretary-General, John S. Billings, M.D., LL.D., U.S.A., of Washington.

Treasurer, John Mills Browne, M.D., U.S.N., of Washington.

General Committee: Robert Battey, M.D., of Rome, Ga.; Clarence J. Blake, M.D., of Boston; Henry P. Bowditch, M.D., of Boston; Samuel C. Busey, M.D., of Washington; James R. Chadwick, M.D., of Boston; J. M. Da Costa, M.D., of Philadelphia; John C. Dalton, M.D., of New York; W. W. Dawson, M.D., of Cincinnati; Francis Delafield, M.D., of New York; George J. Engelmann, M.D., of St. Louis; William A. Hardaway, M.D., of St. Louis; I. Minis Hays, M.D., of Philadelphia; David L. Huntington, M.D., U.S.A., of Washington; Abraham Jacobi, M.D., of New York; Hosmer A. Johnson, M.D., LL.D., of Chicago; Christopher Johnston, M.D., of Baltimore; R. A. Kinloch, M.D., of Charleston, S. C.; George M. Lefferts, M.D., of New York; Joseph Leidy, M.D., LL.D., of Philadelphia; S. Weir Mitchell, M.D., of Philadelphia; Henry D. Noyes, M.D., of New York; Thaddeus A. Reamy, M.D., of Cincinnati; Thomas F. Rochester, M.D., of Buffalo; Lewis A. Sayre, M.D., of New York; Jonathan Taft, M.D., of Cincinnati; W. Chew Van Bibber, M.D., of Baltimore; Horatio C. Wood, M.D., of Philadelphia; David W. Yandell, M.D., of Louisville, Ky.

Executive Committee: I. Minis Hays, M.D., of Philadelphia, *Chairman;* The President; The Secretary-General; The Treasurer; The Chairman of the Finance Committee; Samuel C. Busey, M.D., of Washington; Abraham Jacobi, M.D., of New York; Christopher Johnston, M.D., of Baltimore.

Standing Committee on Finance, William Pepper, M.D., LL.D., of Philadelphia, *Chairman.*

[The organization of this Committee will be announced hereafter.]

Section I.—Medical Education, Legislation, and Registration.—*President*, Henry P. Bowditch, M.D., of Boston. *Vice-Presidents:* Stanford E. Chaillé, M.D., of New Orleans; Alfred Stillé, M.D., of Philadelphia. *Secretaries:* Samuel J. Mixter, M.D., and William P. Whitney, M.D., of Boston.

Section II.—Anatomy. *President*, Joseph Leidy, M.D., LL.D., of Philadelphia. *Vice-President*, Samuel Logan, M.D., of New Orleans. *Secretaries*, William W. Keen, M.D.; George E. De Schweinitz, M.D., of Philadelphia.

Section III.—Physiology. *President*, John C. Dalton, M.D., of New York. *Vice-Presidents:* James F. Hibberd, M.D., of Richmond, Ind.; H. Newell Martin, M.D., of Baltimore; Middleton Michel, M.D., of Charleston, S. C. *Secretary*, John G. Curtis, M.D., of New York.

Section IV.—Pathology. *President*, Francis Delafield, M.D., of New York. *Vice-President*, William Pepper, M.D., LL.D., of Philadelphia. *Secretaries:* Theophile M. Prudden, M.D., of New York; William H. Welch, M.D., of Baltimore.

Section V.—Medicine. *President*, J. M. Da Costa, M.D., of Philadelphia. *Vice-Presidents:* Alfred L. Loomis, M.D., LL.D., of New York; James B. McCaw, M.D., of Richmond, Va.; Richard McSherry, M.D., of Baltimore; Alonzo B. Palmer, M.D., LL.D., of Ann Arbor, Mich.; Thomas F. Rochester, M.D., of Buffalo. *Secretary*, William Osler, M.D., of Philadelphia.

Section VI.—Surgery. *President*, David W. Yandell, M.D., of Louisville. *Vice-Presidents*, D. Hayes Agnew, M.D., LL.D., of Philadelphia; William T. Briggs, M.D., of Nashville; Samuel W. Gross, M.D., of Philadelphia; W. H. Hingston, M.D., of Montreal; R. A. Kinloch, M.D., of Charleston, S. C.; Edward M. Moore, M.D., of Rochester, N. Y.; Lewis A. Sayre, M.D., of New York. *Secretary*, John Collins Warren, M.D., of Boston.

Section VII.—Obstetrics. *President*, Thaddeus A. Reamy, M.D., of Cincinnati. *Vice-Presidents*, William T. Howard, M.D., of Baltimore; R. B. Maury, M.D., of Memphis; John C. Reeve, M.D., of Dayton, O.; Albert H. Smith, M.D., of Philadelphia. *Secretary*, Paul F. Mundé, M.D., of New York.

Section VIII.—Gynæcology. *President:* Robert Battey, M.D., of Rome, Ga. *Vice-Presidents:* William

H. Byford, M.D., of Chicago; Thomas Addis Emmet, M.D., LL.D., of New York; Henry P. C. Wilson, M.D., of Baltimore. *Secretaries:* James R. Chadwick, M.D., of Boston; George J. Engelmann, M.D., of St. Louis.

Section IX.—Ophthalmology. *President*, Henry D. Noyes, M.D., of New York. *Vice-Presidents:* William Thomson, M.D., of Philadelphia; E. Williams, M.D., of Cincinnati.

Section X.—Otology. *President*, Clarence J. Blake, M.D., of Boston. *Vice-Presidents:* Charles H. Burnett, M.D., of Philadelphia; H. N. Spencer, M.D., of St. Louis.

Section XI.—Dermatology and Syphilis.—*President*, William A. Hardaway, M.D., of St. Louis. *Vice-Presidents:* Louis A. Duhring, M.D., of Philadelphia; James Nevins Hyde, M.D., of Chicago; James C. White, M.D., of Boston. *Secretary*, Arthur Van Harlingen, M.D., of Philadelphia.

Section XII.—Nervous Diseases and Psychiatry. *President*, S. Weir Mitchell, M.D., of Philadelphia. *Vice-Presidents:* Charles F. Folsom, M.D., of Boston; John P. Gray, M.D., LL.D., of Albany, N.Y.; J. S. Jewell, M.D., of Chicago. *Secretary*, Charles K. Mills, M.D., of Philadelphia.

Section XIII.—Laryngology. *President*, George M. Lefferts, M.D., of New York. *Vice-President*, Frederick I. Knight, M.D., of Boston. *Secretary*, D. Bryson Delavan, M.D., of New York.

Section XIV.—Public and International Hygiene. *President*, Hosmer A. Johnson, M.D., LL.D., of Chicago. *Vice-Presidents:* Ezra M. Hunt, M.D., of Trenton, N. J.; John Berrien Lindsley, M.D., LL.D., of Nashville; James E. Reeves, M.D., of Wheeling, W. Va.

Section XV.—Collective Investigation, Nomenclature and Vital Statistics. *President*, Nathan S. Davis, M.D., LL.D., of Chicago. *Vice-Presidents*, Jerome Cochran, M.D., of Mobile; Edwin M. Snow, M.D., of Providence, R. I. *Secretary*, James F. Todd, M.D., of Chicago.

Section XVI.—Military and Naval Surgery and Medicine. *President*, David L. Huntington, M.D., of U. S. Army. *Vice-Presidents:* Frank H. Hamilton, M.D., LL.D., of New York; Hunter McGuire, M.D., of Richmond, Va.; S. P. Moore, M.D., of Richmond, Va.; William E. Taylor, M.D., U. S. Navy (retired). *Secretary*, Benjamin F. Pope, M.D., U. S. Army.

Section XVII.—Practical and Experimental Therapeutics. *President*, Horatio C. Wood, M.D., of Philadelphia. *Vice-Presidents:* Robert T. Edes, M.D., of Boston; F. Peyre Porcher, M.D., of Charleston, S. C. *Secretaries:* Edward T. Reichert, M.D., Robert Meade Smith, M.D., of Philadelphia.

Section XVIII.—Diseases of Children. *President*, Abraham Jacobi, M.D., of New York. *Vice-Presidents:* Samuel C. Busey, M.D., of Washington; J. Lewis Smith, M.D., of New York. *Secretary*, Thomas M. Rotch, M.D., of Boston.

Section XIX.—Dental and Oral Surgery. *President*, Jonathan Taft, M.D., of Cincinnati. *Vice-Presidents:* W. W. Allport, M.D., of Chicago; William H. Dwinelle, M.D., of New York; Jacob L. Williams, M.D., of Boston. *Secretaries*, Edward A. Bogue, M.D., of New York; George H. Cushing, M.D., of Chicago.

In addition to the above, the organization of each Section includes a Council.

Clinical Teaching at the Children's Hospital.—We are informed that arrangements are being perfected at the Children's Hospital, Philadelphia, for the delivery of clinical lectures upon the medical and surgical diseases of children, and upon diseases of the eye and ear. A lecture room has been arranged, and lectures will be given on Wednesdays and Saturdays after May 1.

The material is abundant, and such a course as is proposed can hardly fail to be of benefit to those who attend it.

New York State Medical Association, Fifth District Branch.—The second special meeting of the Fifth District Branch will be held in Poughkeepsie on Tuesday, May 19, 1885.

Fellows desiring to contribute papers, notes, or remarks on any subject of interest, are requested as soon as convenient, to notify the Secretary, E. H. Squibb, M.D., 36 Doughty Street, Brooklyn.

Sir Henry Thompson has recently written a clever novel called "Charley Kingston's Aunt," which has attracted considerable attention abroad.

Violation of Professional Secrecy.—Rumors deemed false having been circulated as to the cause of the death of the great painter, M. Bastien Lepage, Dr. Watelet, his medical attendant, wrote to the *Matin*, stating what, in his opinion, was the true cause. The *Temps* has recently announced that a prosecution *ex-officio* of Dr. Watelet is being undertaken for violation of professional secrecy, and against the *Matin* as his accomplice in the misdemeanor.—*Lancet*, March 7, 1885.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from March 24 to March 30, 1885.

Taylor, M. K., *Major and Surgeon.*—Granted leave of absence for one month, to take effect about April 15th.—*S. O. 40, Department of Missouri*, March 21, 1885.

Howard, Valery, *Captain and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 65, A. G. O.*, March 21, 1885.

Hall, Wm. R., *Captain and Assistant Surgeon.*—Granted leave of absence for one month and fifteen days, to take effect when his services can be spared.—*S. O. 70, A. G. O.*, March 27, 1885.

Raymond, H. I., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Gaston, Cal., as Post Surgeon.—*S. O. 30, Department of California*, March 20, 1885.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the Week Ending March 28, 1885.

Battle, K. P., *Assistant Surgeon.*—To proceed to Memphis, Tenn., for temporary duty, March 27, 1885.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVI. SATURDAY, APRIL 11, 1885. NO. 15.

ORIGINAL LECTURES.

SUPRACONDYLOID OSTEOTOMY FOR THE RELIEF OF GENU-VALGUM BY MACEWAN'S METHOD.

A Clinical Lecture delivered at St. Mary's General Hospital, Brooklyn.

BY GEORGE R. FOWLER, M.D.,
SURGEON TO THE HOSPITAL.

GENTLEMEN: We are indebted to Dr. G. B. Banks, of Huntington, L. I., for the very interesting case which I now have the pleasure of presenting to you. The patient, a little colored girl of four and a half years, and up to a year and a half ago healthy and well-formed, in this latter respect being like her brothers and sisters, in several of which she rejoices. When three years of age, she suffered from an attack of measles of some severity, and when convalescing it was noticed that her lower extremities were "out of shape." You will observe that, when she stands erect, the deformity consists of double genu-valgum, together with both anterior and outward tibial curves upon either limb.

You will notice that the inner condyles are in close apposition, while the malleoli are widely separated, by, say, about ten inches. Now, this is not entirely due to the elongated inner condyles, although it must be evident to you that the deformity is in a great measure due to such elongation, since the latter condition is plainly to be seen. The outward tibial curves, however, occupying the lower two-thirds of each bone, contribute somewhat to the wide separation of the feet. The anterior curve in each tibia adds to the child's awkward appearance. Therefore, we have, first, a genu-valgum due to an overgrowth of the inner condyles, either relative or absolute; second, a long outward curve of each tibia; and, third, an anterior curving of the latter likewise.

I regret that I cannot give you the above changes in the order of their occurrence; my belief, however, is that the tibial curves first developed, and that they occurred probably from some peculiarity of position while sitting in bed and convalescing from her illness; and that the genu-valgum, thus initiated, increased upon attempts at walking being made. It has been thought that the muscles, acting upon the softened osseous structures, were the active agents in the production of this class of deformities; but it must be apparent that, at the time when these develop, the muscles are themselves weakened and inactive.

The patient being chloroformed, we will proceed to have her thoroughly scrubbed with soap and water by means of a rather coarse and stiff flesh-brush, and afterwards douched with a warm solution of mercuric bichloride of the strength of 1 to 1000. The rest of the body, as well as the operating-table, will then be isolated from the parts to be operated upon by means of towels wrung out of the bichloride solution. While the house-surgeon is attending to these details, I will briefly call your attention to one or two operative methods other than supracondyloid osteotomy for the correction of genu-valgum. The method known as Ogston's was the first operation introduced, having for its object the "levelling up," as it were, of the articular extremities of the femoral condyles. Recognizing in the elongated inner condyle the key to the deformity in the vast majority of instances, Ogston, of Aberdeen, devised the operation which bears his name, and by means of which he sought to separate the condyle from the shaft by a subcutaneous section with an Adams's saw, and then forcing the detached mass of bone upwards until the articular surfaces of the condyles were sufficiently near to the same plane as to allow the tibia to be brought into proper line. I have operated by this method, and can testify to both the ease with which it can be performed and its gratifying results. The last patient upon whom I operated by this method, however, was a little girl of not quite three years of age, in whom the result at first was perfect; but, as time wore on, a genu-varum or out-knee developed, due, no doubt, to the interference with the epiphysis and consequent arrest of or retardation of growth in the inner condyle. In a correspondence with one of the most eminent of English surgeons, the late Mr. Callender, just before that gentleman's lamented death, in speaking of this case he expressed to me a fear that the very condition which subsequently supervened, would occur. Owing to this very serious objection to Ogston's operation, it should be reserved, if performed at all, for cases occurring in adult life.

Reeves's operation consists in making the section with a chisel instead of a saw, and not perforating the cartilage covering the articular surface of the femur. The condyle is then pushed up in the same manner as after Ogston's section with a saw. It is difficult to conceive how the normal plane of the two condyles can be restored and their articular surfaces brought to the same level without breaking through or tearing the articular cartilage at a point corresponding to the line of section of the bone; in which case it becomes an Ogston's operation, performed with a chisel instead of a saw.

Chiene, of Edinburgh, made a further modification by removing with a chisel a wedge-shaped portion of the inner condyle at or near its junction with the shaft, claiming to keep entirely outside of the joint and above the epiphysis. There is reason to believe, however, that neither of these points can be assured, in which event no advantage is gained over Ogston's method, and a much more tedious and difficult procedure is substituted.

Taking all things into consideration, therefore, it may be stated as a general proposition that if the deformity can be corrected by making the section in such a manner as to keep well above the epiphyseal line and outside of the joint, the simplest method of accomplishing that result should be chosen. The operation known as Macewan's supracondyloid osteotomy seems to fulfil all

these requirements; and it is this operation that I propose to demonstrate to you upon this patient.

It is but just to state that at the last International Medical Congress, held at Copenhagen in August, 1884, in the course of a discussion upon genu-valgum, both Ogston and Chiene publicly abandoned the operations which bear their respective names in favor of the method of Macewan.

Allow me to call your attention to the instruments necessary for the performance of this operation. They consist of a common scalpel, a set of Macewan's osteotomes, a medium-sized wooden mallet, such as is used by cabinet-makers, and an oil-silk pillow filled with sand, the latter sublimated after the manner of Kümmel, of Hamburg. The object in having the sand sublimated is to avoid contamination of the parts should the pillow become, by any mischance, punctured or bursted, and its contents spilled. The osteotomes of Macewan, although not absolutely necessary, for almost any long, apering osteotome will answer, are undoubtedly the very best instruments for the purpose. There are three of them, and if you will examine them you will perceive that they differ in the character of their wedge shape or taper. The object of this difference is to facilitate the making of the section by withdrawing the one having the broadest base (which is first used) should it become wedged or jammed in the bone, and substituting one having a medium amount of taper, which will work freely in the track previously made by the thicker one. Should this, in its turn, become wedged, it is withdrawn and the one having the least amount of taper used to complete the operation.

The points given by Macewan for the proper performance of the operation are as follows: With the limb extended, ascertain the upper margin of the external condyle, and measure a finger's breadth above the same; draw a line from this point across the anterior surface of the limb, this line to be at right angles to the long axis of the femur, and *not* parallel with the articular surfaces of the condyles. Now draw a line along the inner aspect of the limb parallel with its long axis and about half an inch above the tendinous insertion of the adductor magnus. At the point where these two lines intersect is where the incision is to be made.

Esmarch's bandage having been applied, the child will now be turned slightly upon its side so as to have the limb rest firmly upon the sand pillow, and the operation commenced by driving the knife directly down to the bone at the point just indicated; it is now moved slightly from side to side so as to enlarge the incision, and the osteotome slipped down alongside of it. The knife is now withdrawn, and the osteotome turned a quarter of the way around so as to bring its edge at right angles to the limb, when it is struck a smart blow with the mallet; this first blow being given with sufficient force to drive the instrument well though the exterior hard shell of bone, the extremity of the osteotome being directed toward the point where the first line commenced—*i. e.*, a finger's breadth above the external condyle. A few sharp blows are given, the instrument being made to traverse a fresh path each time across the thickness of the bone, and in a direction radiating, as it were, from the original point of entry; for you will see that I am working all the time through the opening in the exterior shell of bone made by the first blow of my mallet. In this way the entire transverse thickness of the bone is quickly divided, except a small portion immediately anterior and posterior to the first opening; by a few strokes enlarging the latter, this portion is divided. The limb is now firmly grasped above and below the knee, and forcibly straightened; a crunching noise being heard as the femur gives way. Care should be exercised at this stage of the operation, and if the parts do not give way readily, the cause should be sought for in a too limited application of the osteotome; for the exercise of too much force to straighten the limb may lead to either a rupture or overstretching of the external lateral ligament of the knee-joint, and a loose, lateral movement of that articulation occur as a final result.

The wound is now irrigated with the mercuric bichloride solution, and any projecting portions of fat snipped off with a pair of scissors; this, if allowed to remain, interfering with immediate union, and leading to suppuration—a most undesirable circumstance. The edges are now approximated, and a continuous catgut suture used. A little iodoform is dusted over the parts, and a cushion of sublimated paper-wool applied. The tourniquet of the Esmarch bandage is removed, and, no bleeding occurring, the limb is at once encased in a plaster-of-Paris splint.

(The other limb was now operated upon and dressed in a like manner.)

We will now fasten the little one's limbs together and put her to bed, fully assured that if our antiseptic precautions have been thorough, but slight, if any, reaction or disturbance will follow. The tibial curves will be dealt with upon another occasion.

NOTE, JAN. 11, 1885.—Between the second and third day, a slight rise in temperature occurred (100° F.). In a few hours it sank to the normal, and no further rise took place. During the second week, the plaster-of-Paris splints were removed, and a Hamilton's double splint for fracture of the femur in children substituted. To-day, just one month from the day of operation, the dressings from the wounds were removed for the first time; the latter were found to be healed, and but a slight cicatrix marking their site. Passive motion will be practised daily, and for the first few days the limbs will be bound together with a compress of cotton between the knees. After that the child will be allowed to move itself about in bed, and finally to walk with the aid of a chair, pushing the latter before it about the ward.

ORIGINAL ARTICLES.

TWO CASES OF LIGATURE OF THE COMMON CAROTID ARTERY FOR TRIGEMINAL NEURALGIA.[1]

BY JOSEPH C. HUTCHISON, M.D.,
SURGEON TO THE BROOKLYN HOSPITAL.

CASE I.—Daniel C., 45 years old, born in Ireland, and a gold-digger by occupation, entered the Brooklyn City Hospital September 4, 1871, suffering from neuralgia of the left inferior maxillary nerve. His general health had always been good. From 1855

[1] Read before the New York Surgical Society, March 24, 1885.

to 1867 he was engaged in mining in California, and, although much exposed to wet and cold during this time, he was never kept from work by illness. In the autumn of 1867, he was attacked with sharp, stinging pain in the region of the lower jaw, occurring in paroxysms every two or three hours. The paroxysms increased in frequency and severity for the two succeeding years, compelling him to give up work. During this period the three molars and the adjoining bicuspid of the left side of the inferior maxilla were removed, but the removal of the teeth, which were sound, gave no relief.

In the spring of 1871, previous to which time he had been under my treatment for several months with only temporary improvement, the last upper molar of the left side was removed by a surgeon in Boston. The pain ceased, and the case was reported as one of cure.[1] Three weeks after the removal of the tooth the paroxysms of pain returned, and were as severe as before.

When the patient entered the hospital he was somewhat emaciated, and his strength was impaired. Paroxysms of pain, described as stinging, burning, recurred every few minutes day and night. The patient relieved himself somewhat by violent friction with his hand over the seat of pain.

September 6, 1871, Gross's[2] operation of exsection of the alveolar process for neuralgia of the jaw-bones was performed. An incision was made along the edentulous alveolar ridge on the left side of the lower jaw as far forward as the first bicuspid tooth; the soft parts, including the periosteum, were turned aside with a periosteotome, and the alveolar processes were gnawed off with a rectangular gouge forceps to a level with the palatine process. The bone and soft parts seemed to be healthy. No sutures were used. The wound healed rapidly, and the patient was entirely relieved. Twelve days after the operation he was discharged, apparently well, and five months afterward he reported that there had been no recurrence of pain since the operation. The case was again reported as cured; this time by the writer.[3]

He returned to California, and resumed his occupation as a miner. The pain returned in its former severity, but I am unable to state how soon after the last operation. The dental branch of the inferior maxillary nerve was exsected by a California surgeon. This operation relieved him entirely for three years; but whether it was also reported as having cured the patient, I am unable to state.

He again applied to me for treatment in June, 1877, nearly ten years having elapsed since the disease first began. The pain occupied the same locality as before, in his lower jaw, radiating to the corner of his mouth and lips, and occurred in paroxysms of intense severity every half hour. He obtained only temporary relief from electricity and the usual medicinal remedies for this condition, and in desperation implored that operative surgery, which had previously brought him relief, should again be appealed to. For this purpose he was readmitted to the Brooklyn City Hospital, and on June 30, a carbolized catgut ligature was applied to the left common carotid artery. Antiseptic dressings were used. The wound healed by first intention, and after the operation there was prompt and complete cessation of pain. No untoward symptoms occurred, except a slight hoarseness, which continued for a year, and suddenly left him, and he was discharged cured a second time, according to the hospital record, July 16, 1877.

One year and a half after the operation, January 23, 1879, he wrote from California that he was quite well, and entirely free from neuralgia, and I hoped that his untractable enemy was finally subjugated. But I was disappointed. In September, 1883, he again presented himself for treatment, and stated that for three years and eight months after ligature of the common carotid he was free from pain. It then returned, but with less severity, soon after he began to work in damp places. I now advised him to seek employment in a drier atmosphere, and he promised to report himself to me if the pain did not subside. I have not heard of him since.

Case II. *Neuralgia of the first and second divisions of the fifth nerve of thirty years standing. Ligature of the common carotid artery and neurectomy.*—C. N., aged 49, a native of Ireland, and a carpenter by occupation, came under my care at the Brooklyn City Hospital, June 10, 1878, for very severe neuralgia of the first and second branches of the fifth nerve. He stated that March 12, 1848, thirty years before, he was suddenly attacked with severe pain in the right cheek after washing his face in cold water. Previous to that time he had enjoyed good health, and there was no family predisposition to any disease. The pain was very intense, and extended from the right cheek and right side of the nose backwards along the track of the superior maxillary branch of the fifth nerve. He had occasional pain also in the right side of the forehead. The pains were paroxysmal, occurred at short intervals, and were excruciating. He alleges that he was treated at that time by copious bloodletting, and had no more pain for five or six months, when it returned with its former severity, and continued for three years, when he applied to the late Dr. Ackley, of Cleveland, Ohio, for surgical treatment. This eminent surgeon made a long incision through the scalp above the right ear, but the operation gave no relief. He then visited New York and Philadelphia for treatment; various internal remedies were prescribed, but without any benefit, and he was told by Dr. Valentine Mott that he could do nothing for him. September 19, 1856, he sought relief in Bellevue Hospital, and came under the care of the late John A. Lidell, M.D., who at that time reported the case.[1] Dr. Lidell made an incision near the right supraorbital notch, and excised the principal branches of the supraorbital nerves to the extent of about three-eighths of an inch. He then cut down upon the infraorbital filaments near the infraorbital foramen for the purpose of excising them, but the hemorrhage was so free that he was unable to see them, and he contented

himself by simply dividing them. These operations gave the patient six months immunity from pain; it then returned as severely as before, when Dr. Lidell opened the infraorbital canal and excised half an inch of the trunk of the superior maxillary nerve. Six days afterwards he was discharged from the hospital relieved, but how long the relief continued is not known. He was next treated by Dr. Willard Parker, Sr., with internal remedies, but received only transient benefit.

This poor fellow entered the Brooklyn City Hospital in 1860, suffering intensely, and a portion of the right superior maxillary nerve was again excised by Drs. George Cochrane and Charles E. Isaacs. The operation gave him relief only until the incisions had healed. He came under my observation June 10, 1878, as before stated, at the Brooklyn City Hospital. He had frequent paroxysms of severe pain, lasting from five minutes to half an hour, and for the last month he states that the paroxysms have been more severe than ever before. His suffering had now extended over a period of thirty years, with occasional intervals of relief after some grave surgical operation. Medical treatment had given him only transient comfort, and he desired that some operation might again be tried to secure him immunity from pain. Encouraged by the result in a previous case, I suggested ligature of the right common carotid artery, and after having explained to him its dangers and the uncertainty of obtaining relief from the operation, he begged that it should be done as speedily as possible. I applied a ligature to the artery June 21, 1878, above the omohyoid. It came away on the nineteenth day. No cerebral symptoms followed the operations, nor were the paroxysms of pain diminished either in frequency or severity in the slightest degree, notwithstanding the liberal use of hypodermic injections of morphine after the operation. I now decided to try excision of the intraorbital nerve again. A semi-elliptical incision was made along the lower border of the orbit down to the bone, and the soft parts were separated by an elevator from the orbital plate of the superior maxillary bone back to its posterior border. It was my intention to divide the nerve where it enters the infraorbital canal at the spheno-maxillary fissure, and then divide it in front where it emerges from the infraorbital foramen, and draw out of its canal the portion of the nerve lying between the sphenoidal fissure and the infraorbital foramen.[1] I found it impossible to do this operation systematically owing to the altered condition of the parts due to former operations, and I contented myself with scraping out the entire contents of the canal, hoping that the canal might be obliterated and take on new bony formation and prevent a recurrence of the excised nerve. The patient was immediately and entirely relieved of pain by the operation, and remained well until he was discharged, August 31. A few days subsequently he presented himself again, and complained of severe pain in the inferior maxillary nerve, extending from the right mental foramen backwards, over the right cheek, which he declares is as intense as his former pains were. I lost sight of him after this.

Recapitulation of the operations.—First case: 1. Removal of the right upper molar tooth was followed by relief from pain for three weeks, although there had been no pain in the course of the superior maxillary nerve at any time

2. Removal of the alveolar process of the lower jaw gave complete relief for more than five months, but how much longer I cannot state.

3. Excision of inferior maxillary nerve relieved the pain for three years.

4. Ligature of the left common carotid resulted in relief from the neuralgia for three years and eight months. No cerebral symptoms followed the operation, and none has appeared after a lapse of nearly four years.

Case second: 1. Incision of the scalp with no benefit.

2. Excision of the branches of the supraorbital nerve near the supraorbital notch, and at the same time incision of the infraorbital filaments of the superior maxillary nerve near the infraorbital foramen, relieved the neuralgia for six months.

3. Removal of half an inch of the superior maxillary nerve from the infraorbital canal was followed by freedom from pain for an unknown period of time.

4. Excision of the superior maxillary nerve in the infraorbital canal was repeated ten years after the last operation, but the neuralgia returned as soon as the incisions had healed.

5. Ligature of the right common carotid, twelve years after the last operation. There was no relief from pain, and no cerebral symptom followed the operation.

6. Removal of the superior maxillary nerve from the infraorbital canal a third time, a little more than ten years since it was last removed. During the two and a half months after the operation that he was under observation he was free from pain, but then began to complain of neuralgia in the inferior maxillary nerve. I now lost sight of him.

The operation of tying the common carotid artery for trigeminal neuralgia, which was first recommended and practised by Nussbaum and Patrubau, has been practised by other surgeons with a fair amount of success. Hüter[1] refers to fifty-four cases, of which three died—5 per cent.—and remarks, incidentally, that the operation was performed after all other treatment, medical and surgical, had failed. Prof. John A. Wyeth[2] has tabulated fourteen cases, one of which was the first case reported in this paper. He classed it among the cured, but the disease returned since the publication of his paper, three years and eight months after the artery was tied. Ferdinand H. Gross, M.D., of Philadelphia,[3] has added one case, and the writer has reported another in this paper. Of these 16 cases, which were quite fully reported, 1 died; 15 recovered; 2 total failures; 8 were cured; 6 temporarily relieved—one for two years, one for three years and eight months, one for four years, one for eight months, one for eleven months, and

[1] This operation was described by Hodgen, of St. Louis. See Transactions American Medical Association, vol. 31, p. 773

in one relief was not of long duration. The operation, it seems to me, is worthy of further trial in severe cases which have resisted all other treatment, medical and surgical. It has been suggested that the same results would be accomplished by ligature of the external carotid, where branches supply the trigeminal nerves.

The treatment of trigeminal neuralgia is, it must be confessed, largely empirical in its character. A rational and discriminating treatment must be based upon a more thorough knowledge of the morbid conditions which produce the symptom. Such investigations have thus far been very incomplete.

CASE OF TONIC SPASM OF THE ACCESSORIUS SUCCESSFULLY TREATED BY GYMNASTICS AND MASSAGE.

By H. G. BEYER, M.R.C.S.,
PASSED ASSISTANT SURGEON, U. S. NAVY

Miss L. S. M., thirty-five years of age, consulted me about the first week in April, 1884, concerning some trouble in her neck and head. She said she could not retain her head in the desired position, and complained of more or less severe pain in the back of her neck, somewhat indefinitely located between the posterior upper angle of the left scapula and the vertebral column. She was lying in bed at the time, and had been occupying this recumbent position for several months. On rising, her face would immediately turn toward the left side, her chin at the same time moving slightly upwards, and she could only, by the greatest effort of her will, succeed in turning it in the opposite direction for a moment, when it would immediately return to its former one-sided position, toward the left. The only way she could make herself comfortable was to lie down and keep her head well supported by pillows.

Her father, a very successful and much respected physician of New York State, died of pneumonia; her mother, at an advanced age, died of heart disease. Several of her brothers and sisters are now living and enjoy good health.

She is a highly educated and refined lady of regular habits, having spent much of her life in New York, and has remained free from any serious disease up to date. While yet a child she had the measles, scarlatina, and the whooping-cough. There are no traces of any hereditary or constitutional taint about the patient, so far as can be made out.

In October, 1882, she received news of the sudden death of a gentleman to whom she was soon to have been united in marriage. The shock was so great, and the grief so overpowering, that she was unable to eat or sleep during the following week. On the 22d, the seventh day after receiving this news, while seated at the dinner table, she noticed a twitching movement which was, to use her own words, "quick, sharp, and noticeable as an electric shock."

From this time on it grew gradually worse; and she was constantly obliged to rest her head against the back of a high chair while in a sitting position. Not thinking it very serious, although very annoying, she did not deem it necessary to call in medical aid until April following. Several irregular physicians then were consulted in succession; the trouble, however, grew worse instead of better. She then applied to several prominent nerve specialists of New York City. At this time, July, 1883, she was utterly unable to manage her head by force of will, but was obliged to use her hands to support it in the desired position: the exertion required to do this, made the otherwise constant pain in the back of the neck more severe and intolerable.

From July to October, she was treated by electricity, and hypodermic injections of atropia, made all along the right sterno-cleido-mastoids, taking zinc pills internally. The thermo-cautery was also freely used over the back of the neck. After a three months' course of this most rigorous form of treatment, conscientiously carried out by the most experienced hands of the profession and faithfully submitted to by the hopeful patient, and finding herself growing steadily worse, she lost hope and courage and gave up the treatment in October. She afterwards received magnetic treatment at the hands of a doctor in Geneva, N. Y. This also proved of no avail, and so a number of physicians were consulted without benefiting her in the slightest. Thus, thoroughly discouraged and disheartened, and thinking perhaps that a change of climate might prove beneficial she came to Baltimore, in February. At this time one of her sisters accompanied her. Upon her arrival she spent most of her time in bed, going out only occasionally, deeply veiled, her head held in the middle line by a bandage peculiarly contrived by herself for the purpose. She always returned very much exhausted and resumed her accustomed position in bed. This, in a few words, is the history of the condition I found her in when I first had an opportunity of seeing her, which was about the middle of March, 1884.

This visit was merely a social one, and my professional services were not solicited until about three weeks later, and then only for some trouble which suddenly supervened. The case as it appeared when I was called in, may be briefly described as follows, viz.: Patient was lying in bed, having become very weak and emaciated since the last time I saw her, complaining of severe pain in the epigastric region; this pain was accompanied with a constant, almost uninterrupted retching, and nourishment of any kind could not be retained. In this condition she had been for twenty-four hours previous to the time of my visit. Her pulse was very weak and somewhat increased; temperature was 102° F.,- respiration more frequent than normal, probably from mechanical interference from the constant retching. With perhaps a slight bulging over the epigastric region and a certain amount of pain on pressure, there was nothing abnormal whatever about the abdomen.

She had always been regular and had never had any uterine or ovarian disease; firm pressure over those regions did not produce the slightest discomfort at the time.

The two per cent. hydrocyanic acid was prescribed, and two drops of it ordered to be taken every half

hour. After four doses had been swallowed, the retching grew less and only recurred at much longer intervals. Patient slept a good portion of the night, taking the medicine when awake. The retching ceased entirely twenty-four hours after she first began taking the medicine.

She now asked me to treat her for the spasmodic trouble, which I promised to do on condition that the treatment, which I had already in my own mind dertermined upon, should be faithfully carried out.

I think that no physician, from what has already been said, can doubt that the case in hand was one of *spasm of the spinal accessory nerve* of the right side, and that, moreover, if we have to differentiate between spasm and spasm, it might be called a mild case of *tonic spasm*, originating in a central disturbance of the motor portion of the nerve.

It did not seem to me to be a case of clonic spasm for the following reasons, viz.: Her head would remain on the left side when she was in the sitting posture and, although for a few seconds and by great effort of the will, she could turn it in the opposite direction for a couple of times, the time did arrive when no amount of will-power was sufficient to stay it from turning to the left. On the other hand, it did not present the characters of the condition known as caput obstipum spasticum. It was central in origin, because both the trapezius and sterno-mastoid were involved. It was *not hysterical* in nature, as may well be inferred from the history of the case, and also from the fact that general sensibility over both sides of the body was uniformly normal and the tendon reflexes well marked. The head was turned strongly to the left, the chin raised considerably and the occiput approximated slightly to the right shoulder. Besides this, the left shoulder and clavicle were very much higher when compared with the corresponding shoulder and clavicle of the right side.

There was also a slight lateral curvature of the cervical portion of the spinal column (convexity to the right), due probably to the habit into which patient had fallen—from necessity, of course—of forcibly throwing her head with the left hand, and aided by the spasmodic contractions of the trapezius muscle of the right side. There was a constant pain at the back of her neck, exaggerated when in the upright position for any length of time. While in this latter position the right sterno-cleido-mastoid and trapezius muscles felt firm without being exactly rigid, the corresponding muscles of the left side were flabby and much less prominent even when in active contraction..

Regarding the *etiology* of the trouble in this case, the circumstances point clearly to grief from the loss of her friend. No history of exposure of any kind is given, as she kept closely in her room during the seven days that intervened between the receipt of the sad news and the first beginning of the trouble.

The *treatment* at first was, of course, directed toward improving her general health, without which no local trouble can be expected to yield permanently to any kind of treatment. During the first week, therefore, little was done excepting to regulate her diet on the best principles of nutrition adapted to the needs of her own special case and requirements. At the end of only one week she had gained so much, and felt so much better, that it was deemed advisable to begin a systematic and graduated course of gymnastics and massage. She received one thorough general massage three times a week, and a local one applied to the neck only every day for the first two weeks. For the following two weeks of the treatment general massage was applied twice a week, and local massage to her neck four times a week. The strictest attention to diet was constantly observed: her appetite improving wonderfully during that time. Besides massage she was enjoined to take active exercise, which consisted in swinging a bar, which she grasped with both her hands and threw out in different directions a certain number of times, according to her powers of endurance. While performing this exercise she was directed to look constantly at a certain object a short distance in front of her, and so placed as to keep her head and face in the middle line when looking at it. For the purpose of exercising the lower limbs she was made to pace the floor after the manner which is best calculated to reach all the muscles of the lower extremities, as well as those of the lower portion of the trunk, and keep them all in active exercise. During any and all of these exercises she was never allowed to put her hand to her head to steady it. It required constant reminding to break her of this habit. Whenever she could not keep her head erect, her nose pointing straight forwards, she was told to lie down. This always formed the guide with regard to the length of time the exercise might continue. Twice every day, generally morning and evening, this exercise was superintended by myself, and during it every means was employed to keep the patient in the best possible spirits. She was, however, directed to resume the exercise of both upper and lower extremities during the intervals of my visits, and keep an account of the number of times she had gone through it. From the second week on, she was ordered to take daily walks out of doors, observing the same rules as during in-door exercise. At first she thought it was an impossibility, and it was only after the strongest kind of urging that she consented. From the latter part of the second week her improvement was so rapid that it was not only astonishing to herself, but also to her friends. As she grew better she finally recognized the fact that it was as necessary for her complete recovery to exercise her will as it was to exercise her muscles.

During the last week of my treatment she visited her friends, staying for hours at a time, keeping the movements of her head under perfect control; only now and then, when feeling a little tired, she rested her head against the back of a high chair.

In this condition she left Baltimore to go to the seashore about the first of June, under orders not to give up the exercise and other treatment. I saw her the following September, meeting her on the street, when she looked a perfectly healthy woman. It is now nearly a year ago, and every occasional letter I receive convinces me of the permanent success of this treatment in her case.

By CHARLES SMART, M.D.,
SURGEON U. S. A.

It is well known that, when a saccharine liquid undergoing fermentation has attained a certain alcoholic strength, the further growth of the yeast plant is prevented by the action of its alcoholic product. It is, perhaps, equally well known that an inhibition of the acetous fermentation takes place when the liquid has reached a certain percentage of acetic acidity. But it is not so generally known that the bacteria of putrefaction elaborate, as products of their vital action, organic substances that are destructive to the organisms which determined their formation. The ultimate products in the retrogression of albuminous matters by bacterial or putrefactive agency are ammonia and carbonic acid; but a vast number of complex organic substances, concerning which our knowledge is meagre, constitute intermediate steps in the process. One of these, phenol, or carbolic acid, was at the time of its discovery as a product of putrefaction already well known as an antiseptic, and probable disinfectant. Recently E. and H. Salkowski separated from these intermediate products two aromatic acids of the acetic series, hydrocinnamic or phenyl-propionic and phenyl-acetic acid.

Wernich[1] submitted these to experiment, and found that as antiseptics they were superior to carbolic acid, the phenyl-propionic acid being the more active of the two. Klein[2] followed up these researches by an inquiry into their germicidal value. Some of his experiments bear with greater interest on the life history of the organisms subjected to the influence of the acids than on the germicidal value of the latter; but, to complete this series of preliminary papers, it has been deemed advisable to submit a summary of his results.

This able experimenter recognized the difference between antisepsis and disinfection that has been insisted upon in the reports of this Committee. He exposed the organisms that were the subject of the experiment to the action of the acids, and then introduced them into a suitable culture medium; or, if they were of a pathogenic nature, inoculated animals with them,—a failure to cultivate, or a failure to reproduce the disease being respectively in each case the test of a germicidal or truly disinfectant action.

The non-specific organisms subjected to experiment were a small micrococcus derived from the blood of rabbits, a large micrococcus of similar derivation, bacterium termo and *Bacillus subtilis*. An exposure of twenty or twenty-five minutes in a solution of either acid of the strength 1 : 200, failed to destroy the vitality of any of these specimens; the last mentioned, indeed, was not destroyed by an exposure of twenty-four hours.

The pathogenic matters treated were the spores and bacilli of anthrax, the virus of swine-plague, and that of tuberculosis.

Anthrax *spores*, exposed for two or more days in either acid of the strength 1 : 400, were found to have retained their virulence when subsequently injected into guinea-pigs, and to be susceptible of cultivation in culture liquids, with the retention of virulence in their progeny. But, although the spores withstood the influence of the acids, the *bacilli* of anthrax were killed immediately, or as soon as they were thoroughly mixed with this strength of either of the acids. The phenyl-propionic acid, however, was manifestly more efficient, for a dilution of 1 : 800 destroyed the bacilli in ten minutes, while the phenyl-acetic acid under similar conditions failed to accomplish disinfection. Greater dilutions required a longer period to effect the destruction of the bacilli, and in all instances the phenyl-propionic acid showed the greater potency. Thus, while this acid, in the strength 1 : 3200, required from twenty-five to thirty-five minutes to be effective, the phenyl-acetic acid of the same strength required fully thirty-five minutes.

Several other points of interest were developed. It was noted that in greater dilutions than 1 : 400 of either acid, a stronger solution or a longer exposure was required to kill bacilli grown from a previous culture containing spores than those from a culture started from blood bacilli. It was observed further that bacilli cultivated from bacilli of the blood have a greater resistance than the latter, so far as these acids are concerned, for the first week or ten days of the cultivation, but that after this their power of resistance decreases, so that ultimately it becomes even less than that of the original blood bacillus. The fact was also shown that bacilli in the blood of a guinea-pig dead from inoculation with spores have a greater resistance to the influence of the acid than those from an animal dead from inoculation with bacilli.

The virulence of swine-plague, taken directly from an animal dead of the disease, and also that of the artificially cultivated microbe, were destroyed by an exposure of twenty or twenty-five minutes to a phenyl-propionic solution of the strength 1 : 800; weaker solutions were not efficient, and the disinfectant action of the phenyl-acetic acid of this strength was not certain.

The tubercular virus, like the spores of anthrax, resisted the influence of these acids. An exposure of ninety-six hours to a strength 1 : 200 did not prevent the caseous matter of pulmonary tuberculosis from producing its characteristic effects when injected into a guinea-pig. But considerably stronger solutions showed the exercise of an inhibitory power. Bovine virus manifested a greater resistance against the influence of the acids than the tuberculous virus of man.

IODIDE OF POTASSIUM IN ECZEMA.

By HENRY W. STELWAGON, M.D.,

PHYSICIAN TO THE PHILADELPHIA DISPENSARY FOR SKIN DISEASES, CHIEF OF THE SKIN DISPENSARY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, ETC.

The importance of having at command a number of constitutional remedies which are capable, either directly or indirectly, of exerting a favorable influence in so obstinate a cutaneous disease as eczema, is appreciated by all whose practice calls upon them to treat such cases. Probably the most reliable remedy in the average case of eczema is arsenic; but often enough it fails to have an appreciable effect, and, indeed, not infrequently its action is prejudicial, even in cases in which the probability of its good effects was scarcely questionable.

Iodide of potassium is a remedy, which in a number of cases has rendered me good service, and is one, moreover, that is rarely capable of seriously aggravating the disease, as occasionally happens in the administration of arsenic. With the experience so far at command, it would be impossible to say in what particular class of cases it may be found useful. The impression formed, however, would indicate that it is of greatest advantage in subacute and chronic eczema, in which the inflammation is of a moderate grade. Moreover, it seems to have a greater influence in the eczema occurring in persons otherwise apparently in good health. In fact, if a positive conclusion were yet warrantable, it would be to the effect that the remedy finds its greatest use in those cases in which such tonics as cod-liver oil, iron, and bark, are contraindicated. In broken-down subjects, and especially in cases in which the disease has been superinduced by mental worry and overwork, it seems to have but little value; and in cases in which dyspepsia is the main predisposing cause, it rarely benefits, but, on the contrary, will often aggravate. In eczema of the lower extremities, due in part to a varicose condition of the veins, it has but little influence. Nor is its use confined to the adult. In several remarkably obstinate and relapsing cases of eczema in children, it brought about a permanent cure where other remedies failed to have the slightest effect.

The beginning dose for a child of the age of six months to a year, should be a half grain, increased to a grain, or even to two grains, and given three times daily. In children past the age of one year and under three the dose may be one grain, and increased to three grains; in older children, five-grain doses may be reached with favorable effect. It is best administered to children in water flavored with syrup of orange-peel or ginger; in some cases in which the remedy thus prescribed causes gastric uneasiness, a small quantity of a bitter tincture may be substituted for the syrup with advantage. In the adult, the dose at first should be not more than five grains, three times daily, and later increased, if found necessary. If ten-grain doses fail, it is more than probable that larger doses will also be without effect, or may even aggravate. The remedy is not to be continued if it causes persistent nausea. It is borne much more readily when given in Huxham's tincture, or the compound tincture of gentian, than in syrup mixtures. As a rule, it should be taken well diluted about thirty minutes before meals. There are, of course, exceptions to such a rule. With some persons a dose of medicine before the morning meal excites nausea and vomiting; with such, a dose may be prescribed before the midday and evening meals, and at bedtime. Occasionally it is best borne about two hours after eating. Certainly the remedy seems to have more effect taken when the stomach is empty, provided, of course, it causes no gastric disturbance.

To rely upon any internal treatment exclusively, however, for the relief and cure of an eczema, would mean invariable disappointment. With the potassium iodide, no less than any other remedy, a suitable plan of external treatment is a necessity, if relief is to be expected. Constitutional remedies will often modify the morbid action of the skin so as to promote the favorable effect of external treatment, and render such favorable results permanent; to expect more than this would lead to repeated failures. In conclusion, this particular remedy—potassium iodide—although of great benefit in some cases, will, unfortunately, be found valueless in others.

MEDICAL PROGRESS.

Subcutaneous Injection of Caffeine.—M. Huchard in the *Revue Thérapeutique* of February 15, 1885, suggests the subcutaneous injection of caffeine when its administration by the stomach is contraindicated by its irritating action upon that organ.

The formula he suggests is the following:

R.—Salicylate of soda	. . .	gr. 45.
Caffeine	. . . .	gr. 60.
Distilled water	. . . .	q. s. ad ℥ ½.

From seven to fourteen grains a day may be administered. The injections lower the temperature in typhoid fever, and combat efficaciously the phenomena due to general depression. The diuretic effects of the drug are especially valuable in the last stages of heart disease.

Injection of Blood into the Pleura.—Dr. B. Silva, in *Il Morgagni*, after experimenting on dogs as to the effect of injections of blood into the pleura, gives the following résumé of his results:

1. The pleura absorbs the defibrinated blood as readily as the peritoneum.

2. The uniform result of injections of defibrinated blood into the pleura (the blood of the same species being always injected) is an increase, in from four to five hours, of the hæmoglobin in the red blood-corpuscles. This increase persists beyond the fourth day after the injection.

3. The maximum increase of hæmoglobin is perceptible in the first twenty-four hours.

4. The absorption of hæmoglobin is greater when the injections are small. If the injected blood produce atelectasis, there is frequently no visible increase in the hæmoglobin.

5. Transfusion of blood into the pleura increases the excretion of urea.—*Centralblatt für Gesammte Therapie*, March, 1885.

Presence of Albumen in the Urine after the Administration of Chloroform.—MM. Ferrier and Patin have experimented upon the production of albumen in the urine by the administration of chloroform. Ten experiments in all were performed, and the urine in each was tested before and after the operation. In 6 cases out of 9, albumen was found after, though not before, chloroformization. In the tenth, the quantity of albumen was increased from 9 grains per quart before anæsthesia to 60 grains afterward. This patient died.

In résumé, anæsthesia by chloroform is frequently, but not fatally, followed by albuminuria, thus confirming the experiments of Bouchard, who has observed albumen in the urine of hares after peripheral nervous lesion and after the inhalation of chloroform, even without production of anæsthesia. Under the last condition, hæmaturia has also been observed. M. Ferrier is inclined to attribute the albuminuria to a certain tendency to asphyxia produced by the chloroform.—*Revue de Chirurgie*, Jan. 1885.

Porro's Operation.—Dr. Vincini, on 15th of January, performed Porro's operation upon a rachitic woman. The woman at the time of operation had been in labor twelve hours.

Strict antiseptic precautions were observed, and both mother and child are reported as alive and in good condition.—*Gazzetta Medica di Torino*, Feb. 25, 1885.

Surgical Treatment of Varicocele.—M. Horteloup, at a recent meeting of the *Académie de Médecine de Paris*, advocated the surgical treatment of varicocele. The following are his conclusions as to the operation:

1. The new methods of antiseptic dressing no longer permit a refusal to operate for painful varicocele, and for varicocele whose weight and length render them burdensome to life.

2. Resection of the scrotum and of the veins of the cord is a harmless operation.

3. The operation need cause no fear of atrophy of the testicle, and seems to increase the genital powers.

4. From a surgical point of view, it gives excellent results.

5. It causes the pain to disappear, and obviates the weight and discomfort.

6. It causes a notable diminution of the varicose spermatic veins.

As a dressing M. Horteloup employs lint soaked in carbolized oil. Death has in no case resulted from the operation, and in three cases only has hemorrhage into the scrotum occurred, an accident which is followed by no bad consequences.—*Journal de Médecine de Paris*, Feb. 28, 1885.

Total Extirpation of the Uterus through the Vagina.—On January 17, Professor Bottini performed an operation for total extirpation of the uterus through the vagina.

The patient was forty-two years of age and was suffering from uterine cancer. The growth was very vascular, and had caused severe metrorrhagia, from which the woman had become very anaemic. A myoma also coexisted on the anterior uterine walls. The operation was nevertheless successful, the woman recovering without any sensible rise of temperature.—*Gazzetta Medica di Torino*, March 5, 1885.

Traumatic Cataract; Absolute Disappearance of the Lens and Capsule without Operation; Perfect Vision with (?) Power of Accommodation.—Dr. T. H. Bickerton, in *The Lancet* of March 21, 1885, reports a case of traumatic cataract in which the lens and capsule had entirely disappeared without operation, and in which perfect vision with (?) power of accommodation was present.

Testing showed that not only near vision was perfect, but that at a distance sight was not only good, but of an acuteness beyond the normal.

Two points of interest are present in the case—the idiopathic and complete disappearance of the lens and capsule, and the apparent existence of accommodative power in an eye minus its lens. The first is a pure example of the operation of solution, and the result is that aimed at by every oculist who operates upon a soft cataract. The piece of steel acting the part of the surgeon's needle must have wounded the lens capsule, admitting the aqueous fluid to the lenticular substance. This in its turn would undergo disintegration and eventual absorption, but the process here went further and caused absorption of every particle of the capsule, thus making a perfect result. Though this latter does occasionally occur after operations both on soft and hard cataracts, it is not of common occurrence. Apparent existence of accommodative power in an eye, minus its lens. It is well known that on either side of our strictly mathematical focus for near objects (p.p.) there is a small range of space in which we can see, provided the circles of diffusion are cut off by means of a stenopäic hole, but this space is never very great, and in no experiment that I have made does it extend to six inches. To what, then, can the range for near vision (nearly six and one-half inches) in the present case be ascribed? To accommodation? If so, in what manner does it act?

Double Oöphorectomy.—Professor Spediacchi recently performed double ovariotomy upon a woman affected with hystero-epilepsy which had resisted all treatment.

The operation was entirely successful, and both ovaries were found to be normal. From the time of the operation the convulsions which previously had occurred seven, eight, and ten times daily, ceased, and have not since returned. The mental condition of the patient is also much improved.—*Lo Sperimentale*, January, 1885.

Cocaine Mixture for Relief of Cough and Vomiting in Chronic Pharyngitis.—Jahn, in the *Gazette Médicale de Paris*, of March 14, 1885, recommends the following formula for the relief of the cough and vomiting of chronic pharyngitis:

R.—Cocaine	. . . . .	gr. iss.
Glycerine	. . . . .	f℥ iv.
Aquæ dest.	. . . . .	f℥x ℥ij.
Acidi carbol.	. . . . .	gr. ⅙.—M.

S.—Apply morning and evening with a suitable brush.

Meningocele of the Cranium; Treatment and Cure by Elastic Ligature.—Dr. A. Lazzari, in the *Gazzetta di Torino* of February 25, 1885, reports a case of cranial meningocele successfully treated by elastic ligature. The patient, a child, was first seen when four days old, and there was present over the occipital bone a tumor about the size of an orange. According to the statement of the mother, there had been no increase in its dimensions since birth. The child was normally developed, suckled well, and presented no other physical anomaly. The circumference of the tumor was about ten inches, and its diameter about three inches. The base was much constricted. Examination revealed a deficiency in the bone structure, and pressure showed conclusively that the tumor was in direct communication with the interior of the cranium. Having decided to attempt the operation, by ligature, Dr. Lazzari applied three turns of a small elastic tube about the base of the tumor. The child endured the operation without exhibiting any nervous phenomena, and the night following slept and suckled well. In the morning the tumor had assumed a violaceous hue. The third day the tumor was amputated above the ligature and dressed with iodoform with antiseptic precautions. The twelfth day the pedicle and ligature came away, and on the twenty-second day the wound was entirely healed, the cicatrix having the consistency of fibro-cartilage.

Chloride of Methyl as a Topical Remedy for Pain.—Mm. Tenneson and Bègue at a meeting of the Société des Hôpitaux held February 27, 1885, reported their joint observations on the use of chloride of methyl as a topical application for the relief of pain. They have used the remedy in various diseases, other than sciatica, for which it was first recommended by Debove, with some success. Among the diseases treated, are muscular rheumatism, articular rheumatism, acute or subacute, chronic articular rheumatism, and the pain due to pulmonary tuberculosis, purulent pleurisy, and lobar pneumonia. The success attained has been such as to encourage further trial of the agent.

The writers close their communication with a reference to the accidents which may occur in the application of the remedy. These are prolonged erythema, hyperæsthesia, of the skin, vesication, and eschar. To avoid these bad effects, the use of the remedy must not be prolonged more than five or six seconds, or even a shorter period, in regions where the skin is very delicate. To avoid blistering and eschar, the spray must be directed obliquely, not perpendicularly upon the skin.

Pigmentation, also, sometimes occurs, but it is not so marked as that produced by blisters. Whether it is permanent or in what length of time it will disappear cannot yet be affirmed. — *Gazette Hebdomadaire de Médecine et de Chirurgie*, March 6, 1885.

Report of the German Vaccine Commission.—The Vaccine Commission which a short time since was appointed by the German Imperial Health Society have returned the following report relative to the pathological and physiological basis of vaccination:

1. A single attack of smallpox, with rare exceptions to the contrary, prevents the possibility of a recurrence of the disease.

2. Vaccination offers a similar protection.

3. The length of time during which vaccination is protective against the disease, widely varies, but the average period is ten years.

4. In order to secure protection against smallpox by vaccination, at least two well-developed vesicles must be obtained.

5. Revaccination is necessary at the end of ten years after the first vaccination.

6. Vaccination of a community affords a common protection against smallpox.

7. Vaccination under certain circumstances may be dangerous, inasmuch as by use of human lymph, syphilis may be communicated. This danger is, however, slight, and with ordinary care can be so reduced that the possible harm therefrom is incomparable with the actual protection attained against smallpox.

8. Since the introduction of vaccination there has been no disease or unusual mortality, which, from a scientific standpoint, can be attributed to the effect of the operation.

Experimental Thyroidectomy in Rabbits.—Professor Guido Tizzoni, after much experimental research upon thyroidectomy in rabbits, reaches the following conclusions:

1. Complete extirpation of the thyroid body in the rabbit, is compatible with the life of the animal and produces no change in its health.

2. The functions of the nervous system and the composition of the blood, at least in regard to its richness in hæmoglobin, and the relation between the number of the red and the white blood corpuscles, are not influenced by the removal of this organ.

3. The nutrition and growth are maintained when the operation is performed upon a very young animal.

4 Splenectomy is followed by no graver consequences in animals deprived of the thyroid body than in those from which the organ has not been removed.—*Gazzetta degli Ospitali*, March 28, 1885.

New Method of Administering the Bromide and Iodide of Potassium.—The repugnance with which patients, who for a long time have been under treatment with iodide or bromide of potassium, regard the drugs, and the gastric symptoms so frequently produced by them, have led M. Poisson to introduce them into chocolate. The preparations are in the form of pastilles, each containing four grains of one or the other salt. The disagreeable taste of the drugs and their injurious effect upon the gastric mucous membrane are entirely obviated, and they are thus acceptable to the most delicate stomach.—*Journal de Médecine de Paris*, Feb. 28, 1885.

Contribution to the Study of Albuminuria.—Professor Albert Riva, in an experimental study of albuminuria, reaches the following conclusions as the solution of the questions:

a. What forms of albumen are more or less filtered through the kidney?

b. What effect does such filtration have upon the renal tissue?

c. What effect does the albumen assimilated or non-assimilated produce upon organic change?

1. The albumen of the egg is filtered most easily, and for this reason produces the most marked albuminuria.

2. Albuminuria is not caused by the peritoneal injection of inflammatory or simple exudates, whatever may be the period of the disease from which they arise.

3. The absence of albuminuria from such causes is verified by cases in which the exudates injected are taken from persons already suffering from albuminuria, either mechanical or nephritic, no matter what the stage may be.

4. Peritoneal absorption does not seem to modify the albumen. There is no difference in results whether the injection is made into the peritoneum or directly into the blood current.

5. The albuminuria disappears rapidly after the albuminous injections are discontinued, though they may have been maintained a long time.

6. In the albuminuric urine are found numerous granular cylinders, which disappear along with the albuminuria, and sometimes even before it.

7. During artificial albuminuria the kidneys are more or less congested, the tubules plainly enlarged, and the epithelium turbid. These changes, however, are equally as transitory as the albuminuria.

8. Organic change, specially studied by examination of the composition of the urine, and from the weight of animals fasting, or fed as usual, is without doubt modified under the influence of albumen, diffusible or non-diffusible; but to determine these modifications exactly, further investigations are necessary.—*Gazzetta degli Ospitali*, January 28, 1885.

Variation in the Menstrual Function.—Dr. Jules Rouvier completes a careful study of variations in the menstrual function with the following conclusions:

1. Deviations from the normal menstrual phenomena assume the form of congestion, hemorrhage, or of morbid supplementary manifestations, such as jaundice, erysipelas, cutaneous diseases, neuralgia, and perversion of the secretions.

2. They may exist in old women; may affect any part of the system, but especially the mucous membranes; and may or may not accompany normal menstruation.

3. They generally coincide with ovulation.

4. They are always referable to some cause which should be sought for as exerting a more or less determining influence upon the locality affected.

5. When there is atresia of the genital organs, arrest of development, or absence of the uterus, exaggerated sensibility of the nervous system, or hysteria, the deviation may be manifested by any organ whatever.

6. When the above conditions do not exist, such deviation will select for its chief location: *a*. a diseased organ; *b*. an organ recently cured of a disease; *c*. an organ in which the physiological demands are intense and transient.

7. When such variation is manifested without apparent cause in the lungs, breast, or stomach, a cancerous or tuberculous diathesis should be suspected.

8. Variation in the menstrual function being a morbid manifestation, necessitates medical intervention and treatment either local or general.

9. Pregnancy and lactation exercise the same influence upon deviations in the menstrual function as upon the normal catamenial flow.

10. Though ordinarily confined to one or several epochs, menstrual deviations may begin at puberty and persist until the menopause.—*Annales de Gynécologie et d'Obstétrique*, March, 1885.

The Pseudo-rheumatism of Mumps.—Drs. M. Lannois and G. Lemoine, in the *Revue de Médecine* for March, 1885, give clear clinical proof that pseudo-rheumatic complications frequently supervene upon an attack of mumps. Complete recovery from the attacks has always resulted. As to treatment, little or nothing can be said. Rest in bed and sedative embrocations are in most cases all that is necessary. Salicylate of soda, in the cases in which it has been used, seems to be without effect.

The general conclusions arrived at concerning the disease are the following:

1. Mumps are sometimes accompanied by rheumatic manifestations, the relative frequency of which remains to be determined.

2. These manifestations are shown either at the same time as the mumps or rather at their decline, and assume the same behavior as *orchitis* due to mumps. They may not remain limited to the articulations, but attack also the synovial sheaths of the muscles.

3. They affect a subacute condition, and give rise to only moderate pain and swelling, and to general reactions which are not serious.

4. They recur readily and thus prolong the duration of the disease, the cure of which is the rule.

5. They are not truly rheumatic in their nature, but are only local manifestations of the parotiditis.

6. Pseudo-rheumatism may be compared with the pseudo-rheumatism of the infectious diseases, erysipelas, scarlatina, etc.

Complications Observed in the Various Organs of Sense during the Course of Mumps—Dr. Fournié, in an exhaustive review of the numerous authorities citing cases in which the several organs of sense have been affected during, or subsequent to, an attack of mumps, concludes his paper with the following résumé:

The auditory apparatus is relatively the location of the most serious and frequent effects of mumps. Absolute or temporary deafness and catarrh of the auditory meatus are the principal expressions of such localization.

I. Absolute Deafness.—This is of anatomical origin, uncertain in its nature, but resulting probably from a direct miasmatic impression produced by the infectious principle of the disease upon the nervous system. The deafness is characterized by:

a. Early appearance.

b. Rapidity of production.

c. Independence of glandular and other complications incident to mumps.

d. Incurability.

No appreciable otoscopic lesion is present, but the symptoms may more or less perfectly simulate those of Ménière's disease. There is no symptom by which the occurrence of deafness is foreshown, or by which the extent of the disease may be prognosticated. All ages, sexes, and forms of mumps are liable to such complication.

II. Temporary Deafness.—As a result of mumps, clinical facts well establish the possibility of a transient deafness, different in the time of its appearance, its in-

tensity, and its duration, from that above described. It is rarely complete, and lasts usually about two weeks.

III. Catarrh of the Meatus.—In some instances there is produced an auricular catarrh similar to that of the conjunctiva or urethra. This determination of the disease is habitually contemporaneous with the glandular affection, and is produced by a sero-purulent discharge little different from that of ordinary otorrhœa. Its duration is relatively short, and it plays no special part in the determination of those diseases which, occurring subsequently to mumps as well as other diseases, may result in suppuration of the auditory meatus.

As ocular complications of parotiditis have been observed:

1. Conjunctivitis.
2. Inflammation of the lachrymal gland.
3. Sensorial derangements of diverse nature.

The ocular catarrh is usually of little import and of rare occurrence, and only deserves attention from the fact that keratitis sometimes results as a complication.

Inflammation of the lachrymal gland is rare and of the same nature as that of the parotid.

Sensorial derangements are either of early or late appearance. If early, they are only observed in cases of extensive inflammation with abundant discharge. They are due to impediment in the intraocular circulation, and are benign and of short duration.

When they appear late in the disease they are, similar to deafness of the same origin, not dependent upon an exaggerated glandular flux, but have for their origin anatomical atrophy of the pupil, produced by direct impression of the morbific principle of the disease upon the nervous centres. They are serious in their nature and the prognosis is grave.—*Archives de Médecine et de Pharmacie Militaires*, March 16, 1885.

SPLENECTOMY IN THE RABBIT; ABSENCE OF FUNCTIONAL RELATIONS BETWEEN THE SPLEEN AND THYROID BODY.—In the *Arch. per le Scienze Mediche*, vol. viii., PROF. G. TIZZONI records the results of experimental splenectomy practised upon rabbits. The number of animals operated upon was eighteen. They were killed at various times after the operation, ranging from twelve to two hundred and forty days and the results as observed carefully noted. The conclusions reached by Prof. Tizzoni are as follows:

1. Splenectomy practised upon the rabbit does not produce appreciable modification in the health of the animal.

2. The age of the animal does not influence the results of the operation, which is endured equally well whether the animal be young or old.

3. The development of the body and the conditions of nutrition are not modified by splenectomy.

4. Absence of the spleen, moreover, exercises no influence upon the function of fecundation and the reproduction of species.

5. Those rabbits born of parents from which the spleen had been removed, presented no variation in size, form, or structure of the spleen, nor alteration in the hæmatopoietic organs or other parts of the body.

6. In the rabbit—different from the dog—splenectomy causes no great modification in the hæmatopoietic organs and tissue, indications being found only in young animals, as would indicate a greater activity in medulla of bones.

7. The thymus and thyroid bodies are not affected by removal of the spleen.

8. The conditions of glandular neoplasia—whether in diffuse form or in circumscribed nodules—which were observed in some animals, probably represented only physiological increase of the organ.

9. From the above conclusions, which represent the immediate results of his experiments, Prof. Tizzoni draws the following inferences:

a. Neither in the dog nor rabbit do there exist any physiological relations between the spleen and the thyroid body; or, at least, in the functions of these organs there does not exist such relations as will enable the one, in the absence of the other, to perform its functions when removed.

b. In the rabbit the spleen and connective tissue of great peritoneal folds cannot in extrauterine life be regarded as hæmatopoietic organs.

c. The differences which are observed in various animals in the results of splenectomy, depend on physiological differences in the function of the spleen in various animals, and do not contradict or disprove each other.

d. From facts observed in experiments entirely upon a single species of animals, general conclusions must not be drawn concerning the hæmatopoietic process.—*Lo Sperimentale*, January, 1885.

CREASOTE WATER AS A LOCAL ANESTHETIC.—DR. E. R. SQUIBBS, in the *Ephemeris* for March, 1885, says:

The officinal aqua creasoti, or creasote water, is so important as a preparation for one special use that it is well to notice it in order to emphasize that special use. It is a simple one per cent. solution of wood creasote in water, and, like similar solutions of carbolic acid and of cresol, it is a most effective local anæsthetic, and topical dressing to burns and scalds. It is no better than the solutions of carbolic acid, or of coal-tar creasote, for this purpose, but it is quite as good, so that whichever is most accessible or most convenient may be used. This creasote water, as made by the above formula,—or diluted with an equal volume of water, or with more water for delicate surfaces in women and children,—and applied by means of a single thickness of thin muslin, or worn-out cotton or linen, such as handkerchief stuff, and the application renewed from time to time, as the return of pain requires it,—will relieve the pain of burns and scalds in five to ten minutes, and will maintain the relief as long as the applications are properly renewed, or until the painful stage is over.

It is also very effective as a local anæsthetic for general use in all painful conditions which affect the surface only, such as the pain of erysipelas. The benumbing effect of these phenols upon the skin is very promptly reached, and can be carried to almost any degree that is desirable, by simple management of the strength of the solutions and the mode of application. They are true anæsthetics to the skin, while the much lauded cocaine is not.

This statement has been published so often during the past twenty years, and the treatment has been so effective in so many hands, that it is wonderful to notice how the common practice is still to use the old and comparatively useless hot dressings, such as carron oil, white lead ground in oil, flour, liniments, etc, or the newer application of solution of bicarbonate of sodium.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, APRIL 11, 1885.

THE SURGERY OF PYLORIC STENOSIS.

An important contribution to the operative treatment of carcinomatous and fibrous obstruction of the pylorus may be found in the *American Journal of the Medical Sciences* for April, in which the author, Dr. Winslow, of Baltimore, has collated nearly all the examples that had been recorded up to February 9, 1885, of pylorectomy, and its substitutes, gastroenterostomy, gastrectomy, gastrostomy, duodenostomy, and digital divulsion of the pylorus. In all, he has collected 61 excisions of the pylorus, including 1 of his own, 13 gastroenterostomies, 1 gastrectomy, 1 gastrostomy, 3 duodenostomies, and 6 examples of digital divulsion; and he has given a most satisfactory résumé of the indications for, prognosis of, causes of death after, and technique of these different procedures. In the present article, we propose to draw some conclusions as to the justifiability of these operations and their comparative value, availing ourselves not only of the material furnished by Winslow, but of 8 additional examples of pylorectomy from the practice, respectively, of Kuester, Czerny, Lauenstein, Schede, Koehler, and Rydygier, 2 jejunostomies by Surmay and Robertson, 2 pyloric divulsions by Loreta, referred to by Holmes in the *British Medical Journal* for February 21, 1885, and 1 gastroenterostomy by Rydygier, the details of which, as well as of 3 new pylorectomies by that surgeon, may be found in the *Deutsche Zeitschrift für Chirurgie*, Bd. xxi., Hefte 5 and 6, 1885.

1. Carcinoma of the Pylorus.—The operations that have been practised up to the present time for carcinomatous stenosis are pylorectomy, gastroenterostomy, gastrostomy, and duodenostomy. The single case of extirpation of the entire stomach need not detain us, as there is no probability that it will be repeated.

Pylorectomy has been resorted to at least 60 times, of which 45, or 75 per cent., succumbed—29 from collapse, 6 from peritonitis, 4 from gangrene of the transverse colon, 2 from inanition, 1 from exhaustion, and 3 from undetermined causes. Of the 15 survivors, 5 died subsequently of recurrence, respectively, at the expiration of three, four, ten, eleven and a half, and nineteen months; 2 were living with recurrence, respectively, at eighteen months, and three years and nine months; the disease recurred in 1 in eleven months, and Socin performed a gastroenterostomy, the patient being alive at the end of four months, the date of the last report; 3 patients were alive without recurrence at the expiration, respectively, of two, seven, and eleven months; and in 4 the fate is uncertain. In other words, of 56 cases in which the result is known, 75 per cent. perished as the direct result of the procedure; in 72.72 per cent. of the survivors there was a return of the disease; and in 27.27 per cent. there was freedom from recurrence for less than one year. Hence, not a single patient was permanently cured, that is to say, remained free from recurrence for three years. These facts are quite sufficient to condemn the operation, and the opinion that it is unjustifiable is rapidly growing.

Gastroenterostomy, a procedure devised as a substitute for excision of the pylorus when the latter is rendered impracticable by adhesions or the extent of the disease, has been performed 11 times, with 3 recoveries, and 8 deaths, or a mortality of 72.72 per cent. Of the survivors, 1 died in four months, and 2 were still alive at the expiration, respectively, of two and four months. As the mortality is nearly as great as that of pylorectomy, and as the cases in which the operation has been practised were more serious than those in which pylorectomy was done, death in a short time being inevitable without any operation, it is obvious that gastroenterostomy is not destined to become a recognized procedure.

Of gastrostomy and duodenostomy, little need be said. Hahn succeeded in prolonging life for two weeks by opening the stomach and feeding the patient through a tube passed into the duodenum; while Langenbuch's case of the establishment of a duodenal fistule for the purpose of feeding died on the seventh day of inanition.

The frightful mortality of all the operations of which we have presented statistics, the almost inevitable recurrence of the disease, the failure to have effected a single permanent cure, and the slight knowledge which we possess of the extent to which nutrition can be sustained by intestinal digestion alone, are, in our opinion, grave objections to oper-

ative interference in carcinoma of the pylorus. Hence, we believe that such cases should be left to their fate, suffering being palliated by anodynes, and nourishment being afforded by the rectum.

2. Fibrous Obstruction of the Pylorus.—The operations that have been done for fibrous stricture of the pylorus are pylorectomy, gastroenterostomy, duodenostomy, jejunostomy, and digital divulsion.

Excision of the pylorus has been practised in 9 cases, of which 5 recovered, and 4, or 44.44 per cent., died, the causes of death having been peritonitis in 1, collapse in 1, and gangrene of the transverse colon in 2. The survivors were doing well, respectively, at the expiration of one month, three months, six months, six months, and nearly three years.

Gastroenterostomy has been done 3 times, with 1 death from collapse, and 2 recoveries. Of the ultimate fate of the survivors we have no information.

Duodenostomy has been resorted to by Southam in one case, the patient dying from inanition on the third day. Surmay and Robertson lost their patients after jejunostomy, respectively, at the end of eight and thirty hours, so that these measures have proved to be useless.

Digital divulsion of the stomach, as first done by Loreta, has been practised in 8 cases, of which 6 recovered, and 2, or 25 per cent., died of collapse. Of the survivors, 1 was doing well on the third day, and the remainder had perfectly recovered, their digestion being normal, and there being not the slightest evidence of recontraction. In three cases indeed, eighteen, twenty-four, and twenty-seven months had elapsed since the operation.

From the above facts, we think that the conclusion is warranted that Loreta's operation should be preferred in cases of cicatricial stricture of the pylorus. It is far less fatal than pylorectomy, is much more easy of execution, it exposes the peritoneal cavity for only a comparatively short period, and it does not sacrifice a portion of the stomach. We may further conclude, with Winslow, that when digital divulsion is impracticable from the great thickening of the walls of the pylorus, resection is indicated in those who are well nourished, and that gastroenterostomy should be resorted to in greatly debilitated subjects.

In connection with the operative treatment of pyloric stenosis, attention may be called to an entirely opposite method of treatment carried out by Dr. Russell, of Birmingham, and recorded in the *British Medical Journal* for February 21. In a man, now aged 55, suffering from a stationary constriction of the pylorus with great dilatation of the stomach, washing out the organ, through which every impurity which would act as a ferment was removed, succeeded in restoring the digestive powers and in sustaining a useful existence for five years, the patient being still alive. If further experience with this treatment should prove it to be as valuable as in the case of Dr. Russell, Loreta's operation should not be undertaken until irrigation has had a fair trial.

ARE WE A NERVOUS PEOPLE?

In a pamphlet addressed to "The Medical Profession of Brooklyn," that we are a nervous people, is affirmed with all the emphasis given by a ponderous load of vital statistics. It is further assumed as proven in this pamphlet, that a people so oppressed with nervous ailments need a dispensary at whose doors the burden may be unloaded. If the good city of Brooklyn is so afflicted, why not the rest of the country? It is true, in the City of Churches, there are such emotional moralists as Beecher and Talmage, such ingenious men of business as young Ferdinand Ward, and such "tempest-tossed" men of letters as Theodore Tilton; but have we not in Philadelphia an Antivivisection Society? It will be found, we think, on a proper study of the vital statistics of any part of our country, that in every town there are sources of emotional disturbance not unlike those which agitate Brooklyn.

Are we really a nervous people? Is it true, as alleged, that our climate and social condition tend to develop disorders of the nervous system in greater ratio than the zymotic, tubercular, and respiratory diseases? If so, we can reëcho the exclamation of the pamphlet above quoted: "It is then the more startling, that whilst every city in the country has one or more hospitals for the reception of these three classes, there is not one in the land for the adequate reception of the next most frequent class"—*i. e.*, the nervous.

To all the attempts, statistical and otherwise, to demonstrate the greater prevalence of nervous diseases in modern times, we have to oppose two reflections, which may or may not have the dignity of arguments. The first is, the steady increase in the average duration of human life; the second is, the more stable condition of modern society, in respect to both its moral and political relations. Now, as nervous diseases are peculiarly intractable to remedial agencies, and in their very nature prone to a fatal termination, their remarkable extension seems hardly compatible with the increasing longevity of the civilized portion of the human family. The second consideration seems even more weighty. The improved social state; the greater comforts in the home life of the people, in consequence of which the mere struggle for existence is much less harassing; and the more benign and stable governments, leaving the people, for the most part, in the enjoyment of their own possessions, must be conducive to the development of an unexcitable state of the nervous system. In ancient and mediæval times—up to the middle

of the nineteenth century, indeed—society was frequently convulsed with political and moral throes, so that if such influences are causative of nervous derangements, they ought to have been more abundantly manifested in those momentous eras. That nervous derangements should occur more freely when human society is in a less disturbed state, and all the conditions more favorable to a general well-being, seems to us hardly credible, how peremptorily, soever, vital statistics may affirm the opposite position. But all the world knows how very elastic statistics are. The Brooklyn statistics could be made to prove far more than that a dispensary for nervous diseases is needed there; in fact, they could readily establish the proposition that the apparent increase in nervous affections is an outcome of the moral teaching of Brothers Beecher and Talmage.

An examination of the Hippocratic and other ancient medical writings discloses the important fact that affections of the brain and nervous system are treated of just as fully as are other maladies—as fully, relatively, as the same diseases in modern systematic works. In our day, because of the great advances in physiology and pathology, nervous affections are more carefully differentiated, and become thus apparently more numerous. Furthermore, modern society is fructified with a new variety of the human animal—the neurological expert. It is true, in the time of the Egyptian Pharaohs, according to Herodotus, there were specialists for nervous diseases but they subsequently became extinct. We do not find, amongst the records of the brick tablets, or in the cuneiform inscriptions, any references to vital statistics proving the need for Asclepiadæ devoted to nervous diseases, but they must have existed for all that. The neurological expert of ancient days, like his modern prototype, could only have arisen under favoring conditions; hence we must infer, despite the absence of statistics capable of this interpretation, that when this variety of the genus *medicus* flourished, it had abundant material for the exercise of its powers. Although this inference partakes rather of the nature of a syllogism, in which, possibly, we fail to dispose of our middle term, we take refuge in the statement of Mill, that "this inference of one particular fact from another, is a case of induction."

After this dispassionate review of the medicine of all ages, *more medico*, we are conducted to the conclusion that man has always been a nervous animal, and despite the Brooklyn statistics, not more so in our day than in former times.

THE ALBUMINURIA OF DIPHTHERIA AND SCARLET FEVER.

It is well known that albuminuria is a very common complication of both diphtheria and scarlet fever; that it is as frequent, and probably more so, in the former than the latter. Few, however, have paused to consider whether there is any difference in the immediate conditions which cause it. That the albuminuria of scarlatina is the result of a nephritis is generally understood, and we incline to believe that most physicians would ascribe the albuminuria of diphtheria to the same immediate cause. At the same time no very close examination is necessary in order to reveal important differences in their conditions. How rare, for example, is it to find uræmia or renal dropsy in diphtheria!

Senator has called attention to this difference in some remarks recently made before the Berlin Medical Society, and published in the *Berliner klin. Wochenschrift*, Dec. 1, 1884. According to him, the albuminuria of diphtheria is an albuminuria of congestion, altogether unassociated with the phenomena of inflammation, unless the congestion continue a very long time, when we may have superadded what is known as congestion-nephritis, or cyanotic induration. The congestion may be brought about in two ways: first, by an extension of the diphtheritic process to the larynx, the consequent dyspnœa producing a general engorgement which the kidneys share with the rest of the body; or it may occur later in the disease, from paralysis of the vagus, and feebleness of the heart. Such congestion is not infrequently associated with œdema of the lower extremities, which is also favored by the anæmia which is by this time present. An albuminuria from such causes seldom occurs in scarlet fever.

Another form, associated with diphtheria, may be called infectious-febrile albuminuria. This occurs, frequently, early in the disease, or when the throat affection is at its height, and is unaccompanied by any other symptoms of nephritis, such as blood, leucocytes, or epithelium in the urine. Sometimes, indeed, hyaline tube-casts are present, but these do not indicate inflammation. This albuminuria is comparable to that associated with the acme of other fever processes, disappearing with the subsidence of the fever. After death no changes are found in the kidney, or they are confined to limited areas of cloudy swelling of the epithelium, such as is often found without albuminuria.

There is, indeed, a third form of albuminuria in diphtheria, which is neither congestive nor febrile-infectious, but which is due to a mild nephritis, differing from the majority of cases of scarlatinal nephritis in its slighter anatomical changes, as well as in the mildness of its clinical features. In it, interstitial and vascular changes, as well as changes in the Malpighian capsules, are much less marked than in scarlatinal nephritis, and although it is true that higher degrees of nephritis, with their characteristic

clinical phenomena, are sometimes present, their great rarity must be admitted.

It should be stated, however, that Henoch, to the reading of whose paper on diphtheria succeeded the remarks of Senator, to which we have called attention, is inclined to believe that the diphtheritic albuminuria ascribable to asphyxic congestion, is the rarest form; that the cases in which albuminuria is present are often unattended by fever of any severity. He claims that the albuminuria of diphtheria is almost always the result of infection, and is to be included in the extensive group of infectious nephritis, notwithstanding the fact that Weigert and Fürbringer have failed to discover bacteria in the kidney under these circumstances.

There has always seemed to us a marked difference between the albuminuria of most cases of diphtheria and scarlet fever, and Senator has clearly indicated these differences as they have often presented themselves.

MUNICIPAL SANITATION.

The recent action of the Philadelphia Councils in requesting Chief Engineer Ludlow of the Water Department, to maintain silence upon sanitary matters connected with the water supply of the city, has received the prompt and vigorous condemnation of press and people, as it richly deserved. Fortunately some of the members who foolishly voted for the resolution have been relieved from further municipal duties, yet some of their compeers remain, and as the new Councils are just assembling, a few words on the subject may not be amiss.

Of all the business which will come before them, nothing can approach in importance the question of sanitation; and public agitation on this subject should be welcomed as an evidence that the people will heartily support them in the performance of their highest duties. Instead of being an injury to the city, a vigorous expression of public opinion is a benefit, inasmuch as it tends to impress upon outsiders the fact that sanitary matters are claiming their proper share of attention.

In spite of obvious sanitary defects, Philadelphia is exceptionally healthy when compared with other cities, but such a flattering comparison becomes a positive misfortune if it closes our eyes to the fact that the only true standard of sanitation is the absence of preventible diseases. If 1000 persons die every year from preventible diseases, the burden of responsibility falls no less heavily upon the municipal authorities if they can show that 1500 die yearly of the same diseases in a neighboring city. The bare facts remain that these lives, which might have been saved, have been lost, and that they have been sacrificed in no small measure to the apathy of Councilmen and the greed of contractors.

Guided by the sad lessons of the past, Councils should determine at once to check, so far as lies in their power, this wanton waste of the costliest treasures in the universe—human life and health. To accomplish this end we need a purer water supply, better pavements, actual street-cleaning, the abolition of cesspools and drinking-wells, modern sewers, and popular instruction in the grand truth that filth is poison. The chiefs of the Departments of Highways, Surveys, and Water, should be selected because they possess a thorough knowledge of sanitary engineering and the practical ability for executing public work, and they should not be hindered or insulted while they are doing their utmost to secure our welfare.

Above all, let the Manayunk intercepting sewer be completed without further delay, as it will prove of very valuable assistance in preventing the spread of the threatened epidemic of cholera. We learn with pleasure that funds available for this purpose will shortly be at the command of Councils, and we earnestly hope they will see the absolute necessity for the immediate prosecution of this great work.

To obtain the various blessings we have mentioned, sagacity and honesty in expenditure are the sole requisites. The people have learned that patchwork jobs such as they have hitherto been forced to accept are costly at any price, and if they could feel assured that their affairs would be conducted on simple but strict business principles they would willingly assent to an increase in the present low tax rate, and Philadelphia would soon regain its prestige as the cleanest and most healthful city in the Union.

GENERAL GRANT.

The distressing and disquieting symptoms experienced by General Grant on the 28th of March have not recurred, and the only incident of moment in the following week was a period of faintness on the morning of April 1st, which greatly alarmed those about him and was thought to indicate impending death. This period, however, promptly passed, and since that time his condition did not appear to have been much worse than during the preceding week, until last Tuesday morning, when a slight, but sudden hemorrhage ensued on a fit of coughing, and was followed by a rise of temperature, and greater weakness of the heart. It was deemed injudicious to try to ascertain the exact source of the hemorrhage.

The alarm felt has naturally colored the reports given out, and has increased the painful strain experienced by all. We recognize the difficulty of the position occupied by those who are called upon daily, almost hourly, to record the changes in the patient and to forecast the future, and hope that if circumstances warrant it, they may

find means to allay the immediate anxiety of the community, and limit the pain to that which is inevitable. In a disease that destroys by asthenia, death may come any day, but it may also delay for weeks, and since it is impossible to predict the hour, it is the part of kindness to calm suspense and to spare those who must bear the grief of an actual loss, the painful tension of days of hourly expectation.

THE NINTH INTERNATIONAL MEDICAL CONGRESS.

The General Committee is to be congratulated on the successful consummation of the preliminary steps in the organization of the Washington International Medical Congress. The inherent difficulties of the task were very great. The Committee appears to have been deeply imbued with the feeling that while the scientific aspect of the Congress was the foremost consideration, yet, that it must be maintained with a due regard to geographical distribution. Hence the most prominent and learned members of the profession have been selected to fill the various offices in the Congress and its Sections, and almost every State in the Union is represented in the list. So far, the outcome bears evidence of careful deliberation, and it has been received by the profession and the medical press with expressions of general satisfaction.

REVIEWS.

The Science and Art of Surgery. A Treatise on Surgical Injuries, Diseases, and Operations. By John Eric Erichsen, F.R.S., LL.D., F.R.C.S., Surgeon Extraordinary to Her Majesty the Queen; ex-President of the Royal College of Surgeons of England, etc. Eighth Edition, revised and edited by Marcus Beck, M.S. and M.B. London, F.R C.S., Surgeon to University Hospital, and Professor of Clinical Surgery in University College, London.

In noticing the eighth edition of this well-known work, it would appear superfluous to say more than that it has, like its predecessors, been brought fully up to the times, and is in consequence one of the best treatises upon surgery that has ever been penned by one man. The author, however, informs us in his preface that this edition is not, like previous ones, a mere reprint with a few unimportant additions here and there, but that it has undergone "a complete revision." That portion of the work which relates to Pathology has been mainly entrusted to Mr. Beck. It would be impossible within the limits of this notice to examine in detail Mr. Beck's pathological teachings, but as far as we have examined them, they seem to be trustworthy guides to modern pathology. Mr. Beck has also done a share of the work requisite to bring the portions of the book treating of clinical and operative surgery abreast of the times.

The chapter on surgical treatment of some uterine and ovarian diseases has undergone revision at the hands of Wm. A. Meredith, and the chapter describing operations upon the eye has been wisely omitted. Notwithstanding this the book exceeds the previous editions by several hundred pages.

Many of the old cuts have been redrawn, and some cancelled, and about one hundred and fifty new ones added.

The author states that simultaneously with the English edition an American reprint, and new Italian and Spanish translations will be issued.

Although more than thirty years have elapsed since the first appearance of Erichsen's Surgery, this present edition has been carefully brought up to the times in almost all points. It is most creditable to Mr. Erichsen that rather than follow the too common plan adopted by many authors of repute, viz., to issue as a new edition a merely slightly modified reprint, he has associated with him younger men upon whom the hard labor of a complete remodelling to suit modern pathological views has been laid, while he himself still affords the surgical world the benefits of his old as well as his later experience.

We have always regarded "The Science and Art of Surgery" as one of the best surgical text-books in the English language, and this eighth edition only confirms our previous opinion. We take pleasure in cordially commending it to our readers.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 2, 1885.

The President, A. Jacobi, M.D., in the Chair.

Dr. William H. Draper read a paper on

ANTIPYRIN AND ITS EFFECTS,

which commenced with the statement that while no advance had of late been made in our knowledge of the essential nature of the condition known as fever, it was a fact that the means at our command of successfully treating it were constantly being enlarged. Then taking up the subject of antipyrin, which he mentioned was one of the many derivations of coal-tar, he gave an account of the physiological effects which had been noted in experiments with it upon animals. In very large doses it had been found to produce death by cardiac paralysis, and in somewhat smaller doses irritability of the nervous system, and finally paralysis.

It was first used in the treatment of fever by Filehne, of Erlangen, who gave it in doses of two grammes repeated every hour, until three doses had been taken, and who noticed that when the temperature went up again, after having been reduced by the remedy, it did so without the occurrence of a chill, as was the case when kairin was employed. Dr. Draper then referred to Guttmann, Alexander, and several other authors, and said that in many cases the drug had been noticed to produce free diaphoresis. He had himself used it considerably in his service at the New York Hospital since the 1st of October last, and mainly in typhoid fever. His predecessor in charge of the medical wards, Dr. Peabody, had already employed it to some extent, but had been somewhat embarrassed by the small supply of it that could be obtained in the early part of the

autumn. He had, however, been much impressed with its efficiency in reducing temperature, and had also noticed that it seemed to have a very tranquilizing effect upon the nervous system in fever patients.

His own cases of typhoid fever, in which it was used, were twenty in number; seventeen of the patients being males, and three females. Fifteen recovered and five died; the mortality thus being 25 per cent. The highest temperature reached in any of the fatal cases was 107.6°, on the twenty-fourth day of the disease. In one case in which the temperature could not be brought below 104° by the use of baths, it promptly fell to 102°, when antipyrin was given.

In the case in which the temperature was highest among those which recovered, it ranged from 103° to 106.6°; the average range in the whole number of these cases being from 100.6° to 103.6°. Vomiting was quite a frequent symptom. Of the fifteen cases in which recovery took place, there was diarrhœa in seven, and constipation in eight. There was sweating in a considerable number. Nervous symptoms were relatively few.

All the typhoid fever patients were treated either by cold applications (by baths or sponging) or by the use of antipyrin. In giving the latter the general method of Filehne, of Erlangen, was adopted, as a rule; 75 grains of it being divided into two doses of 30 grains and one of 15 grains, and the doses given at intervals of one hour. It was seldom found necessary to use more than 150 grains of the remedy during the twenty-four hours in order to maintain the temperature at an average of from two to three degrees lower than would have been expected if no antipyretic measures had been taken. As a rule, the pulse followed pretty closely the temperature curve; becoming quicker as that rose and slower as it subsided. In all cases antipyrin caused a reduction of the temperature; but in one instance it was found necessary to administer it hypodermically in order to obtain the desired result, no reduction following its exhibition by the stomach. One of the most noticeable effects of the drug was the rapid cleaning up of the tongue under its use; and it also acted very happily in quieting nervous symptoms; depression of spirits being produced by it in only one case. In six cases it caused sweats, and in six an erythematous rash resembling measles; while in a seventh it gave rise to a somewhat purpura-like eruption. These, however, occasioned the patients no annoyance. No change was noted in the urine except in cases in which the complication of parenchymatous nephritis existed.

The largest quantity of the drug was given to one of the patients in whom the disease ended fatally, who took some 350 grammes in thirty days; while the largest quantity given to a case that recovered was 334 grammes during a period of twenty-three days. The latter was a case of great severity. The most marked fall in temperature noted under its use was from 103.8° to 98°. In three cases the antipyretic effect of cold baths and antipyrin was directly compared. In the first case (to which allusion had already been made), it was impossible to reduce the temperature below 104.3° with the baths; but antipyrin promptly brought it down to 102.2°. In the second the lowest point reached under the baths was 102.4°, while under antipyrin it fell to 101.2°. In the third case, however, the difference was not so striking. Dr. Draper then mentioned a case of puerperal septicæmia in which Dr. Peabody had employed antipyrin with excellent effect in reducing the temperature, and also a severe case of abscess at the New York Hospital.

In scarlet fever and tuberculosis he had found that it invariably reduced the temperature and contributed materially to the welfare and comfort of the patient. On the whole, his observations had been altogether confirmatory of those made by European authorities in regard to the apparent value of antipyrin. At present it could only be commended as a sure and probably safe agent for the reduction of temperature. It did not cure the disease, it was true, but it was not right to condemn it on that account. For the present, it was necessary to be content with being able to control the symptom which caused the most discomfort, and not infrequently endangered the life of the patient. Antipyrin was not an antipyretic in the same sense that quinine and the salicylates were. These agents were ideal antipyretics in the class of cases in which they were specially indicated; while antipyrin smothered, but did not extinguish, the fires of fever. In some cases the latter actually caused a temperature as low as that met with in collapse, though with a total lack of the depression and other symptoms characteristic of this condition. As to the *modus operandi* of the remedy, the vomiting, breathing, and collapse-temperature produced by it seemed to indicate that its special effect was upon the nervous centres; but at present any such hypothesis as to its action was mere speculation.

Dr. Draper then announced his conclusions as follows:

First. Antipyrin is an efficient means for reducing temperature.

Second. It is an apparently safe remedy when administered with prudence, and watched with care.

Third. While it does not abort or markedly modify the course of a febrile disease, it undoubtedly contributes greatly to the comfort of the patient.

Fourth. Occasionally unpleasant effects are produced by it which more than counterbalance the benefit derived from its use.

Fifth. Further experience with it, and a more exact knowledge of the manner in which it is best to administer it, may render it an extremely valuable contribution to the art of healing.

Dr. J. Leonard Corning said that from the physiological results caused by it, and from the collateral phenomena observed when it was administered in disease, it was reasonable to suppose that the remedy acted through the agency of the nervous centres, and that he was convinced, therefore, that the author of the paper was right in forming the conjecture that this was the case.

Dr. Leonard Weber said that since the 16th of December, 1884, he had employed antipyrin thus far in fifteen cases. None of them were cases of typhoid fever, but there were cases of pneumonia, bronchitis, and scarlet fever, with high temperature among them, and in not a single instance had he been disappointed by its failure to reduce it. He would like to refer to two or three of them to show the effects of the remedy in his experience. The first case mentioned was that of a child four and a half years old, suffering from

double pneumonia. The temperature was 105½°, and there was violent delirium. He ordered half a gramme of antipyrin to be given per rectum, and that it should be repeated in half an hour. In a short time the temperature was reduced to 102½°, and the delirium had disappeared. The next day he gave two doses, of half the quantity, by the mouth, and resolution then occurring, there was no necessity for continuing its administration.

The next case he mentioned was one of scarlet fever in a child of two and a half years, in which the remedy was given for the purpose of keeping the temperature within bounds. Before the antipyrin was taken the latter was 105°, and in this instance he followed a plan of giving it which, as he had recently seen, had now been adopted at the Dresden City Hospital. This was to use it in smaller doses, and repeat them every two or three hours through the day, according to the necessities of the case. The last case that he referred to was that of a lady forty-three years of age, with pneumonia of the upper lobe on one side, whom he had previously treated in two other attacks of pneumonia. The patient got along without any difficulty for two days, but on the third day he found her with a temperature of 104°, a pulse of 110, a dusky hue of the skin, and a generally adynamic condition. He ordered three doses of twenty grains of antipyrin, each to be given at one, two, and three o'clock respectively, and at two and a half o'clock she had slight vomiting. The temperature fell rapidly, and was now reduced to 100½°, while the pulse came down to 96. After that the temperature never rose above 101½°. Dr. Weber thought it was well, as a rule, to begin with small doses, say eight grains (per rectum) to children, and fifteen grains to adults, and afterwards increase the quantity if it was necessary. In this way it would be possible to avoid the too rapid and perhaps dangerous fall of temperature which was sometimes caused by it. At the Dresden City Hospital there had been six cases in which the temperature was actually lowered to 92° or 93° by it.

Dr. Boldt said that in two cases of puerperal septicæmia he had given it in not thirty, but sixty grain doses, and that it had been followed by marked prostration; the patients sinking into a semi-comatose condition, and the symptoms generally resembling those of carbolic acid poisoning. He had found that the remedy exerted its action in from three-quarters of an hour to one hour from the time it was given, and its effects did not continue more than three or four hours. He thought it well, as a rule, to commence with twenty or thirty grain doses, and then increase them if necessary. He had not noticed the same relation between the degree of temperature and the pulse which had been observed by Dr. Draper, and in the two cases of puerperal septicæmia referred to, no effect whatever was produced upon the pulse.

Dr. Frank H. Kinnicutt said that he had used antipyrin to a considerable extent, both at St. Luke's Hospital and in his private practice, and that the effects which he had observed were almost exactly similar to those mentioned by Dr. Draper. Among the cases in which he had employed it, were facial erysipelas, scarlet fever, pneumonia, pleurisy, phthisis, and intermittent fever. In his experience, gastric disturbance had been exceptional, and he said he had been particularly pleased with the certainty of the action of antipyrin in controlling the usual afternoon rise of temperature in phthisis. In this affection, it had been maintained that it was contraindicated on account of its liability to produce more or less profuse sweating; but, in his cases, he had found that this was as frequently absent as present. In one case, under antipyrin, he had noticed a chill occurring as the temperature went up again, as was very often the case when kairin was given; but there was only the one instance of it. There was one case of pneumonia in which a temperature of collapse, but without other serious symptoms, was produced by twenty grains of antipyrin. The patient expressed herself as feeling greatly relieved, and her general condition remained entirely satisfactory. To children, he thought it was well to give two doses of a grain and one-half for each year of the child's life; and he had found that in scarlet fever the remedy was of special value in controlling the high temperature, and rendering the patient comfortable.

Dr. Guy L. Peabody said that he thought that the lack of effect from antipyrin which had been sometimes noted of late might, perhaps, be explained by a fact which he had recently seen stated in the German journals, viz., that the drug was now largely adulterated. In his own earlier experiments he had never failed to produce rapid reduction of temperature in any case in which he employed it; but during the last six weeks he had more than once been disappointed in finding the remedy apparently inert. Thus, in the case of a negro now under treatment at the New York Hospital, who had a temperature ranging from 103° to 106°, for the past two days he had administered 75 grains of antipyrin a day, in three doses; but without affecting the temperature the fraction of a degree.

At all events, he believed that no harm was done the patient, in ordinary cases, by antipyrin, even if no great benefit might be derived from it; and it had never happened to him to see the force of the heart's action reduced by it. It might be of interest, he thought, to know that it could be given hypodermically with great facility; the drug being readily soluble in hot water and not recrystallizing again, while it was not at all likely to produce any unpleasant local effects. Hence, in any case in which vomiting or other disturbance was produced by giving it by the stomach, the hypodermic method could be substituted for this with advantage. He had personally tested antipyrin in almost all of the ordinary febrile diseases; and in one case of typhoid fever in which no effect whatever was produced by a thorough trial of cold bathing, the temperature was promptly reduced by it. The patient in this case was a very fleshy young woman, upon whose body there was such a thick layer of adipose tissue that it seemed to prevent refrigeration of the external surface from affecting in the slightest degree the temperature of the interior of the system. Before antipyrin was resorted to she had a temperature of 105°, with a marked degree of mental hebetude; but under the use of this drug the temperature was quickly brought down, and the sensorium at once cleared up. Altogether, therefore, he thought the remedy was unquestionably worthy of a further test.

Dr. Draper, in closing the discussion, said that he had himself adopted a plan of administration similar to

that suggested by Dr. Wiln in a number of instances. In one case he found that the use of twenty grains of antipyrin twice a day added very greatly to the comfort and welfare of the patient. All that we could say in regard to this remedy at present was, that it was a very efficient means of treating a symptom. But this symptom of hyperthermy was often one of the greatest importance, particularly in typhoid fever, in which the long continuance of an extreme high temperature in itself was an element of no little danger. By keeping this in control, therefore, we were enabled to save the patient's life in a certain proportion of instances.

DR. ALFRED C. POST read a short paper, in which he gave an account of a

NEW OPERATION FOR RUPTURED PERINEUM

which he had devised, and which he believed to be simpler and to provide a firmer perineal body than the operations now in use, while it involved no loss of substance. He acknowledged, however, that the procedure had not as yet been fairly tested, since it had thus far been resorted to in only three cases.

CHICAGO GYNECOLOGICAL SOCIETY.

Stated Meeting, March 20, 1885.

THE PRESIDENT, H. P. MERRIMAN, M.D., IN THE CHAIR.

DR. J. SUYDAM KNOX read a paper entitled

THE INFLUENCE OF CIMICIFUGA RACEMOSA UPON PARTURITION.

After a *résumé* of the medical history of the drug, Dr. Knox gave the results of his clinical observations in one hundred and sixty cases of labor—fifty-seven primiparæ, ninety-three multiparæ,—in which black cohosh had been exhibited. The average duration of the first and second stages of labor, in normal cases, in primiparæ, was seventeen and three hours respectively. Under the influence of black cohosh, the duration of the first and second stages of labor, in the fifty-seven cases observed, was six and one-quarter, and one and three-quarter hours respectively. The average duration of the first and second stages, in normal cases, in multiparæ, was twelve and one hours, respectively. Under the influence of black cohosh, in the ninety-three cases, observed, the average duration of the first and second stages was three hours and twenty-seven minutes respectively.

From these clinical observations, Dr. Knox drew the following conclusions:

1. Cimicifuga has a positive sedative effect upon the parturient woman, quieting reflex irritability,—nausea, pruritus, and insomnia, so common in the last six weeks of pregnancy, are always rendered less distressing, and often disappear under its administration.

2. Cimicifuga has a positive antispasmodic effect upon the parturient woman. The neuralgic cramps, and irregular pains of the first stage of labor are ameliorated, and often altogether abolished. In fact during the first indiscriminate use of the drug in all cases, I had the mortification, with a few women, of terminating the labor so precipitately, and without prodromic symptoms, as to be unable to reach the bedside before the birth.

3. Cimicifuga relaxes uterine muscular fibre, and the soft parts of the parturient canal, by controlling muscular irritability, thus facilitating labor, and diminishing risks of laceration.

4. Cimicifuga increases the energy and rhythm of the pains in the second stage of labor.

5. It is my belief that cimicifuga, like ergot, maintains a better contraction of the uterus after delivery.

It is my habit, however, to administer from fifteen to thirty minims of the fluid extract of ergot after the birth of the fœtal head, and I have had but few opportunities of testing this effect of the cohosh.

My method of administration has been to give fifteen minims of the fluid extract of cimicifuga in compound syrup of sarsaparilla each night for four weeks before the expected confinement.

One fluidounce of the fluid extract of cimicifuga to three fluidounces of compound syrup of sarsparilla,—dose, one teaspoonful,—makes just the required quantity.

DR. PHILIP ADOLPHUS had employed the cohosh in the manner indicated by Dr. Knox, in one case with negative results.

DR. EDWARD WARREN SAWYER thought the results obtained by Dr. Knox were astonishing. He thought there could be no doubt that the drug had the physiological action to which allusion has been made. He would at once act upon the suggestion in his private practice.

DR. W. W. JAGGARD thought that if the influence upon parturition, so clearly sketched by Dr. Knox, was capable of demonstration, he could agree with Dr. Sawyer's panegyric. Dr. Knox's carefully prepared paper was worthy of study and investigation. Dr. H. Webster Jones, formerly a prominent obstetrician in Chicago, had advanced similar views with reference to the physiological action of black cohosh, in a paper published in the *Transactions of the Illinois State Medical Society*, a few years since. Dr. Jones's advocacy of the drug as an oxytocic was well known to every practitioner in the city.

DR. JAGGARD desired to call the attention of the Fellows to the following subjects in Dr. Knox's paper.

1. Dr. Knox had stated that the average duration of the first stage of labor in primiparæ and multiparæ was respectively seventeen and twelve hours; under the influence of black cohosh the duration of this stage was abbreviated to six and one-quarter, and three hours, respectively. It was a matter of extreme difficulty to define the limits of the duration of the first stage of labor with such mathematical accuracy. The "personal equation" assumes great importance as a possible source of error. The subjective signs and physical exploration are not always sufficient to justify the diagnosis of the commencement of labor. Thus Dr. R. Lumpe (*Archiv fur Gynækologie*, 1883, Bd. xxi. Hft. i. p. 29) concludes, from the observation of several hundred primiparæ, that the cervical canal begins to dilate from eight to fourteen days before the expulsion of the child. Other observers assign a period of much briefer duration than the typical seventeen hours of Spiegelberg, to which Dr. Knox alluded.

Apart from the difficulty in the determination of the commencement of the first stage, the duration is capable of infinite, individual variation.

II. One hundred and sixty cases were insufficient to warrant such positive deductions upon an intricate therapeutical problem. In every one of the cases cited by Dr. Knox, it was clearly indeterminate whether or no the effect was *post hoc* or *propter hoc*.

Black cohosh had been employed on an extensive scale in large lying-in hospitals in Germany. Every condition for accurate clinical observation had been supplied. Such conditions were: competent observers, numerous cases, under absolute control for a sufficient period of time, chemical purity of the drug, and an approximately perfect system of keeping records. Up to the present time results had been of a purely negative character. It was true that Schatz had reported favorably as to the action of the drug in the treatment of certain pathological conditions of the uterus. Dr. Jaggard did not wish to be understood as dogmatically condemning the drug. The evidence in favor of its action as an oxytocic, as collected from experiments upon the lower animals or from clinical observation, was insufficient to warrant the positive conclusions of the author of the paper. The subject was worthy of further investigation.

III. He thought the practice of the exhibition of ergot before the completion of the second stage of labor was reprehensible. It was in conflict with the obstetrical principles of the day, as deduced from clinical experience and the nature of the case. This remark was applicable exclusively to physiological labors.

Dr. Charles Warrington Earle had used black cohosh, at the suggestion of Dr. Jones and Dr. Knox, in a variety of cases with negative results. He had about the same number of precipitate labors as occurred in his practice prior to the introduction of the drug. It was possible that he had not employed doses of sufficient size, nor for a sufficient length of time before labor.

Dr. Henry T. Byford wished to enter a protest against all methods of rendering the process of labor shorter. Quick labors were wrong labors as a rule.

Dr. George M. Chamberlain had no experience with black cohosh, but he was opposed to the exhibition of ergot before the expulsion of the child in physiological cases.

Dr. Knox closed the discussion. In reply to Dr. Jaggard, he said that the results of his clinical experience with black cohosh were of such a convincing character that he would continue the exhibition of the drug in the future. In regard to the exhibition of ergot before the expulsion of the child, he did it to save time. The drug was not absorbed until twenty minutes after exhibition, and long before the expiration of that time the child was born. He could not spare the twenty minutes required to secure retraction of the uterus after delivery of child and placenta. In reply to Dr. Byford, he said that, at the present day, there were no physiological labors. Women were not Eves. By the judicious use of a drug, like black cohosh, labor was made to resemble the ideal, physiological process, as still observed among savages.

The Secretary then read the inaugural thesis of Dr. Edmund J. Doering, entitled

SOME REMARKS ON THE VALUE OF PERMANGANATE OF POTASSIUM IN AMENORRHŒA.

After a brief description of the physical and chemical characters of the drug, Dr. Doering discussed its physiological action. Bartholow, who has great faith in the drug, claims that although it parts with its oxygen with great readiness, this readiness is *not* sufficiently great to prevent the distribution of this gas into the blood. "His opponents deny this and argue that the organic matter contained in the stomach and mucous membrane is sufficient to appropriate the oxygen of the salt and thus prevent its entrance into the circulation."

Prof. N. Gray Bartlett, a Chicago chemist, gives the following opinion:

"From the readiness with which the permanganate of potassium is decomposed by organic compounds, it would seem to be ineligible for internal use. When so administered, it is immediately brought into contact, in the stomach, with a relatively large amount of organic matter and must necessarily be very rapidly destroyed, the manganese of the permanganate separating, in all probability, in the form of the hydrated manganese dioxide. The latter compound is an active oxidizing agent, and is possibly capable of exercising in the economy the oxidizing function which has been ascribed to the permanganate of potassium. It would seem rational, therefore, anticipating the change which follows the administration of the permanganate, to substitute the hydrated dioxide of manganese, which can readily be prepared in a state of purity for medical use.

"Whatever view may be adopted as to the chemical change which the permanganate undergoes in the human economy, the main question is as to its therapeutic value."

Prof. T. Gaillard Thomas, in his address to the New York State Medical Association, expresses faith in the value of the drug as an emmenagogue. Dr. Ringer and Dr. Murrell recommend the remedy. Dr. Doering had given the drug a careful trial in thirty cases of amenorrhœa, depending upon anæmia and general atony of the sexual apparatus. In about half the cases the observations were unsatisfactory from various causes —*i. e.*, inattention to the general directions, want of perseverance in taking the medicine, so that the conclusions arrived at were based upon fourteen cases, in each of which the cause of the amenorrhœa was entirely clear, the remedy carefully and continuously given, and the effect clearly observed.

The cases were tabulated conclusions:

I. Permanganate of potash in doses of from two to four grains is an efficient emmenagogue, if administered for a period of not less than two weeks.

II. Its administration in doses large enough to be effective, is accompanied by severe pain which frequently necessitates a discontinuance of the remedy, and, hence, impairs its value as an emmenagogue.

III. The most efficient method of administering the drug is in capsules, taken midway between meals and followed by large draughts of some pure mineral water, like Silurian.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 24, 1885.

The President, R. F. Weir, M.D., in the Chair.

Dr. A. C. Post presented a patient who had a

GANGLION OF THE WRIST,

which he had treated by puncture and evacuation of the contents, and whose case he had already reported

to the Society about one month ago. There remained only a slight hardness in the situation of the swelling. It was possible that there was a slight reaccumulation of fluid, and it might be necessary to resort to further operative procedure.

Dr. Post also presented a patient on whom he had performed an operation for

HYPOSPADIAS

on the third of February, 1885. The patient was over thirty years of age, the floor of the urethra was deficient to the extent of about two centimetres behind the corona glandis. The operation consisted in making a perineal incision into the membranous part of the urethra, and introducing a short catheter into the bladder, and then dissecting a flap of integument four-fifths of an inch wide on the lower surface of the penis, extending back nearly to the scrotum, and denuding a space two-fifths wide on each of the flaps and extending them forward on the under surface of the glans. The flap was then doubled on itself and drawn forward as far as the glans, and its edges attached by fine sutures to the outer edges of the denuded spaces. The deep layer of the doubled flap, which was designed to form the floor of the urethra, was not attached by sutures, but left to attach itself. The wound was washed with a solution of mercuric bichloride, 1 to 1000, and dusted with iodoform. To take off the tension from the base of the transplanted flap, a V-incision was made behind the base of the flap, the triangular flap of skin dissected up from its base, and the sides of the triangle drawn together with sutures, converting the V into a Y. The wound healed perfectly, and the floor of the urethra was thus extended forward beyond the corona glandis. The catheter was withdrawn from the perineal wound within a fortnight after its introduction, and the patient passed his urine freely through the reconstructed canal. Within a very few days the wound of the perineum was entirely healed.

The PRESIDENT asked Dr. Post if he did not attribute the success in a great measure to the perineal opening.

DR. POST replied that he did.

DR. J. L. LITTLE asked if there was any marked curvature of the penis.

DR. POST answered, "No, sir; there was only a slight tendency to curvature."

The PRESIDENT said that the marked curvature of the penis did not usually take place unless the opening in the urethra was further back.

DR. MCBURNEY said it was noticeable that a prominent author on genito-urinary diseases had stated that to make an opening in the perineum like that resorted to by Dr. Post is adding a major operation to a minor one. It has always seemed to Dr. McBurney as being absurd to make such a criticism on the perineal opening, as it was a simple operative procedure, and the opening was one which readily closed.

THE PRESIDENT said he had had occasion to open the perineum five times in the treatment of anterior fistulas by plastic operations, and in no instance was there any failure in the rapid spontaneous closure of the perineal opening for other genito-urinary troubles, and in no instance was any risk to the patient added by the operation.

DR. MCBURNEY had had one patient with extensive fistulous opening in the urethra which required four operations for its cure, and in that instance he made an opening in the perineum which closed after each operation upon the urethra, so as to make it necessary to reopen it each time before doing the next operation.

THE PRESIDENT said that within a few months he had closed in one patient three openings in the normal urethra from tertiary ulceration situated in the corona glandis. The operation consisted of vivifying the edges of the fistulas after making a perineal opening. The broad, freshened edges of the prepuce and inferior surface of the glans were sewed up with several rows of catgut sutures, and in this manner a perfect success was obtained. He thought the multiple rows of fine catgut sutures, as well as the perineal opening, contributed to the good result.

DR. LITTLE remarked, with reference to Dr. Post's case of ganglion of the wrist, that it seemed to him the sac was beginning to refill. He had had a similar case under treatment in which the swelling extended above and below the wrist, and in which he made a free incision, and followed it by the application of a compress for some time, and it seemed to be entirely cured. Subsequently, however, the patient came under observation, and it was found that the sac had refilled, and Dr. Little made a second incision. The tumor was a kind of double swelling, and contained the fluid ordinarily seen in ganglia, with the exception that he did not find any of the so-called rice bodies.

DR. POST said that if the sac in his case should refill he should make a more free opening and treat it as an open wound.

CARCINOMA OF THE PAROTID; SUCCESSFUL REMOVAL OF THE ENTIRE GLAND.

DR. L. A. STIMSON presented a patient, a man sixty-four years of age, from whom, twenty days previously, he extirpated the parotid for carcinoma. The growth made its appearance four years ago, and of late had increased in size rather rapidly, and when the patient came under observation the tumor involved the skin to the extent of about one and one-hal inches by two inches.

Dr. Stimson brought the case before the Society, first, because complete extirpation of the parotid is said by some writers to be too hazardous to be undertaken. In this instance there was no difficulty in removing the gland, and the only vessel of much size which was divided and ligated was what seemed to be the temporal branch of the external carotid, the bifurcation into it and the internal maxillary appearing to be much lower than usual.

Of course, there was complete facial paralysis. The entire gland was involved in the tumor, except at the deeper part, where it seemed to be healthy. The growth had invaded the sterno-cleido-mastoid muscle just below the mastoid process.

At the close of the operation, Dr. Stimson was able to cover the entire wound by a skin-flap, and at the end of a week it had all healed except at the orifice of the drainage-tube; but during the second week it became evident that the deeper upper part of the cavity left by removal of the gland had not closed, and that is now present as an opening about one-third of an inch in

depth, running up in front of the mastoid process. There was also another point low down under the chin, which marked the position of a defective suture where the borders of the incision had not united. At the same time, the wound has remained practically without pus. It was treated by irrigation and bichloride solution during the operation, and dressed with iodoform afterward.

In reply to a question, Dr. Stimson said that the tumor superficially was movable, but the deeper posterior and upper portion was very firmly adherent.

ABNORMALITY OF THE INTERNAL CAROTID ARTERY.

In making a dissection before the operation, Dr. Stimson encountered a peculiarity of the internal carotid artery, which consisted in an S-shaped fold or turn, about one inch above the bifurcation, which drew the artery into a loop three-fourths of an inch across, placed transversely in the neck, so that the upper portion of the loop was three-fourths of an inch superficial to the line of the artery itself.

PARALYSIS OF THE TRAPEZIUS, SERRATUS MAGNUS, AND RHOMBOIDEI.

Dr. Stimson also presented a patient, a man thirty-two years of age, who had always been healthy until the present trouble, which began five months ago with pain in the right side of the neck, followed by difficulty steadily increasing in the use of the right arm and inability to raise the hand to the head, which is now very marked, and with which there is inability also to use the shoulder, especially in bringing it forward. He can raise the arm to the horizontal line, but no further; and when he does so, or when he presses with the raised hand against an object in front, the vertebral border of the scapula becomes very prominent, and the soft parts between it and the spine are deeply depressed to fill the space left between the scapula and the wall of the chest. The line running from the point of the shoulder to the side of the head, formed by the trapezius, is much less full and prominent than on the other side. The deltoid and scapular muscles seem normal, and the inability to raise the hand to the head appears to be due to weakness of the upper fibres of the trapezius.

Recalling the patients whom Dr. Gerster presented to the Society some time ago, he had presented the man partly that the Society might have the opportunity to see him, and partly to obtain a diagnosis. The muscular reaction had been tested by some neurologists with electricity, and the patient had been told that there was marked degeneration of the rhomboid muscle and of the trapezius, but not of the serratus magnus, and that the reaction was not that of degeneration.

The question in Dr. Stimson's mind was, What muscles are at fault, and what is the cause of the paralysis?

The posterior border of the scapula is held down to the chest not by the action of the serratus magnus alone, but by the conjoined action of the posterior fibres of the trapezius, the rhomboidei, and the serratus magnus, and, therefore, when either one of these muscles is paralyzed, the border of the scapula can leave the chest; and the question therefore arises, Which of them, in the present case, is affected, or are all? The levator anguli scapula seemed to be perfect. There was no specific history, and there was no wasting of the muscles of the hand, as might be expected in progressive muscular atrophy; nor was there any history of traumatism.

Dr. Gerster had seen a somewhat similar case in an adult girl after dislocation of the shoulder-joint, in which instance there was paralysis of the serratus magnus on the injured side, due to traumatism accompanied by paralysis of almost all the muscles surrounding the shoulder-joint, a complication which, according to Busch, of Bonn, was not at all uncommon.

Dr. Post remarked that it was hardly conceivable that any single muscle should be paralyzed by itself, unless it was supplied by a single nerve, which distributed branches to no other muscle, as in the case of the fourth and the sixth cerebral nerves.

Dr. McBurney presented a patient upon whom he had performed

EXCISION OF THE KNEE-JOINT.

Henry J., thirty five years of age, a coachman, was admitted to the hospital May 19, 1884. The patient's family history was good; his previous health had been excellent, and there was no history of venereal disease. Four years ago he slipped and struck his left knee, and was laid up for four days. Two years after this the knee became swollen, and the leg was fixed upon the thigh at an angle of forty-five degrees, which lasted for two weeks. There was then an interval of eighteen months, in which the knee seemed to be nearly well. Six months ago the knee began to swell, and to be painful, and three and a half months ago an incision was made, from which pus discharged very freely. Since that date four additional openings in the thigh and leg had been made for the evacuation of pus. Last May Dr. McBurney found the patient with a general suppurating joint, eroded cartilages, sinuses burrowing in every direction through the thigh and leg, and almost down to the ankle-joint, separating the muscles of the calf. He performed complete excision and removed all the joint structures, and thoroughly curetted all the sinuses. The dressings from the date of operation to July 15th were changed as occasion demanded. On August 30th, the sinuses on the anterior and posterior surfaces of the limb were laid open, and again, also, on October 2d, sinuses on the outer side of the leg were laid open and curetted. On November 26th, there was excellent bony union; the foot was in a state of talipes equinus. On February 23, 1885, there was a small sinus, not leading to bone, on the anterior surface of the limb, which, on March 24th, had been healed for some weeks.

The result was a shortening of the limb of not quite three inches, with bony union, which was found to be complete six months after the operation. The bone was treated without either wire, or nails, or other apparatus, except an external apparatus to obtain apposition of the fragments, a method which Dr. McBurney thought possessed advantages. The incisions through the bone were straight. There remained some paralysis of the flexors of the foot which also existed before the operation. The result was not a handsome leg, but Dr. McBurney thought it was much better than a wooden one.

He had performed excision of the knee-joint in nine cases, and in all union had taken place rapidly, the

longest period being six months after the operation, and the shortest six weeks, in the case of a child.

He had had another case in which union took place, and in which he did not use either wire or nails, but simply an outside splint, and the result was satisfactory. Concerning a third case treated in this manner, he was unable to report.

Other things being equal, it was desirable to avoid the introduction through bones of substances which where not absolutely essential.

Dr. Post remarked that the evil resulting from the introduction of wires was not very formidable.

Dr. McBurney remarked that the results were not very serious, but at the same time he had seen prolonged discomfort, considerable pain, and suppuration resulting from the presence of such foreign bodies, and unless the advantage attending the presence of the wire or nails was very compensating, he thought they had better not be used. This was an important point which could, however, only be decided by further experience. In a case like the one just reported, which was the worst he had ever seen, he thought the result was in favor of not using wire to hold the surfaces in apposition.

Dr. Gerster thought that the question could not be decided so simply as this. He believed that there were cases in which the use of wires and nails was not necessary, whereas they might be in some cases essential to get good apposition of the fragments. For instance, if the surgeon had to deal with a fat or very muscular subject, where the fixation of the resected joint in the splint was more difficult than in lean individuals. He had not wired many bones, but he had used nails in six or seven cases—two of exsection of the knee-joint, two in the performance of Mikulicz's operation, and after a number of necrotomies—and had found them exceedingly useful and non-irritating. In the first case of knee exsection, the nails had not been disinfected properly, some suppuration took place, and tuberculous granulations sprung up which rendered revision of the knee-joint necessary, and on laying open several sinuses and removing the granulations, the wounds healed, excellent bony union of the same surfaces had taken place almost immediately after the operation. In other cases no reaction followed the use of nails, and as soon as the nails were withdrawn the tracts closed up without suppuration. Dr. Gerster thought the trouble experienced in the removal of nails was far smaller than from the use of wire, but that their proper disinfection was essential.

Dr. Little asked how long the nails were allowed to remain.

Dr. Gerster replied that it depended upon circumstances. He had left them in as long as four weeks. The nails need not do any harm, as they are no more irritating than so much clean silver wire.

The President remarked that the nails certainly added firmness to the limb, and were easily removed.

Dr. McBurney agreed with Dr. Gerster with regard to the use of nails and wires, but he thought there were few cases in which exsection of the knee or shoulder was demanded in the fat subject. Of course, the operation might be demanded in some cases of traumatism, but the point was not whether nails could be borne without causing irritation, but whether nails were necessary. That they could be borne, there was no question whatever; but, on the other hand, there were cases not infrequently, in which the bone was so disorganized, and abscess cavities were so large, that practically there was not sufficient bone left in which the nail could enter and be of any service.

Dr. Yale said that he had seen one of Dr. McBurney's cases in which he thought that neither nails nor wire would have held the bone together.

Dr. McBurney remarked that it was a case of this character which first led him to try to keep the bony surfaces in apposition without any special kind of retentive apparatus.

Dr. Stimson said that there was another question of importance in the treatment of these cases, laying aside the question of how much benefit either wire or nails afforded. It was well known that the bone encountered in excision was not tough strong tissue, but was spongy, could be readily broken down with the gimlet, and that whatever instrument was used for making the holes for inserting the wires or nails usually made a hole much larger than itself.

The leg and thigh together constitute a very long, heavy body, and any lack of support of the foot will produce a change of angle at the section unless the union there is stronger than that furnished by a nail driven into the spongy bone, as he had seen it, was likely to be. The same was true of wires; those which are used are ordinarily not strong enough to stand any heavy strain, such as can be given by partial weight of the foot, but even if they were, the bone through which they pass is rapidly absorbed about them. In his own last case, one yielding an excellent result, the wire loops promptly became loose and feel out spontaneously.

Dr. Stimson thought that the result desired which could not be obtained with wire could be obtained by attention to one point in the dressing, that is, to support the limb with the heel considerably higher than the buttock in a splint which does not take hold of the limb below the knee, and thus allow the thigh to sink away from it. If this method is observed, simply lifting the limb and placing it upon a posterior splint, gravity keeps the leg in apposition with the thigh, and all that the wires can do in addition is to keep the segments from being rotated one upon the other. The simple action of gravity alone will keep the two cut surfaces of bone in contact, unless the limb is so suspended that the leg alone is fixed and the thigh allowed to sag away from it. The limb should lie loose on a posterior splint, a gutter, so that the leg can follow the thigh as the buttock sinks in the bed.

The President said that he must, however, add that from his experience the introduction of nails did stiffen up the divided bones.

Dr. Sands said that his experience in the use of nails in excision of the knee was limited to two cases. The first was that of a man upon whom he performed the operation a little more than one year ago, employing three nails, which from his lack of experience were not very skilfully introduced. One of the nails which was driven in the median line from below upwards, penetrated so near the popliteal space that, as a matter of precaution, it was removed on the second day. The other nails were allowed to remain two weeks, when being found quite loose they were removed.

The other case was one in which he had excised the knee-joint two weeks ago. It was one of white swelling

of an aggravated character, occurring in a girl sixteen years of age, with very extensive abscesses and sinuses running up to the middle of the thigh as well as down the leg. He introduced three nails in the usual manner, and although the osseous tissues were somewhat soft, considerable force was required to insert them. Dr. Sands was satisfied that the mechanical advantage derived from their use in this instance was very great. It became necessary to dress the wound forty-eight hours after the operation, and three dressings had since been made on account of the soiling of the bandages. While changing the dressings the advantage of using the nails was shown in the fact that the limb could be readily lifted without disturbing the apposition of the sawn surfaces, and at the present time, two weeks after the operation, the nails had not loosened their hold. His own inclination would be to use nails in preference to wire, and if they could be shown to be harmless, as it seemed to have been demonstrated, they should be tried as a means of getting better apposition than could be obtained by the use of external splints, they would also appear to be particularly useful in a case like this one, in which frequent dressings were required.

Dr. Gerster asked Dr. McBurney how he treated the abscesses situated about the knee-joint.

Dr. McBurney replied that they were all freely laid open and curetted; that they were heavily lined with granulations, and they were as thoroughly scraped as possible, after which they were thoroughly irrigated by bichloride solution, and, wherever possible, were packed full with iodoform gauze. Some of them required several scrapings; but, as far as possible, they were laid open at the first operation.

The President remarked that he was very much impressed with the treatment of such sinuses which he saw at Kiel, at Esmarch's clinic, where they were laid open and dissected out and sutured together with deep catgut sutures, after which they healed promptly.

Dr. Gerster said that he raised the question for the purpose of referring to what he regarded as a widespread error. It had been said that if drainage-tubes were used after exsecting tuberculous joints, and were left in for a certain length of time, persistent and troublesome sinuses would remain behind as a consequence of the use of the drainage-tubes. This seemed to him to be erroneous, since he thought that any sinus kept open by a drainage-tube, whose walls were in a healthy condition, would close up almost immediately after removal of the tube. If a sinus did not close up, it was due to the fact that it was lined with granulations of a specifically morbid character, containing tubercle bacilli, whose granulations are prone to decay and lack the tendency to form cicatricial tissue. The form of treatment referred to by Dr. McBurney was the only proper one, and removal of the entire capsule and all the tuberculous, viz., cheesy and gelatinous, tissues about the joint was essential to a speedy and thorough cure. In Germany all these foci were methodically removed as if they were malignant disease, the entire capsule was excised, and in almost all cases the operation wound healed by primary union. He had seen seventeen cases in Kiel in which this had taken place. Whenever such diseased tissues were left behind, a relapse of the tuberculosis was established, and generally all the remaining healthy parts of the granulating wound were again infected.

Dr. Briddon said that he had seen three cases illustrating this condition within the last two or three months. In one there was a sinus nearly in front of the head of the humerus, which was opened and scraped out thoroughly. It contained tuberculous tissue. The cavity was filled with iodoform, a bone-drain was introduced, and the operation wound required only one dressing afterward. The sinus healed completely, and all the motions of the shoulder-joint were restored within one month. In another case the sinus was in a similar condition, and was treated in the same way with the same good result. Both of these cases occurred in children, and the first dressings were removed at the end of two weeks. In another case of tuberculous disease of the knee-joint all the granulations were removed from the deep recess of the sinuses, and three bone-drains were introduced. When the dressings were removed, at the end of thirty days, it was found that union had not taken place, and it was doubtful whether it would ever occur.

Dr. J. C. Hutchison then read a paper entitled

TWO CASES OF LIGATURE OF THE COMMON CAROTID ARTERY FOR TRIGEMINAL NEURALGIA.

(See page 394.)

Dr. Post remarked that one important point brought forward by the reader of the paper was the influence of dampness on neuralgic affections. He believed it had been shown that change of climate exerted a powerful influence on such affections, especially going from a dry to a damp climate. This miner had a recurrence of his difficulty after returning to his occupation. Dr. Post regarded this as an important point with reference to the treatment of these forms of neuralgia.

MULTIPLE RUPTURE OF THE ILEUM.

The President presented a specimen which showed the possibility of laparotomy in abdominal injuries. An employé of the elevated railway got caught between two cars and was severely jammed. The immediate effects were not specially prostrating, as the patient walked from the Chatham Street Station to the Grand Street Ferry, also three or four blocks on the other side of the river before reaching his home. When he arrived he complained of considerable pain in the abdomen, and called a physician. This occurred on a Sunday. With the exception of some increase in the frequency of the pulse and tenderness of the abdomen, the patient did very well until Wednesday evening, when he began to vomit. After a very short time the vomiting became stercoraceous, and the physician in attendance, supposing that he had to do with obstruction, administered a very large enema, which was followed by a great deal of pain, and the patient's condition rapidly grew worse. Dr. Weir was asked to see him on Thursday evening, and to be prepared to perform laparotomy, but on his arrival the man had been dead about two hours.

The autopsy was held three hours after death. There was a sharply outlined ecchymosis stretching across the belly just below the umbilicus. It was found that the contusion had torn apart the fatty tissues to the extent of four or five inches on each side of the median line,

but that the muscular tissues had not been torn except a very few fibres, and that there were several blood extravasations under the peritoneum, which, however, was not torn. The ileum at the distance of nearly two feet from the cæcum bore marks of injury, consisting in three lacerations, and between two of these openings for a distance of six inches there was a mass of gangrenous gut, from the damage done apparently to the mesentery. Around this there was some fecal extravasation, bound in generally by recent adhesions. At one place there was apparent giving away of this limitation of inflammatory product, and there a slight extravasation of fecal matter toward the loin on that side had taken place.

It was a case which had it been seen earlier, and the abdomen opened, would have offered a very good chance for a successful issue, as the injury was limited, and up to Wednesday evening the patient was in a fair condition.

Dr. Sands asked if there were any signs by which a diagnosis could have been made early.

The President replied that the appearance of the symptom of vomiting, conjoined with the history of the case, would have warranted the surgeon in making an exploratory incision.

NEWS ITEMS.

Cholera Precautions in Illinois.—In connection with the Sanitary Survey of the State and House-to-house Inspection, now being prosecuted under direction of the State Board of Health with reference to the probable appearance of Asiatic cholera in this country, the Board has just issued circular-letter No. 6, addressed to county clerks, and requesting that the work of getting public institutions into good sanitary condition be completed with as little delay as possible. Much work of this character was done during the past summer and fall, in response to the circular-letter of the Board issued in July last. But, in addition to what remained to be done when cold weather suspended operations, there must since have accrued, in many cases, accumulations of filth and refuse which should now be promptly removed; defects in plumbing, drainage, and sewerage, disclosed during the winter, should be repaired; and the effects of the occupancy of dormitories, workshops, wards, cells, and other apartments should be remedied by a thorough spring cleansing.

The officers in charge of almshouses, jails, and all other public buildings under the control of the County Board, are notified to commence this work at once.

Especial attention should be given to the location and condition of privies and water-closets at these places, as also at court houses and elsewhere. Vaults should be emptied before warm weather makes such work dangerous, and then be thoroughly disinfected with sulphate of iron (copperas). Where these vaults are within fifty feet of any source of water-supply—well, spring, pond, lake, or running stream—their further use should be abandoned, and, after being emptied, they should be disinfected and filled up with clean, dry earth—one of the best disinfectants. The new vault should not be less than fifty feet from the nearest water-supply; should be water-tight; ventilated by a four-inch shaft, opening above the roof; the contents should be kept inoffensive by the use of some cheap disinfectant; and the building and its surroundings should be kept in the cleanest attainable condition. Where practicable, the substitution of the earth-closet system for the subterranean vault-storage is recommended. In either case the frequent removal of the contents, and their safe disposal, by use as fertilizers, are necessary sanitary measures.

The source of water-supply, and its storage and distribution, should be carefully inquired into, and all possible causes of pollution should be removed. A pure water-supply is of the first importance to health under all circumstances; but among numbers of persons living under the conditions which obtain in county institutions, its importance is increased. Epidemics of diarrhœa and dysentery may be caused by impure water; while typhoid fever and Asiatic cholera are spread more commonly through the water-supply than in any other way.

These remarks and suggestions will indicate the character of the work which the Board considers it desirable should be accomplished before warm weather sets in, not alone through fear of cholera, but in the interest of public health, and, consequently, of true economy.

A similar circular was recently issued to railroad managers, setting forth that the spread of Asiatic cholera is due oftener to the pollution of the water-supply than to any other one cause. There is no commoner mode of such pollution than through foul, badly constructed and improperly located privies and water-closets. The disease, in this country, being always due to importation, and its spread being, most commonly, by persons travelling from place to place, it follows that railway privies and water-closets are especially exposed to the danger of cholera infection. In view of these facts, it is requested that all such places in connection with stations, freight houses, shops, and round-houses be at once inspected and put in good sanitary condition.

Responses have been received from nearly all the roads, and one of the most important lines has already completed the work indicated along the entire extent of its road.

The International Medical Congress, Washington, 1887.—The Committee on Organization of each Section is composed of the President, the Vice-Presidents, and Secretaries of the Section, and of the Council. The list of the officers was published in our issue of last week. The following are announced as the members of the several Councils.

Section I.—Medical Education, Legislation, and Registration.—*Council:* Nathan S. Davis, M.D., LL.D., of Chicago; Henry D. Didama, M.D., of Syracuse, N. Y.; Henry Gibbons, M.D., of San Francisco; Daniel C. Gilman, LL.D., President Johns Hopkins University, of Baltimore; James F. Harrison, M.D., of University of Virginia; Charles A. Lindsley, M.D., of New Haven, Conn.; William Pepper, M.D., LL.D., of Philadelphia; J. F. Prioleau, M.D., of Charleston, S. C.; John H. Rauch, M.D., of Springfield, Ill.; L. McLane Tiffany, M.D., of Baltimore.

Section II.—Anatomy. *Council:* Harrison Allen, M.D., of Philadelphia; Frank Baker, M.D., of Washington; Thomas Dwight, M.D., of Boston; Francis L.

Parker, M.D., of Charleston, S. C.; Charles T. Parkes, M.D., of Chicago; Thomas T. Sabine, M.D., of New York; Nicholas Senn, M.D., of Milwaukee; Francis J. Shepherd, M.D., of Montreal; Robert W. Shufeldt, M.D., of U. S. Army; Burt G. Wilder, M.D., of Ithaca, N. Y.

Section III.—Physiology. *Council:* G. Baumgarten, M.D., of St. Louis; Henry G. Beyer, M.D., of U. S. Navy; Henry P. Bowditch, M.D., of Boston; Henry F. Campbell, M.D., of Augusta, Ga.; Austin Flint, Jr., M.D., of New York; William Lee, M.D., of Washington; John J. Mason, M.D., of Newport, R. I.; S. Weir Mitchell, M.D., of Philadelphia; Henry Sewall, M.D., of Ann Arbor, Mich.

Section IV.—Pathology. *Council:* Christian Fenger, M.D., of Chicago; Reginald H. Fitz, M.D., of Boston; Edward G. Janeway, M.D., of New York; James B. Johnson, M.D., of St. Louis; Thomas E. Satterthwaite, M.D., of New York; George M. Sternberg, M.D., of U. S. Army; James Tyson, M.D., of Philadelphia; William F. Whitney, M.D., of Boston.

Section V.—Medicine. *Council:* Samuel C. Chew, M.D., of Baltimore; William H. Draper, M.D., of New York; William H. Geddings, M.D., of Aiken, S. C.; William W. Johnston, M.D., of Washington; George A. Ketchum, M.D., of Mobile; Francis Minot, M.D., of Boston; William Pepper, M.D., LL.D., of Philadelphia; Beverley Robinson, M.D., Andrew H. Smith, M.D., of New York; James T. Whittaker, M.D., of Cincinnati.

Section VI.—Surgery. *Council:* John Ashhurst, Jr., M.D., of Philadelphia; David W. Cheever, M.D., of Boston; Phineas S. Conner, M.D., W. W. Dawson, M.D., of Cincinnati; George E. Fenwick, M.D., of Montreal; Frederic H. Gerrish, M.D., of Portland, Me.; J. C. Hutchison, M.D., of Brooklyn; Christopher Johnston, M.D., of Baltimore; Levi C. Lane, M.D., of San Francisco; Thomas M. Markoe, M.D., of New York; Alan P. Smith, M.D., of Baltimore; J. Ford Thompson, M.D., of Washington; Theodore R. Varick, M.D., of Jersey City; Samuel B. Ward, M.D., of Albany, N. Y.; Robert F. Weir, M.D., of New York.

Section VII.—Obstetrics. *Council:* Robert P. Harris, M.D., of Philadelphia; Alfred F. A. King, M.D., of Washington; William T. Lusk, M.D., of New York; Matthew D. Mann, M.D., of Buffalo; Theophilus Parvin, M.D., of Philadelphia; John Scott, M.D., of San Francisco.

Section VIII.—Gynæcology. *Council:* William H. Baker, M.D., of Boston; William Gardner, M.D., of Montreal; William Goodell, M.D., of Philadelphia; A. Reeves Jackson, M.D., of Chicago; J. Taber Johnson, M.D., of Washington; George H. Lyman, M.D., of Boston; Emil Noeggerath, M.D., T. Gaillard Thomas, M.D., of New York; Ely Van de Warker, M.D., of Syracuse, N. Y.

Section IX.—Ophthalmology. *Council:* Cornelius R. Agnew, M.D., Charles S. Bull, M.D., of New York; Swan M. Burnett, M.D., of Washington; A. W. Calhoun, M.D., of Atlanta, Ga.; Hasket Derby, M.D., of Boston; Samuel J. Jones, M.D., of Chicago; Herman Knapp, M.D., Edward G. Loring, M.D., of New York; William F. Norris, M.D., of Philadelphia; W. W. Seely, M.D., of Cincinnati; Samuel Theobald, M.D., of Baltimore; Oliver F. Wadsworth, M.D., Henry W. Williams, M.D., of Boston.

Section X.—Otology. *Council:* Albert H. Buck, M.D., of New York; John Green, M.D., of St. Louis; J. Orne Green, M.D., of Boston; Stephen O. Richey, M.D., of Washington; Daniel B. St. John Roosa, M.D., LL.D., Samuel Sexton, M.D., of New York; George Strawbridge, M.D., of Philadelphia.

Section XI.—Dermatology and Syphilis. *Council:* I. Edmondson Atkinson, M.D., of Baltimore; L. Duncan Bulkley, M.D., Edward L. Keyes, M.D., Fessenden N. Otis, M.D., Robert W. Taylor, M.D., of New York; Edward Wigglesworth, Jr., M.D., of Boston; Henry C. Yarrow, M.D., of Washington.

Section XII.—Nervous Diseases and Psychiatry. *Council:* Roberts Bartholow, M.D., LL.D., of Philadelphia; Allen McLane Hamilton, M.D., of New York; Walter Hay, M.D., LL.D., of Chicago; Francis T. Miles, M.D., of Baltimore; James J. Putnam, M.D., Samuel G. Webber, M.D., of Boston; Horatio C. Wood, M.D., of Philadelphia; John P. Van Bibber, M.D., of Baltimore.

Section XIII.—Laryngology. *Council:* F. H. Bosworth, M.D., of New York; William H. Daly, M.D., of Pittsburg; E. Fletcher Ingals, M.D., of Chicago; J. N. Mackenzie, M.D., of Baltimore; George W. Major, M.D., of Montreal; E. Carroll Morgan, M.D., of Washington; William Porter, M.D., of St. Louis; E. L. Shurley, M.D., of Detroit, Mich.

Section XIV.—Public and International Hygiene. *Council:* Henry B. Baker, M.D., Lansing, Mich.; Alfred L. Carroll, M.D., of Albany, N. Y.; Granville P. Conn, M.D., of Concord, N. H.; William H. Ford, M.D., of Philadelphia; Daniel W. Hand, M.D., of St. Paul; Jerome H. Kidder, M.D., of Washington; Charles A. Lindsley, M.D., of New Haven, Conn.; J. N. McCormick, M.D., of Bowling Green, Ky.; J. H. Rauch, M.D., of Springfield, Ill.; Joseph H. Raymond, M.D., of Brooklyn, N. Y.; Joseph R. Smith, M.D., of U. S. Army; Stephen Smith, M.D., S. O. Van der Poel, M.D., LL.D., of New York; H. P. Wolcott, M.D., of Cambridge, Mass.

Section XV.—Collective Investigation, Nomenclature, and Vital Statistics. *Council:* Nathan Allen, M.D., of Lowell, Mass.; Richard A. Cleeman, M.D., of Philadelphia; J. H. Hollister, M.D., of Chicago; Abraham Jacobi, M.D., of New York; James T. Reeve, M.D., of Appleton, Wis.; James Tyson, M.D., of Philadelphia.

Section XVI.—Military and Naval Surgery and Medicine. *Council:* Edmund Andrews, M.D., of Chicago; Delavan Bloodgood, M.D., of U. S. Navy; R. B. Bontecou, M.D., of Troy, N. Y.; John H. Brinton, M.D., of Philadelphia; Julian J. Chisolm, M.D., of Baltimore; P. O. Hooper, M.D., of Little Rock, Ark.; E. J. Marsh, M.D., of Paterson, N. J.; Claudius H. Mastin, M.D., of Mobile; George Peck, M.D., of U. S. Navy; W. F. Peck, M.D., of Davenport, Iowa; Charles Smart, M.D., of U. S. Army; J. Rufus Tryon, M.D., of U. S. Navy; Alfred A. Woodhull, M.D., of U. S. Army.

Section XVII.—Practical and Experimental Therapeutics. *Council:* Robert Amory, M.D., of Boston; Edward Curtis, M.D., Laurence Johnson, M.D., of New York; Henry M. Lyman, M.D., of Chi-

cago; Samuel Nickels, M.D., of Cincinnati; Isaac Ott, M.D., of Easton, Pa.; Daniel Webster Prentiss, M.D., of Washington; Charles Rice, M.D., of New York; Charles H. White, M.D., of U. S. Navy; Thomas F. Wood, M.D., of Wilmington, N. C.

Section XVIII.—Diseases of Children. *Council:* F. Forchheimer, M.D., of Cincinnati; John M. Keating, M.D., of Philadelphia; William Lee, M.D., of Baltimore; John H. Pope, M.D., of Marshall, Texas; John H. Ripley, M.D., of New York.

Section XIX.—Dental and Oral Surgery. *Council:* W. C. Barrett, M.D., of Buffalo; Thomas Fillebrown, M.D., of Boston; F. J. S. Gorgas, M.D., of Baltimore; Edward Maynard, M.D., of Washington; H. J. McKellops, D.D.S., of St. Louis; W. H. Morgan, M.D., of Nashville; C. Newlin Peirce, D.D.S., of Philadelphia; L. D. Shepard, D.D.S., of Boston; James Truman, D.D.S., J. W. White, M.D., of Philadelphia.

The American Surgical Association will hold its annual meeting in the Army Medical Museum, Washington, on April 21st, 22d, 23d, and 24th. The following papers are announced as the programme:

1. The Field and Limitation of the Operative Surgery of the Human Brain. By John B. Roberts, M.D., of Philadelphia.
2. An Experimental and Clinical Study of Air Embolism. By N. Senn, M.D., of Milwaukee.
3. Nephrectomy; its Indications and Contraindications. By Samuel W. Gross, M.D., of Philadelphia.
4. Nephrolithotomy. By L. W. McLane Tiffany, M.D., of Baltimore.
5. The Healing of Arteries in Man and Animals after Ligature. By J. Collins Mann, M.D., of Boston.
6. The Immediate Cure of Fistula in Ano. By Stephen Smith, M.D., of New York.
7. Etiology of Tetanus. By P. S. Conner, M.D., of Cincinnati.
8. A Case of Cholecystotomy. By C. T. Parkes, M.D., of Chicago.
9. Some Points in the Surgery of the Hypertrophied Prostate. By J. W. T. Gouley, M.D., of New York.
10. Phosphorus Necrosis; its Causes, Treatment, and Prevention, with Reports of Cases. By J. Ewing Mears, M.D., of Philadelphia.

State Medical Society Meetings.—The Medical Society of the State of Tennessee meets at Nashville, and the Medical Association of the State of Alabama meets at Greenville, on Tuesday, April 14th.

The Medical Society of California meets at San Francisco, the Mississippi State Medical Association meets at Greenville, and the Medical Association of Georgia meets at Savannah, on Wednesday, April 15th.

The German Surgical Congress met in Berlin on the 8th inst., and the following papers were announced to be read:

1. Bruns (Tübingen), Concerning Cretinism after Extirpation of the Thyroid Body.
2. Vogt (Greifswald), *a*. The Simple Method for the Radical Cure of Hydrocele; *b*. The *Technique* of Gastrotomy.
3. Bidder (Berlin), The Origin and Cure of Intestino-utero-vaginal Fistula.
4. Braun (Jena), The Operative Treatment of Intussusception.

The committee in charge of the organization of the meeting suggest that members of the Congress will on the occasion of the present meeting make known either verbally or in writing their experience concerning the more recent operations for harelip. It is desirable to state:

a. To what extent and how often the palatal bone probably heals.

b. What method of operation gives most favorable final results.

c. And the results of total removal of the palatal bone.

It is also desirable that information be afforded as to the relative condition of adults who were operated upon during childhood by a given method.

It is also proposed to discuss the surgical aspects of tuberculosis.

The Chair of Physiology at the University of Pennsylvania.—At a meeting of the Board of Trustees of the University held on Tuesday last, Dr. Edward T. Reichert, Demonstrator of Experimental Physiology at the University, was assigned to deliver the lectures on physiology during the coming year, pending a vacancy in the professorship of physiology.

Jefferson Medical College, of Philadelphia, held its annual commencement on the 2d instant, and the degree of M.D. was conferred on 176 candidates. The degree of LL.D. was also conferred on Dr. Austin Flint, Jr., M.D.

Obituary Record.—Died in New York on April 4th, of peritonitis, James Lawrence Little, M.D., Professor of Clinical and Operative Surgery in the New York Post-Graduate Medical School, and Professor of Surgery in the University of Vermont. Dr. Little was born in Brooklyn, on February 19, 1836, and studied medicine under the late Dr. Willard Parker, and graduated from the College of Physicians and Surgeons. He served as an army surgeon during the civil war.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 31 TO APRIL 6, 1885.

Gardner, Jno. de B. W., *Captain and Assistant Surgeon.*—Ordered for temporary duty at Fort McHenry, Md.—*S. O. 64, Department of the East*, March 28, 1885.

Carter, E. C., *First Lieutenant and Assistant Surgeon.*—Granted one month's leave, with permission to apply for one month's extension, to take effect upon the arrival of another medical officer at his post.—*S. O. 30, Department of Arizona*, March 23, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING APRIL 4, 1885.

Murray, R. D., *Surgeon.*—Granted leave of absence for one week, March 31, 1885.

Bratton, W. D., *Assistant Surgeon.*—To proceed to New York, N. Y., for temporary duty, April 2, 1885.

Watkins, R. B., *Assistant Surgeon.*—To proceed to New Orleans, La., for temporary duty, April 2, 1885.

APPOINTMENTS.

The following candidates having passed the examination required by the Regulations were appointed Assistant Surgeons by the Secretary of the Treasury, April 1, 1885, viz.:

William D. Bratton, M.D., of South Carolina, and

Ralph B. Watkins, M.D., of Connecticut.

ORIGINAL LECTURES.

CHRONIC INTERSTITIAL NEPHRITIS (CONTRACTING KIDNEY).

A Clinical Lecture, delivered March 12, 1885.

BY ROBERT T. EDES, M.D.,

JACKSON PROFESSOR OF CLINICAL MEDICINE IN HARVARD UNIVERSITY.

LECTURE II.

THE case before us presented, you recollect, another important sign—*i. e.*, albuminuric retinitis. There are two entirely different causes for the loss of sight met with in renal diseases; one cerebral, coming, and perhaps going, suddenly, unattended by any ocular lesion, and closely connected with the condition which may lead to convulsions; the other, developing more slowly perhaps, never becoming extreme, perhaps being detected almost accidentally, and depending on changes taking place in the nerves and retina. These changes have been often described and figured, and you may see here (*Boston City Hospital Reports*, Second Series) a plate drawn by Dr. Wadsworth from such a case. They are not, however, absolutely characteristic, although sufficiently so, when found in a case not known to be otherwise diseased, imperatively to demand examination of the renal and cardiac condition. It has happened not infrequently that these changes have occurred at so early a period as to be the first intimations of the approach of Bright's disease.

An erroneous diagnosis may for a time be entertained on the basis of retinitis and an accidental albuminuria.

Last Spring I saw a middle-aged man, who, on account of failing sight and severe headache on the right side, consulted his own physician and two oculists. The condition of the retina, with white patches and extravasation of blood, led to an examination of the urine, which was found to contain albumen. The left eye was, however, normal. When I saw him he had intense headache, the eye was tense and prominent, with dilated pupil and a mere remnant of vision; the urine contained a small amount of albumen, had a specific gravity of 1025, with a very few transparent casts mostly mucous, beside strings of mucus. There were no localized paralyses, but the severe pain led me to suspect an intracranial tumor, so that I administered iodide of potassium. In a few days, however, the pain became so intense that after a consultation Dr. Derby removed the eye. There was no morbid growth therein, or behind it in the orbit.

Several months afterward he appeared nearly well, the urine being of specific gravity 1018, with still a slight trace of albumen, and a few small transparent casts. He thought he was passing a considerable quantity of urine, but according to more detailed statements it was not in excess of 1500 c. c.

The absence of heart signs, of exaggerated tension, of vomiting, the disappearance of the headache after removal of the eye, and the freedom of the other retina from lesion, as well as the normal quantity and specific gravity of the urine, made me consider this case as an ophthalmitis of unknown origin rather than albuminuric retinitis, notwithstanding the presence of albumen and a few transparent casts. I shall, however, be much interested in his future history.

The knowledge of the existence of retinitis is a strong point in the diagnosis of nephritis, but does not definitely decide it to be of the interstitial form, although adding to the probability in that direction. The prognosis of the lesion of itself is not absolutely unfavorable. It may be recovered from independently of the general disease, but is usually closely connected with it.

You are aware of the intimate relationships which exist between cerebral and renal affections and which are of various kinds.

Headache is a very common symptom in these cases, and was at one time present in the one which has been serving as our text. Such a headache is often apparently independent of any cerebral lesion, and is spoken of as uræmic. I doubt the correctness of the name, if it is intended to signify that the pain is caused by an accumulation of urea in the blood. Bartels has shown, and some quantitative analyses made on the urines of patients in this service by Dr. Wood confirm the statement, that during the most of the period of interstitial nephritis the kidneys are amply sufficient to carry off all the urea that is made. The secreting structure of the kidney, like that of other organs, is more than necessary for ordinary needs, and may suffer considerable diminution, as by the ablation of one kidney or the partial destruction of both, before the obstruction to secretion begins.

What is the cause of this sort of headache we cannot say with positiveness, any more than we can with many other kinds, but when we recollect how prominent a part in the theory of headache has been played by supposed vaso-motor constriction and dilatation, it is quite as easy to refer it to the condition connected with more or less rigid arteries and increased tension, as to a poison circulating in the blood.

It may often be relieved by measures which appeal much more directly to nervous function than to the excretions, such, for instance, as caffeine, or a small dose of morphia, both of which act too quickly for their beneficial effects to be accounted for by the removal of any excrementitious substance. It might be said that the hot air bath relieves by eliminating substances by the skin which should normally pass off by the kidneys, and in some cases this is no doubt true, and the same remark will apply to pilocarpine, but it must be remembered that the extensive and intense determination of blood to the skin caused by these agencies, produces a notable fall in the arterial tension and may relieve independently of elimination. If we choose to call these headaches uræmic, we must recollect that in many instances we are indulging in a figure of speech which serves only to mark

their connection with renal disease, and does not accurately describe their true causation.

Cerebral hemorrhage is well known to be so frequently connected with interstitial nephritis, that this latter condition may be very strongly suspected to exist, even in default of other marked symptoms, when apoplexy, not dependent on heart disease, occurs in young or middle-aged persons. In one well-marked case of this kind an excessively severe headache partially relieved by morphine was followed by a rapidly developing left hemiplegia. After death, some four months later, beside the small kidneys, large heart, and degenerated arteries, the brain was found unusually firm with small, cyst-like cavities in the white cerebral substance, and reddish-brown spots (old hemorrhages) in the corpora striata.

When you are asked, as you undoubtedly will be, why Bright's disease is so much more common now than formerly, I think you will be justified in attributing a part of the apparent increase to a transfer of a considerable number of cases from the headings, apoplexy, heart disease, etc., under which they would have been registered, to that of the now so popular nephritis.

When we remember that some organic cerebral diseases may give rise to certain symptoms supposed to be characteristic of nephritis, such as albumen, a few casts, and even poluria, it can be easily understood that difficulties in diagnosis may arise requiring considerable attention to solve. The decision must be made largely, I think, by a careful search for further symptoms of either disease, as, for instance, constancy of the headache in one locality, localized paralyses as of the ocular or facial muscles, localized convulsive movements, or paræsthesiæ, pointing to cerebral disease; or, on the other hand, hypertrophy of the heart, slight dropsy and especially casts of the kind which indicate serious inroads upon the secreting structure of the kidney, epithelial, fibrinous, and fatty, instead of purely hyaline, pointing to the nephritis and arterial sclerosis as the primary troubles, and the cerebral symptoms as secondary.

There may be cases, however, as of severe nervous headaches with vomiting, in which the cerebral disturbance is not constant and is apparently not dependent upon any special change in the condition or function of the kidney, where we may doubt, even in the presence of albumen and casts, exactly how intimate a connection exists between them.

Among other nervous symptoms there is one which some of you have seen to perfection in our patient, in the ward, since he was before the class. You know how common a symptom dyspnœa is in such cases. It may be due to effusion of serum into the pleuræ (hydrothorax), into the lung tissue (œdema), or to congestion of the lungs when the heart is failing. There is, however, a purely nervous dyspnœa, and one form of this is seen in our patient as the so-called Cheyne-Stokes respiration. This is a rhythmical rise and fall of the intensity of respiration, so that if we begin with the period, of apnœa, the respirations, at first barely perceptible, grow stronger and stronger until, after reaching the maximum of dyspnœa (which is not necessarily intense), they gradually fade away again and cease. The complete cycle generally takes somewhere in the neighborhood of a minute, the period of apnœa lasting for from ten to twenty or more seconds. Singularly enough the pulse, during these changes, does not alter its rate or force. This breathing is not all the time present in our patient, but I presume denotes "the beginning of the end."

This symptom does not denote, as was at one time supposed, fatty degeneration of the heart, but may be present with that as with other cardiac lesions. It is not uncommon in cerebral disease, and, as you see here and will probably see in other cases, it is not at all an infrequent accompaniment of interstitial nephritis. Unless I am mistaken, I have seen something of the kind, but with shorter intervals (four or five respirations between the pauses), in a person sleeping heavily under opium.

Its mechanism is not clear, but for an exposition of various theories as well as one of his own, you may consult the recent work of Dr. Bramwell on *Diseases of the Heart*. Whatever the details of its production may be, its meaning in general is diminished sensibility of the respiratory centre in the medulla oblongata, and it is usually a sign of very evil significance. It is not, however, of absolutely fatal import, or the immediate forerunner of death. You may see it during the early days of a cerebral hemiplegia in a patient who lives for months afterward. A woman told me that her husband, at a time when he was going into town every day to his business, used to "hold his breath so long" when asleep that it frightened her. This was, however, not many weeks before his death with atrophied kidneys and hypertrophied heart; and I always supposed that this "holding of the breath" was Cheyne-Stokes respiration. He certainly had it afterwards, but for a few days before his death the respiration became regular, though he was completely comatose. At some times it seems to be accompanied with very little disturbance of any kind, but at others the period of commencing respiration is attended with uneasy movements and manifestations of distress.

Convulsions, which you may have wondered not to hear me say more about, as of the nervous symptoms of interstitial nephritis, are more common in parenchymatous nephritis, and I shall speak of them in that connection should a suitable case occur during my term of service.

True epileptic convulsions may occur with interstitial nephritis, as a mere accidental coincidence and would be very likely to lead to a diagnosis of so-called uræmia in a case in which nothing was known of previous history.

A man aged about 52, was for two or three years in the habit of coming to the hospital after a "fit." He used to appear rather stupid, as often happens after an epileptic convulsion, but went out after a few days in his usual condition of health. He said he had the fits ever since childhood, and professed to be well in the intervals. Whenever his urine was examined it was found to be of low specific gravity, and to contain albumen and casts. The area of cardiac dulness was increased, and there was a systolic murmur at the apex. He finally entered for dyspnœa and died here. He was found to have pericarditis, hypertrophy of the heart with mitral stenosis (not excessive), and atrophied kidneys.

In further illustration of interstitial nephritis at an earlier stage, let me call your attention to this German, a beer drinker, aged 45. Four years ago his eyesight failed, but for this we find corneal opacities to account. Last year his legs were painful and swollen. Further

questioning as to the exact location and character of the swelling makes it probable that there was œdema in addition to some genuine rheumatic swelling, since it existed between the joints as well as at them. For a year he has had to get up in the night to pass urine. This is a circumstance which should lead to further investigation, but is not to be taken as proof positive of increased quantity of urine, as it may be due to prostatic irritation or even a mere nervous trick. Measurement is the proper test for polyuria, and, so far as we can make out, this man passes a little above the average. It is of specific gravity from 1007½ to 1010, contains a trace of albumen, a very little free blood, with hyaline and granular casts, and a little fatty epithelium.

The area of the heart's dulness is a little increased to the left, with rather a strong impulse and a slight systolic souffle at the apex. The tracing shows rather a slight elevation of the tidal wave, but a gradual and almost unbroken line of descent—that is, considerable resistance to the passage of the blood out of the vessels without a powerful action of the heart; a sort of relative high tension, though not of the most characteristic kind. He has white spots in both retinæ, but no hemorrhages. He came in for pain and swelling in his legs which symptoms soon disappeared, probably under the influence of rest and warmth, as he has had no very active treatment. He will go out in a few days with cautions as to keeping warm, not taking too much beer, and keeping his bowels in good order.

This coincidence of interstitial nephritis with rheumatism is not rare, but is perhaps not so intimate as that with gout, of which we in this country see much less, but to which the English writers on the subject attach much importance in the etiology of the contracting kidney.

Our next case I certainly should not pick out as a typical one to illustrate a clinical lecture, but as the patient is here, we will see how far it belongs to the class we have been talking about. It is that of a man, J. P., aged 53, who has experienced many vicissitudes and endured hardships. He has been a drinker, but is said not to have indulged much of later years. Two months ago he began to vomit, usually in the morning before breakfast, sometimes vomiting his breakfast, seldom his dinner or supper, never blood. Headache and failing eyesight for two months. His urine of specific gravity 1011, 1014; very slightly increased in quantity (about 60 ounces per diem), with a very large trace of albumen. Hyaline, fine and brown granular casts, and some free blood. He has hemorrhages in both retinæ; the heart's dulness terminates well within the nipple, and the impulse is barely perceptible. The sphygmograph shows nothing characteristic, certainly not high tension. He entered the hospital chiefly for weakness and "nervousness," and I suspected at first from his general appearance that alcoholism had a good deal to do with his condition. This suspicion I soon found to have little foundation. I must confess the diagnosis is not clear; the absence of cardiac enlargement (rather the contrary condition being present) and of increased tension, as well as the character of the urine; indicating a more active process, are strongly against the supposition of interstitial nephritis. It is true that the increased tension might have disappeared as the general nutrition and especially that of the heart became impaired under the influence of the long-continued vomiting, but this would not have destroyed the signs of cardiac hypertrophy. On the other hand, the urine was not typical of that of advanced parenchymatous nephritis, and the absence of the slightest trace of dropsy would be strongly against this supposition. His appearance and the history of failing health for some years, will hardly allow us to consider it a case of acute disease. We have nothing definite, not even irregularity, to point to the heart, and if this organ were the principal seat of disease, we ought, by this time, to have dropsy and much more dyspnœa than he appears to suffer from.

Postscript.—Since our last lecture two cases which have been before us have died. In one of them (J. P.) I regret that no autopsy could be obtained, so that we can add little to our deficient diagnosis. His urine became quite scanty and the vomiting, which had entirely disappeared after his entrance into the hospital, returned to a slighter extent. He became "nervous," not liking to be left alone and finally somewhat delirious. Notwithstanding the diminution in the urine, there was no dropsy whatever, and nothing which could be properly called uræmia, unless the excessively slow respiration unaccompanied by coma during the last few days of his life is to be accounted as such.

Three days before his death he had a severe attack of thoracic distress, and very loud to and fro, evidently pericardial, friction sounds were heard for the first time. There was no enlargement of the area of dulness either to right or left, or upwards; after the first attack it seemed to give him almost no trouble. At this time, or possibly a little before, a pulsation was noticed in the veins of the neck, especially on the right side.

I think we must regard the case as one of those exceptional ones in which interstitial nephritis, with very probably more or less parenchymatous superadded, is unaccompanied by cardiac hypertrophy—that it was a local, and not a general disease.

The other case was that (B. S.) which was our starting point in these lectures. His somnolence and stupor deepened until he died. The autopsy showed the kidneys to be in a condition of interstitial inflammation, being somewhat reduced in size, the surface irregular, although the capsule was not adherent. The cortical substance was not disproportionately diminished, but appeared more transparent than normal. The microscope showed patches of new cell formation throughout the cortical substance, but especially near the surface. There were casts in some of the tubes. The small arteries within the kidneys were thickened and in some places atheromatous. Everywhere throughout the body, so far as examined, the arteries were thickened, stiffened, and atheromatous. So extensive was the latter process that it could be observed in the little vessels, as large as a pin, on the surface of the brain. The coronary arteries were also much involved. The heart, especially the left ventricle, was hypertrophied, and the valves, although containing some yellowish patches, in every way competent. Notwithstanding their atheromatous condition, the coronary arteries contained no thrombi, and the muscle of the heart, with the exception of the tips of the papillary muscles so often affected, was everywhere free from fibrous or fatty degeneration.

We find then our former estimate of the case fully confirmed by this examination, and can realize that in-

terstitial nephritis, although present, was not the whole disease. The general arterial sclerosis was undoubtedly as important a factor as the not excessive destruction of kidney substance.

DISINFECTANTS.[1]

PRELIMINARY REPORTS OF THE COMMITTEE ON DISINFECTANTS OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

IX.

THE object of *disinfection* is to prevent the extension of infectious diseases by destroying the specific infectious material which gives rise to them. This is accomplished by the use of *disinfectants*.

There can be no partial disinfection of such material; either its infecting power is destroyed or it is not. In the latter case there is a failure to disinfect. Nor can there be any disinfection in the absence of infectious material.

It has been proved for several kinds of infectious material that its specific infecting power is due to the presence of living microörganisms, known in a general way as "disease germs;" and practical sanitation is now based upon the belief that the infecting agents in all kinds of infectious material are of this nature. Disinfection, therefore, consists essentially in the destruction of disease germs.

Popularly, the term disinfection is used in a much broader sense. Any chemical agent which destroys or masks bad odors, or which arrests putrefactive decomposition, is spoken of as a disinfectant. And in the absence of any infectious disease it is common to speak of disinfecting a foul cesspool, or bad-smelling stable, or privy-vault.

This popular use of the term has led to much misapprehension, and the agents which have been found to destroy bad odors—*deodorizers*—or to arrest putrefactive decomposition—*antiseptics*—have been confidently recommended and extensively used for the destruction of disease germs in the excreta of patients with cholera, typhoid fever, etc.

The injurious consequences which are likely to result from such misapprehension and misuse of the word disinfectant will be appreciated when it is known that:

Recent researches have demonstrated that many of the agents which have been found useful as deodorizers, or as antiseptics, are entirely without value for the destruction of disease germs.

This is true, for example, as regards the sulphate of iron or copperas, a salt which has been extensively used with the idea that it is a valuable disinfectant. As a matter of fact, sulphate of iron in saturated solution does not destroy the vitality of disease germs, or the infecting power of material containing them. This salt is, nevertheless, a very valuable antiseptic, and its low price makes it one of the most available agents for the arrest of putrefactive decomposition in privy vaults, etc.

Antiseptic agents also exercise a restraining influence upon the development of disease germs, and their use during epidemics is to be recommended, when masses of organic material in the vicinity of human habitations cannot be completely destroyed, or removed, or disinfected.

While an antiseptic agent is not necessarily a disinfectant, all disinfectants are antiseptics; for putrefactive decomposition is due to the development of "germs" of the same class as that to which disease germs belong, and the agents which destroy the latter also destroy the bacteria of putrefaction, when brought in contact with them in sufficient quantity, or restrain their development when present in smaller amounts.

A large number of the proprietary "disinfectants," so called, which are in the market, are simply deodorizers or antiseptics, of greater or less value, and are entirely untrustworthy for disinfecting purposes.

Antiseptics are to be used at all times when it is impracticable to remove filth from the vicinity of human habitations, but they are a poor substitute for cleanliness.

During the prevalence of epidemic diseases, such as yellow fever, typhoid fever, and cholera, it is better to use, in privy-vaults, cesspools, etc., those antiseptics which are also disinfectants—*i.e.*, germicides; and when the contents of such receptacles are known to be infected this becomes imperative.

Still more important is the destruction at our seaport quarantine stations of infectious material which had its origin outside of the boundaries of the United states; and the destruction, within our boundaries, of infectious material given off from the persons of those attacked with any infectious disease, whether imported or of indigenous origin.

In the sick-room we have disease germs at an advantage, for we know where to find them as well as how to kill them.

Having this knowledge, not to apply it would be criminal negligence, for our efforts to restrict the extension of infectious diseases must depend largely upon the proper use of disinfectants in the sick-room.

GENERAL DIRECTIONS.

Disinfection of Excreta, etc.—The infectious character of the dejections of patients suffering from cholera and from typhoid fever is well established; and this is true of mild cases and of the earliest stages of these diseases as well as of severe and fatal cases. It is probable that epidemic dysentery, tuberculosis, and perhaps diphtheria, yellow fever, scarlet fever, and typhus fever may also be transmitted by means of the alvine discharges of the sick. It is therefore of the first importance that these should be disinfected. In cholera, diphtheria, yellow fever, and

[1] This report has been prepared by the Chairman of the Committee in compliance with the request of the Sanitary Council of the Mississippi Valley, as expressed in a resolution passed at its recent meeting in New Orleans (March 10th and 11th). A special meeting of the Committee on Disinfectants, was called to consider the report, at which the following members were present, viz.: Drs. Sternberg, Raymond, Smart, and Rohé. Dr. James E. Reeves, President of the American Public Health Association, was also present by invitation of the Committee. After careful consideration and revision the report was adopted.

scarlet fever, all vomited material should also be looked upon as infectious. And in tuberculosis, diphtheria, scarlet fever, and infectious pneumonia, the sputa of the sick should be disinfected or destroyed by fire. It seems advisable also to treat the urine of patients sick with an infectious disease with one of the disinfecting solutions below recommended.

Chloride of lime, or bleaching powder, is, perhaps, entitled to the first place for disinfecting excreta, on account of the rapidity of its action. The following standard solution is recommended:

Standard Solution No. 1.

Dissolve chloride of lime of the best quality[1] *in soft water, in the proportion of four ounces to the gallon.*

Use one pint of this solution for the disinfection of each discharge in cholera, typhoid fever, etc. Mix well and leave in vessel for at least ten minutes before throwing into privy-vault or water-closet. The same directions apply for the disinfection of vomited matters. Infected sputum should be discharged directly into a cup half full of the solution.

Standard Solution No. 2.

Dissolve corrosive sublimate and permanganate of potash in soft water, in the proportion of two drachms of each salt to the gallon.

This is to be used for the same purposes and in the same way as Standard Solution No. 1. It is equally effective, but it is necessary to leave it for a longer time in contact with the material to be disinfected—at least an hour. The only advantage which this solution has over the chloride of lime solution consists in the fact that it is odorless, while the odor of chlorine in the sick-room is considered by some persons objectionable. The cost is about the same.[2] It must be remembered that this solution is highly poisonous. It is proper, also, to call attention to the fact that *it will injure lead pipes if passed through them in considerable quantities.*

Standard Solution No. 3.

To one part of Labarraque's Solution (liquor sodæ chlorinatæ) add five parts of soft water.

This solution is more expensive[3] than the solution of chloride of lime, and has no special advantages for the purposes mentioned. It may, however, be used in the same manner as recommended for Standard Solution No. 1.

The following powder is also recommended for the disinfection of excreta in the sick-room and of privy-vaults, etc.:

Disinfecting and Antiseptic Powder.

One pound of chloride of lime; one ounce of corrosive sublimate; nine pounds of plaster of Paris. Pulverize the corrosive sublimate and mix thoroughly with the plaster of Paris. Then add the chloride of lime and mix well. Pack in paste-board boxes or in wooden casks. Keep dry.

As an antiseptic and deodorizer this powder is to be sprinkled upon the surface of excreta, etc.

To disinfect excreta in the sick-room, cover the entire surface with a thin layer of the powder—one-fourth inch in thickness—and if the material is not liquid pour on sufficient water to cover it.

Disinfection of the Person.—The surface of the body of a sick person, or of his attendants, when soiled with infectious discharges, should be at once cleansed with a suitable disinfecting agent. For this Standard Solution No. 3 may be used.

In diseases like smallpox and scarlet fever, in which the infectious agent is given off from the entire surface of the body, occasional ablutions with Labarraque's Solution, diluted with twenty parts of water, will be more suitable than the stronger solution above recommended.

In all infectious diseases the surface of the body of the dead should be thoroughly washed with one of the standard solutions above recommended, and then enveloped in a sheet saturated with the same.

Disinfection of Clothing.—Boiling for half an hour will destroy the vitality of all known disease germs, and there is no better way of disinfecting clothing or bedding which can be washed than to put it through the ordinary operations of the laundry. No delay should occur, however, between the time of removing soiled clothing from the person or bed of the sick and its immersion in boiling water, or in one of the following solutions; and no article should be permitted to leave the infected room until so treated.

Standard Solution No. 4.

Dissolve corrosive sublimate in water[1] *in the proportion of four ounces to the gallon, and add one drachm of permanganate of potash to each gallon to give color to the solution.*

One fluidounce of this standard solution to the gallon of water will make a suitable solution for the disinfection of clothing. The articles to be disinfected must be thoroughly soaked with the disinfecting solution and left in it for at least two hours, after which they may be wrung out and sent to the wash.

Solutions of corrosive sublimate should not be placed in metal receptacles, for the salt is decomposed and the mercury precipitated by contact with copper, lead, or tin. A wooden tub or earthen crock is a suitable receptacle for such solutions.

Clothing may also be disinfected by immersion for

---

[1] Good chloride of lime should contain at least 25 per cent. of available chlorine. (*See* preliminary report of Committee on Disinfectants. The Medical News, Philadelphia, February 7, 1885, page 147.) It may be purchased by the quantity at 5 cents per pound. The cost of the standard solution recommended is therefore less than two cents a gallon. A clear solution may be obtained by filtration or by decantation, but the insoluble sediment does no harm, and this is an unnecessary refinement.

[2] Corrosive sublimate costs about 70 cents a pound, and permanganate of potash 65 cents a pound, by the single pound. This makes the cost of the Standard Solution No. 2 a little more than two cents a gallon.

[3] We assume that the solution used will contain at least 3 per cent. of available chlorine, which would give us 0.5 per cent. in the diluted solution. The cost per gallon of the undiluted solution should not be more than fifty cents by the quantity. This would make our standard solution cost between eight and nine cents a gallon.

[1] Mercuric chloride (corrosive sublimate) is soluble in cold water in the proportion of one part in sixteen. Solution is greatly facilitated by heat.

two hours in a solution made by diluting Standard Solution No 1 with nine parts of water—one gallon in ten. This solution is preferable for general use, especially during the prevalence of epidemics, on account of the possibility of accidents from the poisonous nature of Standard Solution No. 4. When diluted as directed this solution may, however, be used without danger from poisoning through the medium of clothing immersed in it, or by absorption through the hands in washing. A poisonous dose could scarcely be swallowed by mistake, owing to the metallic taste of the solution, and the considerable quantity which would be required to produce a fatal effect—at least half a pint.

Clothing and bedding which cannot be washed, may be disinfected by exposure to dry heat in a properly constructed disinfecting chamber for three or four hours. A temperature of 230° F. should be maintained during this time, and the clothing must be freely exposed—*i. e.*, not folded or arranged in piles or bundles, for the penetrating power of dry heat is very slight.

The limitations with reference to the use of dry heat as a disinfectant are stated in a "Preliminary Report of the Committee on Disinfectants," published in THE MEDICAL NEWS, March 14, 1885.

The temperature above mentioned will not destroy the *spores* of bacilli—*e. g.*, of the anthrax bacillus, but is effective for the destruction of all disease germs which do not form spores; and there is good reason to believe that this list includes smallpox, cholera, yellow fever, diphtheria, erysipelas, puerperal fever, and scarlet fever (?) Moist heat is far more effective, and it is demonstrated that ten minutes exposure to steam, at a temperature of 230° F. will destroy all known disease germs, including the most refractory spores.

In the absence of a suitable disinfecting chamber, it will be necessary to burn infected clothing and bedding, the value of which would be destroyed by immersion in boiling water, or in one of the disinfecting solutions recommended.

Disinfection of the Sick-room.—In the sick-room no disinfectant can take the place of free ventilation and cleanliness. It is an axiom in sanitary science that *it is impracticable to disinfect an occupied apartment;* for the reason that disease germs are not destroyed by the presence in the atmosphere of any known disinfectant in respirable quantity. Bad odors may be neutralized, but this does not constitute disinfection in the sense in which the term is here used. These bad odors are, for the most part, an indication of want of cleanliness, or of proper ventilation; and it is better to turn contaminated air out of the window, or up the chimney, than to attempt to purify it by the use of volatile chemical agents, such as carbolic acid, chlorine, etc., which are all more or less offensive to the sick, and are useless so far as disinfection—properly so-called—is concerned.

When an apartment which has been occupied by a person sick with an infectious disease is vacated, it should be disinfected. But it is hardly worth while to attempt to disinfect the atmosphere of such an apartment, for this will escape through an open window and be replaced by fresh air from without while preparations are being made to disinfect it. Moreover, experience shows that the infecting power of such an atmosphere is quickly lost by dilution, or by the destruction of floating disease germs through contact with oxygen, and that even smallpox and scarlet fever are not transmitted to any great distance through the atmosphere; while cholera, typhoid fever, and yellow fever are rarely, if ever, contracted by contact with the sick, or by respiring the atmosphere of the apartments occupied by them.

The object of disinfection in the sick-room is, mainly, the destruction of infectious material attached to surfaces, or deposited as dust upon window-ledges, in crevices, etc. If the room has been properly cleansed and ventilated while still occupied by the sick person, and especially if it was stripped of carpets and unnecessary furniture at the outset of his attack, the difficulties of disinfection will be greatly reduced.

All surfaces should be thoroughly washed with a solution of corrosive sublimate of the strength of one part in 1000 parts of water, which may be conveniently made by adding four ounces of Standard Solution No. 4 to the gallon, or one pint to four gallons of water. The walls and ceiling, if plastered, should be whitewashed with a lime wash containing the same proportion of corrosive sublimate, or they may be brushed over with the aqueous solution. Especial care must be taken to wash away all dust from window-ledges and other places where it may have settled, and to cleanse thoroughly crevices and out-of-the-way places. After this application of the disinfecting solution, and an interval of twenty-four hours or longer for free ventilation, the floors and woodwork should be well scrubbed with soap and hot water, and this should be followed by a second more prolonged exposure to fresh air, admitted through open doors and windows.

Many sanitary authorities consider it necessary to insist upon fumigation with sulphurous acid gas—produced by combustion of sulphur—for the disinfection of the sick-room. As an additional precaution, this is to be recommended, especially for rooms which have been occupied by patients with smallpox, scarlet fever, diphtheria, typhus fever, and yellow fever. It should precede the washing of surfaces and free ventilation above recommended. But fumigation with sulphurous acid gas alone, as commonly practised, cannot be relied upon for the disinfection of the sick-room and its contents, including bedding, furniture, infected clothing, etc., as is popularly believed. And a misplaced confidence in this mode of disinfection is likely to lead to a neglect of the more important measures which have been recommended. In the absence of moisture the disinfecting power of sulphurous acid gas is very limited, and under no circumstances can it be relied upon for the destruction of spores.[1] But exposure to this agent in sufficient quantity, and for a considerable time, especially in the presence of moisture, is destructive of disease germs, in the absence of spores. It is essential,

[1] See Preliminary Report of Committee on Disinfectants in THE MEDICAL NEWS of March 28, 1885.

however, that the germs to be destroyed shall be very freely exposed to the disinfecting agent, which has but slight penetrating power.

To secure any results of value, it will be necessary to close the apartment to be disinfected as completely as possible by stopping all apertures through which the gas might escape, and to burn not less than three pounds of sulphur for each thousand cubic feet of air-space in the room.[1] To secure complete combustion of the sulphur it should be placed, in powder or in small fragments, in a shallow iron pan, which should be set upon a couple of bricks in a tub partly filled with water, to guard against fire. The sulphur should be thoroughly moistened with alcohol before igniting it.

Disinfection of Privy-vaults, Cesspools, etc.—When the excreta—not previously disinfected—of patients with cholera or typhoid fever, have been thrown into a privy-vault this is infected, and disinfection should be resorted to as soon as the fact is discovered, or whenever there is reasonable suspicion that such is the case. It will be advisable to take the same precautions with reference to privy-vaults into which the excreta of yellow fever patients have been thrown, although we do not definitely know that this is infectious material. Disinfection may be accomplished either with corrosive sublimate, or with chloride of lime. The amount used must be proportioned to the amount of material to be disinfected.

Use one pound of corrosive sublimate for every five hundred pounds—estimated—*of fecal matter contained in the vault, or one pound of chloride of lime to every thirty pounds.*

Standard Solution No. 4, diluted with three parts of water, may be used. It should be applied—the diluted solution—in the proportion of one gallon to every four gallons—estimated—of the contents of the vault.

If chloride of lime is to be used, one gallon of Standard Solution No. 1 will be required for every gallon—estimated—of the material to be disinfected.

All exposed portions of the vault, and the woodwork above it should be thoroughly washed down with the disinfecting solution.

To keep a privy-vault disinfected during the progress of an epidemic, sprinkle chloride of lime freely over the surface of its contents daily. Or, if the odor of chlorine is objectionable, apply daily four or five gallons of Standard Solution No. 2, which should be made up by the barrel, and kept in a convenient location, for this purpose.

Disinfection of Ingesta.—It is well established that cholera and typhoid fever are very frequently, and perhaps usually, transmitted through the medium of infected water or articles of food, and especially milk. Fortunately we have a simple means at hand for disinfecting such infected fluids. This consists in the application of heat. *The boiling temperature maintained for half an hour kills all known disease germs.* So far as the germs of cholera, yellow fever, and diphtheria are concerned, there is good reason to believe that a temperature considerably below the boiling point of water will destroy them. But, in order to keep on the safe side, it is best not to trust anything short of the boiling point (212° F.) when the object in view is to disinfect food or drink which is open to the suspicion of containing the germs of any infectious disease.

During the prevalence of an epidemic of cholera it is well to boil all water for drinking purposes. After boiling, the water may be filtered, if necessary to remove sediment, and then cooled with *pure* ice, if desired.

A sheet of filtering paper, such as druggists use, and a glass or tin funnel, furnish the best means for filtering water on a small scale for drinking purposes. A fresh sheet of paper is to be used each day.

[1] One litre of sulphur dioxide weighs 2.9 grammes. To obtain ten litres of gas it is necessary to burn completely fifteen grammes of "flowers of sulphur" (Vallin).

SOME CLINICAL OBSERVATIONS ON THE THERAPEUTIC USES OF BROMIDE OF NICKEL.

By R. LEAMAN, M.D.,
CHIEF OF MEDICAL CLINIC AT JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

As with all else that is new, a certain scepticism has ever prevailed concerning the utility of new drugs. Such conservation is doubtless beneficial, for how can any good come of changing an old drug of known utility for a new one of doubtful worth? Nevertheless, many remedies of great utility receive frequent condemnation at the hands of the profession simply because the proper conditions indicating their use are not known or appreciated.

Some time ago Professor Da Costa introduced the bromide of nickel as a useful remedy in the treatment of epilepsy and kindred diseases, and during the past year or more it has been repeatedly tried in the out-patient department of the Jefferson College Hospital.

During this time it has been found that this salt of nickel is especially useful in a certain class of cases, at the same time its method of administration has been greatly improved by the pharmacist. When first used it was noticed that in some cases great benefit followed its administration, whilst in other cases little relief was experienced from its employ, certainly less than from the combined use of the bromide of sodium and the bromide of potassium. Soon, however, it was remarked that the best results were obtained when the attacks took place regularly and at comparatively long intervals. But, on the other hand, where the attacks are frequent, amounting to several in the twenty-four hours, then better results were obtained from the use of the other bromides. In other words, where the object in view is to keep up a mild impression for a long while, that then the results obtained from the bromide of nickel are most gratifying.

Just here the question will naturally arise, Would not the mild impression of small doses of the other bromides be equally satisfactory?

Now, we must frankly confess that, despite its favorable recommendation by so distinguished an authority as Professor Da Costa, we at first obtained such varying results from its use that our minds were

rather prejudiced against the drug than otherwise. However, difficult as it is to relieve one's mind of a preconceived idea, yet, after frequently employing this remedy in the special class of cases just mentioned, and comparing in the same patient the results which we obtained from this and the other bromides, we have no longer any doubt that this drug is a most valuable addition to the therapeutics of epilepsy.

In the first place, it disorders the digestive tract less than any of the other bromides. Especially is this true when administered in the effervescing form. The bromide of nickel, $NiBr_2$, is formed by combining with the aid of heat eighty parts of bromine with fifty-eight and eight-tenths of pure nickel. As thus formed, it is a dry, slightly granular powder, of a greenish-yellow color, very soluble in water, producing a grass-green solution. The powder is insoluble in both alcohol and ether. The granular preparation of which we speak is made in the same way as the officinal granular citrate of magnesia, namely, by mixing the salt intimately with the bicarbonate of soda and tartaric acid, moistening with alcohol, and passing this moist powder through a sieve and then drying in a warm closet.

The carbonic acid liberated when the powder is put in water, makes it not only more pleasant to the taste, but more acceptable to the stomach, than when administered in any other form. The dose for one adult is from five to ten grains,—each teaspoonful containing five grains of the salt. When first introduced five grains were thought to be a full dose. But, as it was then given in solution, it is probable that the effervescing form does not quite represent the full strength, since although better borne by the stomach, larger doses are required than of the simple solution. In suitable cases we estimate that ten grains of nickel are fully equal in efficiency to half a drachm of the bromide of potassium. Although equal in therapeutic results to this amount of the potash salt, yet at the same time it is much less of a depressant to the nervous system. It is, therefore, especially indicated when a hysterical or hypochondriacal element is prominent in a case. Two marked cases of this kind have recently presented themselves which we deem worthy of special mention.

One was that of a young farmer, twenty-eight years of age, a man of fine physique, but of sluggish intellect; a man who had almost totally abandoned himself to a life of self-introspection, which was of course aggravated by the solitude of his rural surroundings. Moreover, he had fallen a victim to that current of popular literature which addresses powerfully the mind of a susceptible man, and centres his whole attention upon his sexual apparatus—we refer to the "Marriage Guides," so-called. He had read all the works of that character upon which he could lay his hands. He was thoroughly convinced that all of his ailments, which were legion, originated in the early practice of masturbation. To add to his despondency, about six months before presenting himself to us he was seized with an epileptic fit, which lasted for about fifteen minutes. During this time he frothed at the mouth. This was followed by a deep sleep, lasting for nearly an hour, after which he felt exhausted and dull for the remainder of the day.

Since that time he had been having a similar attack about once in three weeks, and these were gradually increasing in frequency. So that from all we could learn his was a case of idiopathic epilepsy. He was put upon five grain doses of the bromide of nickel, but at the end of three weeks had another attack, although much less severe. The dose was then increased to ten grains, and at the end of eleven weeks there had been no sign of another attack. He was much more cheerful and self-satisfied. Unfortunately he insisted that he was entirely cured, and we have not heard of him since. Moreover, we must state that a change of his hygienic conditions had somewhat to do with this result; for, like many epileptics, he was an enormous eater, and allowed himself to pass four or five days without having a movement from the bowels. All of this was, of course, regulated; and, since the mental condition of an individual is much influenced by the condition of his colon, we must, of course, attribute some of this improvement to his altered hygienic conditions.

The other case was that of a lady, thirty years of age, who had been subject to epileptic attacks for twenty-three years subsequent to a spell of scarlet fever. She usually had as many as two or three attacks daily, and this condition was aggravated about the time of the menstrual flow. The longest period during which she had been free from an attack was two weeks. During the seizures she loses consciousness entirely, foams at the mouth, and bites her tongue. This condition is usually ushered in by giddiness, occasionally by the sensation of a puff of air rising from the epigastrium; she has a very poor memory; is highly emotional, begging for relief in the manner almost of an imbecile; tongue is much coated; the urine normal. Having been thus afflicted for many years, and having travelled to a considerable extent, she had tried the numerous remedies of many doctors, both of the quack persuasion and of the regular profession. She was entirely familiar with the action of the bromides, severally and combined. She complained that, although they lessened the number and severity of the attacks, yet their depressant action upon the stomach and nervous system was so disagreeable that she almost preferred the disease to the remedy. Already disgusted with all drugs, when we informed her of our intention to give her a new bromide, it was with the utmost hesitancy that she consented to take the bromide of nickel. However, after some persuasion she consented, and was immediately put upon ten grain doses three times daily.

This was on the twentieth of October, 1884. On the thirtieth day of November following, after having steadily persevered in the use of the remedy, she returned despondent, stating that on the day previous she had a severe attack, the first for nearly six weeks, She would not consent to take the remedy any longer, since it had not entirely cured her. Fortunately for our observations, she continued it long enough to prove that the bromide of nickel was more effective than anything she had previously taken; and that, although her stomach was quickly upset by other bromides, she was able to take this without any inconvenience. This case, of course, proves an excep-

tion to the rule that the best effects are derived from this drug when the attacks are comparatively far apart.

We state these two cases as the types of two general classes of epilepsy in which the bromide of nickel is most beneficial. In these two classes it has been used with marked success in upwards of fifty cases. That the bromide of nickel will relieve headache, especially of the congestive form, was claimed for the drug at its first introduction.

It is a most excellent remedy for wakefulness dependent upon long-continued excitement of the nervous system from any cause. We claim for this drug no specific curative action; we only wish to state our belief that it is a most valuable addition to the therapeutics of epilepsy, especially in that class of cases which we have above set forth, and also a potent remedy in many kindred disorders.

REMOVAL OF LARGE FIBROID TUMORS PER VAGINAM—TWO CASES—RECOVERY OF BOTH.

By R. S. SUTTON, M.D.,
of Pittsburg, Pa.

When a fibro-myoma occupies the cavity of the uterus, or when it is developed beneath its lining membrane, the question of removal, with its dangers and difficulties, is frequently divided between supravaginal hysterectomy and enucleation. But when the tumor is large, occupying not only the distended uterine cavity, but the vagina also, or when the tumor is developed in the body and neck of the uterus and supravaginal hysterectomy cannot be done, enucleation per vaginam is the proper operation.

The cases herein narrated were of the latter class. In both the tumors were large. The patients were greatly exhausted; the operations were difficult. Both recovered.

Case I.—Mrs. L. McF. was sent to me by Dr. James Hasler, of Cochranton, Pa. She was admitted to Terrace Bank Hospital for Women on March 9, 1884. A fibro-myoma occupied, completely filling, the pelvis. The external uterine os could not be reached; it lay behind a point above the symphysis pubis, and above the equator of the growth. The latter was developed in the posterior lip and body of the uterus, and was larger than the head of an ordinary sized child at term. On March 11th she was etherized by the head nurse (Miss Garvin), and placed in the lithotomy position on the table before a window. A second nurse supported one leg; my assistant, Dr. Stone, the other. A Simon's speculum, with a very short, broad blade, was placed in the vagina, and with it the nurse held the perineum down. A second Simon's speculum, with a long, narrow blade, was carefully crowded up between the tumor and the bladder, and held by Dr. Stone. The vagina and presenting enlargement were again carefully washed with five per cent. carbolic water. The parts were perfectly exposed, the rectum was guarded with the posterior, and the bladder and urethra with the anterior speculum.

With Paquelin's cautery I laid open all the tissue covering the tumor exposed to view. The capsule proved to be very thick, but the division of it with the cautery was bloodless. The edge of the capsule was now seized with a pair of long-handled forceps and lifted and steadied until Thomas's spoon saw was pushed well up between the capsule and the tumor. The latter was now seized with a pair of powerful volsellum forceps, with which I dragged the tumor about in aid of the movements with the spoon saw. In a few minutes the tumor was apparently separated from uterine tissue and blood was flowing freely from the vagina.

I now discovered that the incision made with the cautery did not lay open the lip of the uterus all the way to the external os, which I had not yet seen. With a pair of blunt scissors I now succeeded in carrying the incision entirely through the lip to the external os, a distance of only about a half inch. The tumor was now loose in the capsule, and the incision through which it must be extracted was about five inches in length. Whether the cavity of the peritoneum had been opened or not was uncertain, but I had held the saw in the process of enucleation close to the tumor as I worked it along the tumor.

The tumor was now seized with additional pairs of strong volsellum forceps and forcibly pulled out of the vagina, lacerating still more the perineum already lacerated in one of her accouchements.

The delivery of the tumor was followed by a free hemorrhage from the interior of the capsule. The specula were replaced, and the vaginal nozzle of a Davidson's syringe was inserted into the cavity of the capsule, and very hot water was injected until a half gallon was used. The bleeding was diminished, but the flow was still free. The lips of the wound were now held apart with long-handled forceps, and the empty capsule and uterus were pressed down to the ostium vagina, the perineal short-bladed speculum remaining *in situ*. The bleeding points were seized as rapidly as possible with Péan's and Koeberlé's compression forceps. Each pair locked and dropped. Thirty-two pairs were put on their shafts, completely filling the vagina. They were left *in situ*, and the anæsthetic withdrawn. At the end of twenty minutes the forceps were lifted. A little oozing continued. The hot water was again used for four or five minutes, and the interior of the capsule was then dried off and swabbed over with a solution of perchloride of iron in glycerine. The capsule and uterus were then pushed up, the speculum removed, and the patient was put to bed.

The after-treatment consisted of hot vaginal douches (sublimate 1 : 2000) every eight hours, milk punch, beef soup, quinine, and digitalis. She recovered and left the institution four weeks from the date of her arrival. She remains in good health at the present time. At this operation were present: Drs. Huselton, of Allegheny, and Lindley, of Perrysville, both skilful surgeons.

Case II.—On June 23, 1884, I met Dr. Johnston, of Fairview, West Virginia, at the house of Miss S., his patient, with a view of removing per vaginam a fibro-myoma. The patient was a large-boned, stout, unmarried woman, of about thirty-five years of age.

She was pale and thin, her pulse small and rapid. She had been in labor for a month. On examination I found the tumor resting with its lower end on the perineum; the upper end was in the uterus, reaching to a point near the umbilicus. The lower end seemed to fill the vagina; the capsule was sloughing; the perineum was discolored, dark blue in appearance. There had been but little hemorrhage in the whole history of the case, but a discharge of thin serum had been constant.

She was etherized, placed in the lithotomy position, douched with hot water, and a thorough exploration made. The outlet of the vagina was very small. After careful exploration I concluded that the tumor was egg-shaped, the lower end being about the size of a fœtal head; the upper end being nearer the size of an adult head. I had put my hand through the ostium vagina, and thrust my fingers up behind the tumor, but could not distinguish the margin of the dilated cervix. In the attempt I lacerated the perineum, which tore like rotten cloth. Two physicians, friends of Dr. Johnston, whose names I cannot recall, were present; also a young clergyman of the neighborhood. The clergyman gave the anæsthetic; a leg was taken charge of by each of the physicians referred to, and I reserved Dr. Johnston to assist me, which he very ably did.

The mouth of the vagina was well opened up with Simon's speculum and lateral retractors, and with volsellum forceps I seized the tumor, and with heavy scissors began to cut it to pieces, and to remove each piece as cut away. With the scissors and knife I succeeded in an hour in cutting to pieces and removing the entire growth.

While dragging out the last piece, adherent high up in the uterus by the pedicle to the uterine wall I inverted the uterus—it turned inside out. I cast a strong ligature around the pedicle of the tumor, cut it close to the knot, severed the pedicle with the scissors, and the operation was finished. I now replaced the uterus, and carried into its cavity a large rag, well saturated with vinegar, and, seizing the uterus through the abdominal wall with the free hand, I felt it contract on the other hand. The patient was then put to bed.

She recovered under Dr. Johnston's care, and a few months ago I closed the lacerated perineum. She is now in good health; she expresses it, "raised from the dead." While her view of the matter is an exaggerated one, there is no doubt that without operation she must very soon have died.

I am sorry I cannot recall the names of the medical friends of Dr. Johnston, who also contributed valuable assistance.

GALVANISM IN DIPHTHERITIC PARALYSIS.

BY JAMES K. THACHER, M.D.,

PROFESSOR OF PHYSIOLOGY IN YALE COLLEGE, ATTENDING PHYSICIAN AT THE NEW HAVEN HOSPITAL.

The strong tendency of diphtheritic paralysis to recover makes it difficult to distinguish and estimate the effect of modes of treatment. In the case presented below the danger of the fallacy *post ergo propter* is considerably diminished by the making of the conclusions depend on a comparison between the arms.

A. S., æt. 17, in good health till September last, when he had an attack of diphtheria, and for three weeks was attended daily by a regular physician. The diphtheritic process in the throat was followed by inability to talk plainly, diplopia, and weakness and numbness in the extremities. The palatal and ocular paralysis reached a maximum before that of the limbs, and weakness was noticed in the arms earlier than in the legs.

When the patient came into my hands December 18, the paralysis had become almost entirely confined to his limbs. Both his arms and legs were quite weak, and showed partial reaction of degeneration.

There can be no doubt of the diphtheritic nature of the case, nor does there seem reason to question that the paralysis was due to a multiple peripheral neuritis.

The legs were now treated with galvanism and massage, and the usual tonics ordered. The arms were reserved for experiment. The numbers given below indicate the strength of the hands as measured by an ordinary Tiemann's grip dynamometer.

December 18.—Right 31, left 29. Left arm galvanized, strong current, kathode labile, ten minutes daily for ten days. Right arm not treated.

28th.—Right 43, left 46. Right arm galvanized as above for seven days. Left not treated.

January 4.—Right 58, left 56. Left massaged for seven days. No galvanism. No treatment of right.

11th.—Right 69.4, left 64.3. Left galvanized, not massaged for seven days. Right not treated.

14th.—Right 70.3, left 71.7. Right faradized for seven days.

25th.—Right 74.6, left 75.8. The patient then, considering himself well, withdrew from observation.

It will thus be observed that in each of the three periods in which galvanism was used, applied to the weaker arm it reversed the order of strength; and this reversal did not take place with either faradism or massage in the single trials of these modes of treatment.

The gains under galvanism are exhibited as follows:

	Galvanized arm.	Untreated arm.
(1) Ten days to left arm .	17	12
(2) Seven days to right arm .	15	10
(3) Seven days to left arm .	7.4	0.9
Total . . .	39.4	22.9

That is, the galvanized arm made almost double the progress of the other (1 : 1.72).

The gains with faradism and massage were:

	Arm treated.	Arm untreated.
Massage	8.3	11.4
Faradism	4.3	4.1

So that here there appears to be essentially no difference produced by the faradism, while the massage seems to have been the reverse of successful. The conclusion that the massage was injurious can, however, hardly be drawn from a single seven days' trial.

RAPID DILATATION OF THE CERVIX UTERI FOR STERILITY AND DYSMENORRHŒA.

By A. H. GOELET, M.D.,
of New York.

Dilatation of the cervix, although mostly done for the relief of sterility and dysmenorrhœa, has proved most invaluable in the treatment of endometritis or uterine catarrh, as it is termed by some. In fact, we find this condition always associated with contracted cervical canal to a greater or less degree. That is, where there is an abnormally small cervical canal, the normal secretions from the uterine cavity cannot gain free exit, and sooner or later endometritis is the result.

The majority of cases of this disease occurring in women who have not borne children, are produced in this way. After marriage, when the genital organs are called upon to perform all their functions, there is a greater degree of congestion consequent thereon, the secretions are increased, and the disease becomes more apparent and the dysmenorrhœa more intense. In dilating for stenosis there always escapes, after dilation is complete, a plug of thick mucus resembling albumen which would not have been suspected before; and especially is this so where no endometritis is apparent before dilatation. Cases of endometritis which have resisted treatment before, yield readily after free vent is given to the discharge by dilatation and applications can be thoroughly made. Complete dilatation, if maintained, will alone cure slight cases.

Rapid dilatation is a perfectly safe procedure, free from danger if the patient be confined to bed for a few days after, and is effectual and permanent if done in the way described below, and an intrauterine glass stem be used afterwards to prevent recontraction. Although it may be done in many cases without an anæsthetic, the result will be more satisfactory with it. Whether this be due to more thorough relaxation produced by the anæsthetic, or the operator dilates more thoroughly when there is no apprehension of giving pain, I cannot say, but probably the latter. In dilating for stenosis an anæsthetic should always be used.

Much may be accomplished by preparatory treatment if there be much rigidity of the parts or irritation. I use for a few days before, vaginal tampons of absorbent cotton, soaked with glycerine, to which boric acid has been added to saturation. A string being attached to the tampon, it can be removed by the patient in twenty-four hours, and the vagina thoroughly irrigated with hot water.

I use the Palmer dilator and find one size all that is necessary.

The patient is anæsthetized and placed on a table in a good light. A Nott's trivalve or a bivalve speculum is generally used with the patient on her back, or the Sims's speculum may be used with the patient on her side. The cervix is steadied with a tenaculum, and by a slow steady pressure the dilator may be passed through both external and internal os when the direction of the canal has been previously determined by passing the sound. A shoulder on the blades of the dilator prevents its being introduced too far. I have never yet found it necessary to bore the external os with a pair of pointed scissors as recommended by some. When the dilator has been introduced as far as the shoulder, the handles are brought together gradually by the thumb and middle finger, while with the forefinger, the nut which works on the screw is made to follow up the advantage gained, and hold it there when the fingers become tired. Usually the dilatation is carried to the full extent of the instrument, and is not found to be too much. Tearing of the os has never occurred with this instrument in my hands, which is attributed to the way the blades separate—like a pair of scissors and not parallel. After dilatation is complete the screw is loosened and the instrument withdrawn. The thick plug of mucus, already spoken of, is now removed and the cervical canal cleansed by means of a piece of absorbent cotton twisted around an applicator.

If flexion exists, the dilator is again introduced and turned upon its axis, reversing the flexion and the handles are brought together.

The intrauterine stem which is now introduced is a glass rod, two inches long, size of a No. 20 steel sound (French); rounded at one end, very slightly curved, narrowing into a neck near the other or lower end, and terminating in a button-shaped shoulder which limits penetration. This will be found very hard to handle, and is best introduced with a pair of long uterine dressing forceps, the blades of which have been wrapped with cotton, so that the glass button can be grasped firmly without slipping. A tampon of cotton saturated with glycerine and boric acid is placed against the cervix to hold the stem in position and relieve the irritation. During the first twenty-four or forty-eight hours it will be found that the stem is grasped firmly by the cervix, but after this there is some relaxation and it is apt to slip out. This shows that contraction does take place after dilatation, and that the stem should be used to prevent it. In cases in which there is flexon the stem serves to hold the uterus straight or nearly so.

The patient is placed in bed and allowed to recover slowly from the anæsthetic. She very seldom complains of any pain or inconvenience after the operation, and if there is a little soreness it will pass off in a few hours. It will be even difficult sometimes to convince her of the necessity of remaining in bed. Usually the stem is removed every day, cleansed and replaced, but if there be very little discharge from the uterine cavity it may remain in position for two days at a time. After a week it is removed permanently and the patient allowed to get up. And if the weather is favorable, she may go out the following day.

The following cases are given to illustrate the success of the operation:

Case I.—Mrs. C., æt. 22 years. Married two years. Before marriage she suffered very little inconvenience; but after, dysmenorrhœa became troublesome and there was considerable discharge. Operated July 8, 1884, under chloroform. Slight endometritis found. Subsequent menstruations entirely

free from pain. In October she had a miscarriage at two months. No dysmenorrhœa afterwards.

CASE II.—Miss E., æt. 19 years, has suffered with dysmenorrhœa since puberty, and now it has become so intense it is unbearable. Upon examination a very small cervix was found with a pin-hole os which permitted the introduction of the smallest size uterine probe with difficulty and considerable pain. Operated upon her under ether, October 23, 1884. There was no pain with menstruation after, and three months after the sound was passed with ease and without pain.

CASE III.—Mrs. B., æt. 26 years. Married three years. Sterility and dysmenorrhœa since first menstruation, more intense since marriage, which forced her to apply for relief. Operated September 8, 1884, without anæsthetic. With the first menstruation following operation there was a slight pain due to a cold she had contracted. After this time she ceased to have pain. In this case the patient volunteered the information that there was no sensation during intercourse before the operation, but after it was all that could be desired.

CASE IV.—Mrs. R., æt. 25 years. Married fifteen years. Has suffered with dysmenorrhœa since her first period and she has never conceived. She had a severe menorrhagia once, and was treated without examination, and has had pelvic peritonitis. A very irritating discharge which she has had for several years has caused great annoyance. Examination showed endometritis with considerable stenosis. Operated August 26, 1884, without anæsthetic. During the operation she became nauseated, and vomited from irritation of cervix. Menstruation appeared three days after and was free from pain. The stem was removed for a few days. Eight days after the operation when the stem was again introduced, it was found necessary to dilate again, as contraction had taken place.

CASE V.—Mrs. E., æt. 26 years. Married four years. Sent to me by Dr. L. Has suffered with dysmenorrhæa since puberty, worse since marriage, requiring morphia hypodermically. She has remained sterile, and for the past two years has had endometritis, which has been treated. Sponge-tents have been used at different times by other specialists, and rapid dilatation has been performed without success. Operated upon under ether, April 12, 1884. The first menstruation following operation was accompanied with only slight pain at first. After that all dysmenorrhœa ceased and after appropriate treatment the endometritis ceased. Dr. L. wrote me in November that she was pregnant.

CASE VI.—Mrs. J., æt. 22 years. Married three years. Sterility and dysmenorrhœa. Operated June 22, 1883. Permanent relief of the dysmenorrhœa. She became pregnant in December of same year.

CASE VII.—Miss L., æt. 20 years. Intense dysmenorrhœa since puberty. Operated February 27, 1883. No return of pain.

CASE VIII.—Miss R., æt. 18 years. Intense dysmenorrhœa since puberty, worse at times. Operated March 4, 1884; ether. No return of pain.

CASE IX.—Mrs. F., æt. 27 years. Married seven ears. Sterility and dysmenorrhœa, due to stenosis and acute anteflexion. Operated upon March 20, 1884; ether. When last seen, November 25, there had been no painful menstruation since operation, and she was pregnant.

CASE X.—Mrs. A., æt. 24 years. Married five years. Has suffered from painful menstruation always, and has had no children. Stenosis with retroflexion. Operated upon May 17, 1884; ether. Complete relief of dysmenorrhœa followed the operation. She was pregnant and expects to be confined some time this summer.

The above ten cases have been taken at random from my case-book, and will serve to illustrate what we wish to show just as well as if the whole number were given, and much valuable time and space will be saved by limiting the number.

Out of forty cases operated upon, the dysmenorrhœa has always been relieved, except where dependent upon ovarian disease. And in such cases no positive result is expected, and no such promise is made the patient. The operation has been performed in cases in which ovarian enlargement existed to a slight degree without lighting up any trouble, but the practice is not advocated. No unfavorable symptoms have followed any of the operations, except in one case in which a sharp cystitis occurred on the fourth day after, which may have been produced by pressure of the vaginal tampon on the base of the bladder, but the patient had suffered with attacks of it before. It was easily controlled.

Sterility, if dependent wholly upon the stenosis, is overcome by the operation; but if endometritis exist, conception cannot take place until this is cured. But this is easily accomplished after dilatation, unless it be secondary to ovarian disease, which is often the case. Then a cure need not be expected unless the ovarian disease be curable.

243 WEST FIFTY-FOURTH STREET.

MEDICAL PROGRESS.

CALCAREOUS DEGENERATION OF THE HEART.—At a meeting of the Société Medicale des Hôpitaux, held March 13, 1885, M. A. ROBIN reported a case of calcareous degeneration of the heart.

A man, aged 85, vigorous, and having always had excellent health, entered the infirmary complaining of diarrhœa. The heart on examination presented nothing abnormal, the arteries were atheromatous.

He went out cured, but a few days subsequently he was brought back suffering from a right hemiplegia without loss of consciousness. The heart was found to be hypertrophied; its beats dull and irregular. Death soon occurred. Autopsy showed the heart to be overladen with fat, though the man was emaciated. The valves were normal. Upon the interventricular wall from the top to the bottom of the left ventricle a calcareous plate extended, an eighth of an inch in thickness. The coronary arteries were much retracted by the thickening of their walls, but the patient never had presented any of the symptoms of angina pectoris. Microscopic examination revealed hypertrophic sclerotic myocarditis, and a calcareous infiltration of the endocardium to the level of the interventricular wall.

Notwithstanding the indications which Haller and Renoudin consider peculiar to calcareous degeneration, and in spite of the assertion of Laennec, that in this pathological condition heart murmurs can be distinguished at a distance from the patient, recent observations reveal the latest character of this lesion, save, in the present instance, that the sounds of the heart were muffled and remote. There was no symptomatology whatever, which could be explained by the lesions discovered after death.

The case is interesting, as showing that extensive anatomical lesions, if they do not implicate the valves, may exist in the heart without interfering with their action or preventing contraction of the heart muscle.—*L' Union Médicale*, March 17, 1885.

Occlusion of the Trachea by a Caseous and Relaxed Bronchial Gland.—Prof. Petersen-Kiel, in the *Deutsche med. Wochenschr.*, of March 5th, publishes an interesting case of plugging of the trachea by a caseous bronchial gland. As but few cases are recorded in which the entire lumen of the trachea has been closed by a suppurating gland and respiration rendered impossible, the history is of special interest.

The child, aged six years, had a history of hereditary tuberculosis, but externally showed no indication of scrophulosis, and had recovered from a severe attack of measles, and subsequently from an attack of German measles complicated with bronchitis. Since her last illness, however, her health was not so good, and she was subject to frequent attacks of asthma, which progressively became more severe. At last, she was brought to the hospital, and the dyspnœa was so severe that death was imminent, and tracheotomy was hurriedly decided upon, and performed. As a result of the operation, the breathing became but little easier, and it was evident, therefore, that the obstruction was below the incision.

In order to determine the exact condition, Prof. Petersen-Kiel then introduced an elastic bougie into the trachea, which met with no obstruction until it reached the bifurcation. Upon withdrawing the bougie, crumbling masses of caseous matter were found adherent to it, whereby it was rendered clear that the impediment was due to a caseous gland. By means of a Nélaton's catheter, the end of which was cut off, a collection of cheesy matter, more or less calcified, was removed.

The breathing now became freer. No canula was introduced into the trachea, but the edges of the wound kept open by silk stitches. The child soon fell asleep. During the night following the operation, more caseous matter was evacuated in efforts of coughing. The patient recovered without accident, and the wound made by operation healed in twenty-three days. No abnormal condition existed in the lungs, and the portions of the glands evacuated contained no tubercle bacilli.

Fracture of the Urethra.—Professor V. Dittel, in the *Wien. Med. Blätter*, 1885, No. 2, reports the occurrence of this rare accident during the preceding year. The patient, a man aged thirty years, came to the clinic, relating that he four days previously had struck his penis, during erection, against the symphysis pubis of his wife. Severe pain was at once felt throughout the entire organ and on attempting to urinate, burning was experienced at a localized spot in the urethra.

The following day the entire penis was much swollen and urination very painful. The swelling persisted in spite of the application of Goulard's extract, and the man came to the hospital for treatment.

Examination showing normal capacity of the urethra. Retention of urine had persisted for thirty hours and the bladder was much distended. The penis was very much swollen. In the perineum corresponding to the bulbar portion of the urethra, on pressure a very sensitive spot was found. A Nélaton catheter, at this situation, entered a small opening and was only introduced into the bladder after manipulation. Notwithstanding an incision was made, the day following, urinary infiltration became more considerable, and on the fifth day a scrotal incision along the entire raphé was necessary and the bulbar portion of the urethra was found to be completely torn through. The ends were separated about one-fifth of an inch and were perfectly smooth. The edges of the wound were united by suture, but did not come into exact apposition. The urethral and scrotal wounds healed under iodoform dressings. Some time subsequently a secondary suture was introduced into the urethra. A small fistulous opening persisted however, which, while it diminished in size, failed to close entirely. In this condition the man was discharged.—*Centralbl. für die Gesammte Therapie*, March, 1885.

Treatment of Trichinosis.—Dr. Gottlieb Merkel reports a case of a man who had eaten some raw sausage. After eating it, he received a dispatch stating that as several persons in the house of the butcher from whom the sausage was bought were sick, it was probable the meat contained trichinæ. He had as yet felt no ill-effects from eating the meat, but came wishing to be certain whether it did or did not contain the parasites. Examination showed them to be present, and the patient at once entered a hospital. There had been no movement of the bowels since the ingestion of the sausage. Accordingly doses of the infus. sennæ comp., were administered in rapid succession to an aggregate of nearly ten ounces. This was followed first by solid, and then by thin and watery evacuations. In the latter several non-encapsulated trichinæ and fragments of the same were recognized. They seemed of more than ordinary size, though no peculiar characteristics were recognizable. The following day, along with a restricted diet, the patient was directed to take a tablespoonful of pure glycerine every hour. Fifteen tablespoonfuls were taken without any unpleasant symptoms, save a feeling of thirst and dryness in the mouth and fauces (which was relieved by draughts of seltzer water). There was no hæmoglobinuria, and only thin watery stools resulted. On the thirteenth day, the patient left the hospital. He reported subsequently that he remained perfectly well, while the other persons who had eaten of the same sausage had been seriously ill. The case is interesting as showing that prompt treatment of those eating infected meat may result happily, and that glycerine may be prescribed safely in large doses, and merits further trial as a remedy, notwithstanding the adverse opinion hitherto held as to its efficacy.—*Deutsches Archiv für klin. Medicin*, February, 1885.

THE EFFECT OF PAPAYOTIN IN DIPHTHERIA, CROUP, AND CROUPOUS MEMBRANE.—PROF. M. J. ROSSBACH, in the *Deutsches Archiv für klin. Medicin*, reiterates the views by him expressed four years ago concerning the action of papayotin in diphtheria, croup, and croupous membrane. He says: Papayotin is, indeed, as I said in my former publication, no specific against diphtheria and croup. It can not consequently cure all cases of diphtheria, especially those which have persisted for a long time, and in which the heart has grown weak, but it is the best means of dissolving the croupous and diphtheritic membranes which we at the present time possess, and its application opportunely made frequently renders tracheotomy superfluous, reduces the mortality incident to these diseases, and by removing the membrane, renders the danger of new infection less, and has a salutary effect upon the attending fever. Professor Rossbach insists that if these results are not obtained, an inferior preparation of papayotin has been used.

THERAPEUTIC USE OF TERPINE.—R. LEPINE, in the *Revue de Médecine*, of February, 1885, calls attention to the use of terpine as a therapeutic agent. Chemically it is the hydrate of turpentine. Like turpentine, it has direct action upon mucous membranes, the kidneys, and upon the nervous system.

Lepine holds the opinion that its use is preferable to that of the oil of turpentine, and considers it *par excellence* a true diuretic, having special action upon the renal epithelium.

Its action upon the bronchial mucous membrane varies according to the dose. The administration of the drug is very simple. Crystals of terpine are soluble in alcohol. In bronchitis it may be administered in alcoholic solution with the addition of a soluble syrup, and with white wine if a special diuretic effect is desired.

When larger doses are given in nervous subjects whose kidneys are normal, an astringent should be added to prevent diarrhœa. For this purpose the syrup of catechu is well adapted. Lepine has administered twenty-three grains daily for several days in succession without bad effect. If it causes vomiting, it should be given in enemata.

SUBCUTANEOUS BLOOD INJECTION.—PROFESSOR V. ZIEMSSEN, in the *Deutsches Archiv für klin. Med.*, at the conclusion of an interesting paper on the subcutaneous injection of blood, says that "the number of corpuscles in the blood of persons receiving the injection is increased. I am thoroughly convinced the simple procedure is practicable to every physician, so soon as he finds a person willing to supply the blood, which, in times of necessity or danger, is never difficult. The injection, moreover, is not in the least dangerous in its effects to the patient. In a few instances only—in phthisical patients—was there any resultant pain. This lasted only one or two days, and was accompanied by no other unfavorable symptoms. Cases of severe anæmia and chlorosis,—of anæmia after post-partum hemorrhage, due to severe wounds, and epistaxis, and intestinal hemorrhage (I lately had the opportunity to practise subcutaneous blood injection after enormous hemorrhage in typhoid fever), in leukæmia and pseudo-leukæmia, progressive pernicious anæmia, and in poisoning by noxious gases, give in practice, inducement to attempt the restoration of the blood without resorting to transfusion. Accordingly, it happens that transfusion is only tried at the last moment, consequently is seldom or never of any benefit.

Upon repeated blood injection, in many chronic blood diseases, I can lay especial emphasis. Transfusion is a procedure much more advised than practised, and has never gained any considerable significance among the resources of practical medicine. Possibly, owing to its simplicity and freedom from danger, the method of blood renewal by subcutaneous injection will attain a greater popularity.

THE ETIOLOGY AND PROPHYLAXIS OF RACHITIS.—DR. J. COMBY, in a paper based upon extended clinical observation, reaches the following conclusions as to the etiology and prophylaxis of rachitis:

Etiology.—1st. Vicious alimentation of the new-born is the extensive cause of rachitis.

2. By vicious alimentation is meant all aliment other than mother's milk given to the child before the age of one year.

3. Vicious alimentation includes also the milk of the mother when given at improper intervals—when too frequent, or when the milk is poor in quality.

4. The most certain means of producing rachitis is by feeding the child with pap, porridge, or other food, except milk.

5. Artificial nourishment from a bottle with a long tube is a very frequent cause of rachitis. The use of a bottle without a tube, or simply of a glass, or a cup, is less dangerous.

6. Merely nursing, in order to avoid the troubles of artificial feeding, not infrequently produces rachitis.

7. Premature weaning is an infrequent cause of rachitis.

Prophylaxis.—1. Natural nursing is the most certain means of preventing rachitis.

2. Suckling, to have this effect, should be well-regulated (six or seven times in twenty-four hours), exclusive and prolonged. Under these conditions, if the milk is of good quality, rachitis is seldom observed.

3. In case necessity compels mixed-nursing the bottle should be avoided, and the infant should receive the milk directly from a glass or cup, and at intervals of at least three hours.

4. If artificial nursing alone is possible, the milk should always be of good quality, pure, or almost pure, warm, but not boiled, and always given without the bottle.

5. The infant should receive six or seven times a day from three to four ounces of milk, according to its age or development.

6. Under no pretext should there be given to a child naturally suckled mixed or artificial diet, or any food except milk, before it has attained the age of one year.

7. Weaning should not be attempted previous to this age, and alimentation immediately succeeding should be carefully selected.

By following these rules, which are applicable to the great number of cases, the conditions under which rachitis, or at least its more serious manifestation may be avoided, are best secured.—*Archives Générales de Médecine*, March, 1885.

Treatment of Scabies.—Grigorjew, in the *Sborn Kavkask. med. Obcht.*, No. 38, recommends the following treatment of scabies:

Iodoform	℥j.
Cerat simp.	℥iss.
Ol. oliv.	q. s.
Ft. Ung.	

The treatment comprises two periods. In the first, the patient is plunged into a hot bath, and rubbed for half an hour with black soap. The above ointment is then applied. Two baths and two inunctions are necessary to destroy the parasite. The second period is devoted to the consecutive treatment of the disease, this is limited to the application of the ointment once or twice a day to the painful portions of the skin. This treatment is continued five or six days.

According to Grigorjew, the advantages of this method of treatment are the following:

1. The rapid destruction of the parasites and their eggs.

2. Diminished sensitiveness of the skin, and, therefore, the prevention of itching so troublesome in the disease.

3. Absence of irritation of the skin.

4. Speedy cure of the eczema consequent upon the disease.—*L'Abeille Médicale*, March 23, 1885.

Antiseptic Properties of Citric Acid.—The experiments of Schaltz, detailed in the *Journ. d'hyg. e Farmacista italiano*, show that citric acid possesses very powerful antiseptic qualities. Pieces of meat placed in a five per cent. solution of the acid, after five days were removed in a perfect state of preservation. Fresh meat put in a one per cent. solution was disorganized without emitting any fetid odor. Schaltz, pursuing his investigations still further, found that a solution of the acid of 1 to 1000 exercises prompt germicide effect upon vegetable organisms. The salts of citric acid, however, seem not to possess the same antiseptic properties. Thus, meat put in a five per cent. solution of citrate of soda, putrefied as rapidly as in pure water.—*Gazzetta Medica di Torina*, March 5, 1885.

Bacteria Two Hundred Years Ago.—The Amsterdam *Allgemeen Handelsblad* publishes a communication from Professor E. Cohn, of the University of Breslau, who recapitulates the substance of a correspondence of the celebrated naturalist Leeuwenhock with Francis Aston, of London, a member of the Royal Society. Leeuwenhock, writing from Delft, in 1683, reports that among the *débris* of food remaining between his teeth he had discovered, with the aid of the microscope, living organisms moving with great activity. He distinguishes various kinds among them, which he describes so precisely that they would be easily recognizable. One, which occurs least frequently, resembles a rod, the bacilus; others, twisting in curves, are bacteria; a third kind, creeping in snake fashion, is the vibrio ugla; another kind, of extreme minuteness, resembles a swarm of flies rolled up in a ball, and is evidently the micrococcus. Its movements cannot be traced with certainty. He says that this species seems to be made up of parallel threads, varying in length, and remaining immovable, while other specks move in and out through the web. Leeuwenhock marvels that these things could live in his mouth, notwithstanding his systematic habit of cleansing it. He instituted observations which showed that they were also to be found in the mouths of other persons. Some years later he could not discover any traces of those minute organisms, and he was led to attribute their disappearance to the use of hot coffee. But shortly afterwards he rediscovered them as lively as ever. In September, 1692, he sent some sketches of them to the Royal Society. Professor Cohn observes that it would seem from this correspondence that the knowledge concerning those minute entities made no advance for nearly two centuries, and he remarks on the wonderful skill with which Leeuwenhock used the imperfect instruments of his time.—*London Medical Record*, March 16, 1885.

Gastrotomy and Œsophagostomy for the Removal of Foreign Bodies.—Prof. Billroth, in the *Allgemeine Wiener med. Zeitung*, of February 24, 1885, reports two cases in which œsophagostomy and gastrotomy were severally performed for the removal of a foreign body. In each case a set of artificial teeth was swallowed, and necessitated operation. The history of the case in which gastrotomy was performed is as follows.

The patient—a girl nineteen years of age—while asleep swallowed her artificial teeth. All efforts to extract them were fruitless and they finally passed into the stomach. Gastrotomy was performed and the whole hand was introduced into the stomach, but the foreign body was not discovered. Prof. Billroth accordingly enlarged the incision in the abdominal wall and searched the entire abdominal cavity for the teeth, but again failed to discover them. Search was now made in that portion of the stomach posterior to the gastro-splenic ligament, and adjoining the vertebral column.

This part of the stomach, owing to its position and attachments, cannot be withdrawn from the abdominal cavity from such an incision as had been made, and therefore had escaped examination.

Prof. Billroth now renewed the search with both hands and the foreign body was discovered and extracted.

The patient recovered with no bad symptoms.

Bullet-wound of the Liver; Extraction; Recovery.—Dr. W. F. Smartt reports a case of bullet-wound involving the right lobe of the liver, in which the ball was extracted and the patient recovered. The weapon from which the shot was received was a revolver, carrying a bullet weighing eighty grains. The shot was received at a distance of about three yards.

When first seen, at 6.25 A. M., the patient was in a state of extreme collapse, and his shirt was saturated with blood. A wound was found over the sixth rib of the right side, about one inch from the sternum. A probe passed for a distance of about one inch and a half, in a downward and outward direction, to the intercostal space between the sixth and seventh ribs. Pressure over the epigastrium gave rise to considerable pain, more especially at a point opposite the junction of the cartilages of the seventh and eighth ribs. It was, therefore, concluded that the bullet must have penetrated the abdomen.

Having administered fifty drops of laudanum in an ounce of brandy, Mr. Smartt operated, without an anæsthetic. The patient was placed on his left side, the skin was drawn well down over the edge of the ribs, and an exploratory incision, two and a half inches in length, was made through the skin and subcutaneous cellular tissue, over the edge of the cartilage of the eighth rib. When the finger was used as a probe through this opening, the circumscribed pain above mentioned was much more severely felt. Mr. Smartt cut down through the abdominal wall, and was then able to feel a slight elevation on the surface of the liver. On cutting to about the depth of half an inch into its substance, the knife struck the bullet, which was easily extracted with a small pair of artery-forceps. The wound was then well swabbed out with a 1 in 20 solution of carbolic acid, and its edges were brought together with fine carbolized silk ligatures. Dry iodoform, with a pad of marine lint, was used as a dressing; and a broad bandage was firmly placed round the abdomen.

A pill containing one and a half grains of opium, and half a grain of calomel, was ordered to be given every hour for three doses.

At 2 P. M. the patient was in a state of utter collapse. Enemata of brandy and beef essence, in arrow-root starch, were ordered to be given every hour.

A 4 P. M. he had rallied somewhat. He had not passed urine since 4 A. M., and eighteen ounces of high-colored, but otherwise healthy, urine were drawn off.

With the exception of slight pain and tympanites, no unfavorable symptoms were manifested. In two days the urine was passing without difficulty, and the temperature at no time rose above 100° F. Eighteen days from the reception of the injury the patient was discharged, able to attend to his usual work.—*British Medical Journal*, February 21, 1885.

Germicide Treatment of Lupus by Mercurials.—Dr. Ch. Éloy reports a case of lupus in which the patient refusing treatment by the ordinary method, resort was made to mercurial treatment.

The lesions of the disease in the case under consideration were superficial and easy of access, and therefore epidermic applications only were made. A plaster analogous to that suggested by Unna was ordered, of which the following is the formula:

℞.—Hydrarg. chlor. corros. . . gr. 15
Potass. sulpho-ichthyolatis . . ʒiiss.—M.

The border of the plaster extended beyond the marginal zone of the ulceration about one-half inch, and it was directed to be renewed every twenty-four hours until suppuration was well established—and at each renewal the diseased surface was washed with a solution of corrosive sublimate of 1 to 300. Within twenty-four hours there was evident an erythematous swelling about the borders of the diseased tissue the whole tumor had assumed a dark and escharotic appearance, and the patient complained of a very severe smarting sensation. A carbolized poultice was now applied, with the result that the eschar sloughed and left a bare suppurating surface.

The following days—morning and evening—the ulcerating surface was covered with compresses of gauze soaked in corrosive solution of the strength of 1 to 1000, overlaid with wadding and held in position by bandages. The swelling which followed the application of the ointment soon disappeared and a slight desquamation of the epiderm succeeded. Moderate suppuration continued, gradually decreasing however, and in eighteen days the entire ulcer cicatrized. As an adjuvant to the local treatment, Fowler's solution was prescribed internally as recommended by Doutrelepont.

Under the mercurial treatment there were no symptoms of mercurial poisoning, no tendency even to salivation being noticed. Slight pain and congestion of the parts adjoining the diseased surface were the only ill-effects observed during the application of the ointment. Examination of the cicatrix showed it to be healthy, with no signs of a return of the disease. The general condition of the patient is much improved, and she still continues the use of arsenic tonics and cod-liver oil. At the end of nine months there has been no return of the disease, and the method of treatment deserves further attention.

The method of treatment by cauterization requires apparatus and skill on the part of the operator, while the method by scarification is still more inconvenient and chemical cauterization, according to Unna, is a last resort and not a method of treatment properly so-called. If therefore more extended trial confirm the result here attained and show the use of the remedy to be free from danger, the germicide treatment of lupus will put into the hands of the physician, not a specialist, a powerful and at the same time a convenient means of curing a disease hitherto most rebellious to treatment.—*L'Union Medicale*, March 24, 1885.

The Effect of Antipyrin.—Dr. Götze, in the *Berliner klin. Wochenschr*, of March 9, 1885, says, apropos of his experience with antipyrin, that generally it may be used in febrile diseases, such as typhus, pneumonia, exudative pleuritis, phthisis, diphtheria, and facial erysipelas with good results. In a few instances only does it produce, along with the lowering of the temperature, such excessive sweating as to render its use inconvenient. Vomiting also is sometimes caused by its administration, when other remedies, such as naphthalin and chinolin, have been well borne. In some instances it is entirely inoperative, the temperature having even been observed to rise during its administration. On the other hand, it sometimes produces such a rapid decline of temperature that alarming symptoms of collapse are observed, such as cyanosi; feet, ears, and nose cold; pulse small, and with difficulty felt at the wrist.

The weakness of the heart observed, Dr. Götze ascribes to the reduction of temperature, and not to a direct effect of the drug upon that organ.

The exanthem, which appears as a result of the administration of the drug, the writer has observed, in all in five cases, in all of which the disease was typhus fever, and in which, with one exception, the drug was given in oft-repeated doses of seventy-five grains. Excessive itching in one case accompanied the eruption.

Dr. Götze remarks, in conclusion, that in no case has he observed the course of any disease shortened by the use of antipyrin, and that in severe general infection, not only the fever, but the remaining symptoms fail to be influenced by the drug.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, APRIL 18, 1885.

THE CORROSIVE SUBLIMATE TREATMENT OF WOUNDS.

We have on more than one occasion directed attention, in the columns of The Medical News, to the advantages and risks of corrosive sublimate as a germicide in obstetrical and surgical practice, and we have not hesitated to express the opinion that, when judiciously employed, it constitutes the surest, safest, and most manageable of all antiseptic agents. In obstetric practice, especially, its use by injection has been followed by salivation, vomiting, tenesmus, diarrhœa, erythema, and other signs indicating its toxic action in not a few examples, while acute poisoning, ending in death, has been observed by Schroeder, Stadfeldt, Winter, and Vöhtz. In these cases the solutions varied in strength from 1 to 1500 to 1 to 750, and as toxic symptoms and sudden collapse have been observed in similar cases after the injection of solutions of carbolic acid, we may infer that the puerperal genital tract affords a more favorable condition for the quick and dangerous absorption of these agents than any other cavity of the body or any surgical wound.

The bad effects witnessed by obstetricians have not, as a rule, been seen by surgeons after the use of sublimate, and its safety and efficacy are fully demonstrated by the thirty months' experience of Schede, of Hamburg, whose results are published in *Volkmann' Sammlung Klinische Vorträge*, No. 251, 1885. Thus, of 1286 accidents and surgical wounds, 64, or 5 per cent., were fatal, of which only 1 was due to the toxic effects of the remedy. Of 1222 recoveries, union by the first intention was met with in 935, and by the second intention in 278, the parts having failed to unite in 9. Of the entire number, 91 were major amputations, inclusive of 6 at the hip-joint; 117 were resections of the larger joints; 24 were resections of the continuity of the bones; 81 were osteotomies; 16 were cuneiform tarsotomies; 17 were complicated fractures of the skull; 74 were complicated fractures of the long bones; 69 were examples of irrigation of the joints for dropsy, suppuration, and effusion of blood; 13 were cases of drainage of joints; and 84 were herniotomies and operations for the radical cure of hernia. There were, also, 25 ovariotomies, 8 vaginal hysterectomies, 3 nephrectomies, 8 resections of the intestine, 52 amputations of the breast, 162 extirpations of lymphatic tumors and glands, and 149 excisions of other neoplasms.

These results, and we believe them to be the best attained by any surgeon, were brought about by the use of a 1 to 1000 solution for the hands of the operator, the skin of the patient, the sponges, and the drainage-tubes, of a 1 to 5000 solution for irrigation of the wound, and an outer dressing of moss wrung out of a 1 to 500 solution and enclosed in gauze wrung out of a 1 to 200 solution of glycerine and water. Although the glycerine doubtless mitigated the action of the sublimate in the gauze applied over the wound, we believe that the strength used was accountable for the not infrequent excoriation and pustules seen at the first change of the dressing. In four cases an eruption, precisely similar to that of scarlatina, was met with, which was attended with a severe burning pain, and exhibited a tendency to diffuse itself over the entire body. In only one instance, the case being that of an anæmic female in whom supravaginal hysterectomy was practised, was death due to the agent. The single death out of 1286 cases cannot, however, be used as an argument against the use of the corrosive chloride of mercury, when we consider the number of lives that must have been sacrificed had it not been used.

In connection with the experience of Schede, we trust that the surgeons of the New York Hospital may be induced to publish an account of their mode of employing corrosive sublimate, since Dr. Peabody, Pathologist to the Charity, states, in *The Medical Record* for March 14, that the records of that institution show eleven cases of poisoning, with seven deaths, during the past eighteen months. The case of opening a suprahepatic cyst may, we think, very properly be excluded, as the patient suffered from nausea, headache, and partial suppression of urine before the use of the bichloride, and the sac was irrigated with a 1 to 5000 solution. Of the remaining six, one was a compound fracture of the bones of the leg, with amputation four days after the treatment was begun; three were abscess cavities; one was an amputation of the breast with removal of the axillary contents, and one

was a laparotomy for uterine myoma. In the first case a 1 to 1000 solution was employed; in the remainder a 1 to 2000 solution was used. If the irrigation was resorted to continuously during the operation, we do not hesitate to say that the solutions were too strong, since the continuous washing of the wound is not safe with a solution stronger than 1 to 5000. In the vast majority of operations, indeed, we see no necessity for continuous irrigation with even a weak solution, as a careful washing with a 1 to 1000 solution at the completion of the operation answers every purpose.

REMOVAL OF THE CANCEROUS UTERUS.

THE question of the removal of the cancerous uterus seems very well determined so far as method is concerned, since statistics prove that vaginal extirpation is much less fatal than extirpation by abdominal section. But still the question arises,. Is any mode of removal proper?

This subject was recently discussed before the London Obstetrical Society, in a paper by DR. W. A. DUNCAN, containing the report of two cases in which the operation was done. One of the patients had an epithelioma involving only the anterior lip of the womb. The operation—vaginal removal of the uterus—was done in January, and the patient died in November from reproduction of the cancer immediately above the vaginal vault. This was not a case calling for so dangerous an operation, when the simple removal of the vaginal neck would have taken away all the diseased structure. The second patient died twelve hours after the operation.

In the discussion which the reading of the paper elicited, Dr. John Williams stated that he had done the operation four times, and the only patient who recovered died a month after from fecal fistula. Mr. Knowsley Thornton declared his preference in cancer of the cervix for amputation followed by the application of the chloride of zinc. Mr. Doran in support of the position that there were anatomical reasons against the extirpation of the cancerous uterus, stated that Mierzjeewsky and Lebee had shown that in the connective tissue between the body of the uterus and the peritoneum there is a dense network of lymphatics, whilst two wider lymphatic plexuses form a collar round the uterine and vaginal portions of the cervix. The lowest of these communicates freely with the vaginal lymphatics. All these networks form and empty themselves into three large trunks running to the obturator gland, passing along the lower border of the broad ligament. Early enlargement of this gland is observed in cancer of the cervix, and the extension of the disease readily follows. He asserted that it was, therefore, impossible to remove all the affected lymphatics.

Sir Spencer Wells hoped the operation would not be condemned, and thought that there was still much to learn in the details of vaginal hysterectomy; and improvement, both in early diagnosis and in early operation, may give a much lower mortality, retarded return, or even complete recovery. Dr. Edis regarded hysterectomy for cancer justifiable by a mortality of only 28.6, which was no greater than that of ovariotomy in the early days.

A very valuable contribution to this subject may be found in a late number of the *Zeitschrift für Geburtshülfe und Gynäkologie*, by HOFMEIER. It embraces a period of ten years, and includes 812 cases. Comparing these figures with the numbers of all female patients with disease of the genital organs found respectively in private and in hospital practice, it is shown that cancer is much more frequent in the working class. It is also shown that since twenty-one per cent. of those affected were nulliparæ, the importance given by some to tears of the neck of the womb in childbirth in the etiology of the disease is exaggerated, if not doubtful.

In nearly one-half of the cases the part of the uterus first affected was not known, but in the others it was found that this was most frequently the vaginal portion of the neck, the neck next, while in only 3.4 per cent. was the disease primarily in the body of the womb. The average ages of these three classes were forty-two, forty-seven, and fifty-two and a half years. In 160 cases, or 19 per cent., the radical cure was attempted. When the disease affected the vaginal portion of the cervix, supravaginal amputation was done through the vagina; in cancer of the body of the cervix, extirpation of the uterus, at first by Freund's, later by Czerny's method was performed; while in cancer of the body, abdominal supravaginal amputation was selected. 19 per cent. of the patients died in consequence of the operation, the mortality being, for example, as high as 62 per cent. in Freund's method, while vaginal extirpations gave only 26 per cent. of deaths. It may be stated, in this connection, that Staude, of Hamburg, according to the *Centralblatt für Gynäkologie*, has had sixteen vaginal extirpations of the uterus without a single death.

Hofmeier's statistics show that after two years 80 per cent. of those treated by supravaginal abdominal amputation remained well, 33 per cent. each after Freund's operation and after vaginal extirpation, 32 per cent. after supravaginal and vaginal amputation, and 42 per cent. after amputation by the actual cautery. After four and five years there were respectively eight and three per cent. who remained free from return of the disease.

The subject has recently been discussed by the Paris Academy of Surgery, according to the *Journal d'Accouchements* for February, in connection with a report of two cases by Terrier in which he had per-

formed vaginal hysterectomy, one of the patients dying, the other recovering. Desprès took the ground that the operation was impracticable, and that survival proved the disease was not cancer. Berger stated that even in Germany there was a current of opposition to the operation, the return of the disease being so frequent that the chances of success did not balance the dangers of the operation. He called attention to a case recently operated upon by Boeckel in which a wound of the ureter required nephrectomy, and a return of the disease occurred in three months. Polaillon asserted that cancer of the neck rarely involved the body of the womb, and referred to two cases in which the diagnosis was made by Cornil, one patient surviving two, the other five years. Of course, as observed by Terrier, when an error in diagnosis, or the impracticability of the operation was asserted by Desprès, discussion was at an end.

In the *Gazette Médicale de Paris* of February 14th and 21st, Sébileau gives a much more favorable view of the subject. He holds that the operation should be performed, because, if it be not, certain death, ordinarily very rapid from the progress of the disease, very severe suffering, and disgusting infirmity, making life utterly miserable, are sure to ensue. After the operation, in some cases there is a long survival, in some cases the radical cure results, and if the disease returns, lessening of pain and of accidents ensues. In each case physical comfort and moral calm for some months are obtained. On the other hand, the reasons against the operation are its inutility, the disease often returning, and its dangers and difficulties. As stated by Sébileau, these questions must be determined by statistics; so far as the mortality of the operation is concerned, those of Demons and Doche show that it is only 28 per cent.

He observes that the question of colpohysterectomy, reserved for cases in which amputation of the neck was not possible, has been settled in the affirmative in Germany and Italy, and suggests that this will probably soon be the case in France.

We have thus presented the most recent views—British, German, and French—upon this question. We need only add, using the language of Sir Spencer Wells, that the operation should not be condemned. The weight of testimony so far is in its favor, but it must be remembered that the extirpation of the uterus is not to be done when the disease is limited to the intravaginal neck, for then amputation is the proper operation. Moreover, as stated by Hegar and Kaltenbach, the uterus must be quite mobile, bimanual examination should prove that there is no infiltration in the vagina, the broad and the utero-sacral ligaments, and there should not be in the pelvic connective tissue any bead-like nodosities.

IDENTITY OF MICROCOCCI IN DIFFERENT DISEASES.

It must be a relief to those who have been confused, if not confounded, by the many diseases alleged to be dependent upon different microscopic organisms, to learn that the same micrococcus has been found in different diseases; thus Aufrecht, of Magdeburg, according to the *Révue Medico-Chirurgicale des Maladies des Femmes* for January, stated at the last meeting of the German Society of Naturalists and Physicians, that in croup, diphtheria, and pneumonia, the micrococcus was identical. Further, in a case of diphtheritic endometritis he found the same micrococci as in pneumonia. In two patients who had pneumonia, one in the sixth, the other in the eighth month of pregnancy, one dying two days after miscarriage, the other three days after premature labor, there was found in each, at the placental site, a diphtheritic endometritis, and the same micrococci were observed in the first case. Experiments were made upon pregnant rabbits by injecting a solution made from a portion of the triturated pneumonic lung; the animals miscarried and died, and the pus found in the pericardium, peritoneum, and at the placental site, contained micrococci similar to those found in pneumonia. The same results were obtained when pneumonic sputa were used, instead of the lung tissue, thus proving that the cause did not arise from post-mortem changes. The liquid obtained from trituration of a fragment of the liver of a rabbit destroyed as stated, was injected into another pregnant rabbit, and with the same effect. On the other hand, when solutions containing the bacteria of putrefaction were injected, only a local abscess resulted.

If the identity of the micrococcus of pneumonia, of diphtheria, and of puerperal fever be admitted, it is possible, as many have held, that puerperal infection may occur through the respiratory organs. Certainly this hypothesis might explain the occurrence of some of the cases of so-called autogenetic puerperal septicæmia. As held by Aufrecht, this much is plain, that lying-in women should be separated from patients suffering with croup, diphtheria, or pneumonia.

We may add that Hartz stated that the same diplococcus is found in cerebro-spinal meningitis as in diphtheria.

HOUSE-TO-HOUSE INSPECTION.

House-to-house inspection for the purpose of discovering and correcting sanitary defects on private premises is just the kind of work that should be undertaken and vigorously pursued at the present time, not only in anticipation of cholera but of other diseases of the preventable class, which have their contributing or predisposing cause in filth. The most essential condition in the prevention of these diseases is cleanliness, and this can be enforced on

private premises in no better way than by a rigid inspection of every nook and corner of the domiciles of the people. A number of cities have already organized a plan of domiciliary visitations, and, in one notable instance, that of Illinois, a sanitary inspection of this character has been instituted for an entire State

While carrying on this commendable work upon private premises, the sanitary authorities should not overlook the dangers to the public health that are liable to arise from the want of a pure water-supply, from neglect to provide for the proper cleanliness of the public ways and places, for the prompt and complete removal of refuse matters, for the removal of all effluvium nuisances, and for the careful inspection of the food supplies. There should be no delay in inquiring into the efficiency of existing arrangements, and in correcting defects and supplying deficiencies wherever discovered. A judicious, energetic, and extended effort made at the present time by the sanitary authorities in behalf of the preservation of the public health, will certainly reduce the quantity of preventable disease, if it do not entirely avert an epidemic visitation. But something more than a mere spasmodic effort is required to secure durable results. Persistent activity is necessary in order to make headway against the constantly recurring causes of preventable disease.

Preparation should also be made to meet promptly the incipient cases of epidemic disease, so as to limit its progress, if not to stamp it out at once. Provision for medical supervision and the isolation of these cases, and the disinfection of clothing, house, and premises should be prearranged, so that no valuable time may be lost. In the event of an outbreak of sickness, house-to-house visitations by medical officers in districts where there is a suspicion of the concealment of cases will be of great advantage in checking the spread of disease.

LAPAROTOMY IN ACUTE PERITONITIS.

AT a recent meeting of the Royal Medical and Chirurgical Society, the proceedings of which may be found in the *British Medical Journal* for March 14th, MR. TREVES reported the case of a woman, twenty-one years of age, in which the belly was successfully opened and freely irrigated with water, and a drainage tube inserted, on account of diffused peritonitis, the result of the bursting of a pelvic abscess. Mr. Marsh also read the notes of a case of a medical student, nineteen years of age, suffering from critical symptoms of sudden and acute peritoneal inflammation, in which incision gave vent to about two pints of fetid pus. The abdomen was thoroughly washed out with a 1 to 60 solution of carbolic acid, and a drainage tube introduced. Under subsequent injections of a solution of iodine, 1 to 1000, the patient recovered.

In the discussion which followed the reading of Treves's paper, Bryant, Thornton, Powell, Barwell, Goodhart, and Meredith were in perfect accord in commending the practice carried out in the two cases noted. The conviction, indeed, appears to be gaining ground that, in view of the great fatality of acute diffused peritonitis, and the futility of ordinary modes of treatment, laparotomy should be resorted to, thereby placing effusions into the peritoneal cavity on the same footing as pleural effusions. Its success in cases of peritonitis complicated by the presence of an ovarian tumor has long been established; and Mr. Lawson Tait states, in the *British Medical Journal* for March 21st, that he has opened the abdomen in not less than 44 cases on account of peritonitis, and that 41 recovered.

In support of the wisdom of the practice, we may refer to a successful laparotomy, reported by Mikulicz, at the *Versammlung der Deutscher Naturförscher und Aerzte in Magdeburg*, September, 1884, for suppurative peritonitis, the result of a perforating typhoid ulcer. Krönlein, too, has resorted to it for peritonitis due to perforation of the vermiform appendix, but with what result we are not informed. Indeed, we believe that we express the opinion of all thoughtful surgeons when we say that the operation is indicated in all cases of suppurative peritonitis from whatever cause it may arise, as well as in examples of ordinary acute peritonitis, the result of perforating lesions of the stomach and intestines.

THE AMERICAN MEDICAL ASSOCIATION.

SIXTEEN years ago the American Medical Association met in New Orleans, and in a short time it will again convene in the great commercial city of the South. The number in attendance at the former meeting was by no means as large as probably will be present at this. Then desolated homes and shattered fortunes demanded too much of the time of many Southern physicians to permit their attendance, while others had not yet sufficiently buried war memories to clasp hands in cordial greeting with their brothers of the North, so that many of each section failed to be present. But now no such obstacles are presented; we are once more heartily one people, and one profession. The Exposition too, will take many a doctor to New Orleans who otherwise might wait until the Association met nearer home. All things considered, we believe that the coming meeting will be well attended, and trust that its deliberations will result in good to the profession.

Just before the last meeting of the American Medical Association THE NEWS urged the importance of allowing each Section to select its own pre-

siding officers, instead of this being done by the General Nominating Committee. At this meeting, Dr. Foster Pratt, of Michigan, presented an amendment authorizing this change, and action upon it will be had at the coming New Orleans meeting.

We cannot believe any reasonable objection will be made to the adoption of the new plan, while the arguments in its favor are strong, and should not be neglected by those who are sincerely concerned for the welfare of the Association. Without referring to the evils which have in some instances resulted from the method hitherto pursued in the selection of these officers, it will be readily admitted that those who form a Section, are present at its meetings and participate in its work, are the best qualified to judge as to the men most worthy of its honors, most suitable to conduct its deliberations, and most acceptable to those whose affairs they conduct. The best men should be given office, instead of the offices being sought, and in some instances secured, by active, obtrusive medical politicians, while abler, but more modest men, men who truly represent the profession, are left in the background.

REVIEWS.

Lectures on Diseases of the Rectum. Delivered at the Medical Department of the University of New York. By J. Williston Wright, M.D., Professor of Surgery. 8vo., pp. vi. 170. New York: Bermingham & Co., 1884.

This little book is full of excellent advice in regard to the treatment of diseases of the lower end of the bowel, and can be commended as plain, practical, and full of common sense. The author's style is about what one might expect in printed lectures, and bears the mark of the intimacy and familiarity which usually exist between the professor and his pupils. This, in our opinion, however entertaining it may be in the lecture-room, is out of place in a book. Occasionally one finds lecturers who are such Chrysostoms that it would be impossible to improve on their style in their most unpremeditated lectures; but often, we believe, the records of a stenographer would prove rather shocking to a clinical lecturer. For, even when no great literary faults would be found, the freedom from restraint which often adds a decided charm to one who speaks "*en famille*," as it were, to a medical class, looks like looseness when it attains the publicity of print. Sometimes, indeed, there is a real laxness in a lecturer's style, and when his lectures are published one meets with expressions in them which are of questionable taste anywhere, and are decidedly indelicate in a book.

It is to be regretted that the useful and instructive book before us is open to this objection. It may have added to the author's attractiveness as a lecturer in the mind of the medical student, to speak of the "scratcher-ani muscles," but the use of such an expression detracts from his dignity as an author, when it is made indelible in print. We think, further, that when he comes to reflect upon it he will wish he had not printed the story on page 96, in which a joke is repeated which we think it is not too severe to call vulgar. This tendency to be funny, which is illustrated in other parts of the author's lectures is a very dangerous one, and especially dangerous in one who is discussing such delicate subjects as medical books sometimes treat of. Witticisms about parts or functions of the body which are unmentionable in polite society, are much admired by a certain sort of people, and will doubtless be supplied as long as there is an active demand for them. But we believe that, for a right-minded man, it can only be a slip which leads him to seem of this sort, and that to call his attention to the matter would always suffice to prevent his making a similar mistake in the future.

In the case before us it is to be hoped that the merits of these lectures will so commend them to the medical public that the author will shortly have an opportunity, in a second edition, to redeem them from the only blemish worth mentioning which we believe them to have.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, April 2, 1885.

The President, B. F. Baer, M.D., in the Chair.

The President exhibited the specimen and reported the case of a rapidly growing

OVARIAN CYST.

A patient of Dr. A. G. Walls, of Lock Haven, Pa., M. L., æt. 26, single, puberty at fourteen, always well, and possessed of a remarkably fine physique, tall and robust, felt some pain and uneasiness in the ovarian region three months ago. She was examined by Dr. Walls, who found the right ovary enlarged to the size of a large orange. She soon after found that her abdomen was increasing in size.

On March 9th, I saw her. She was beginning to show facial signs of ovarian disease in slight emaciation, pallor, and the peculiar distress of countenance. The menses were regular, the abdomen was distended to the size of the eighth month of pregnancy and was perfectly symmetrical, pyriform in shape, dull on percussion with a resonant corona, extending around from one flank to the other, and there was marked fluctuation. Vagina virginal, cervix uteri pointing slightly forwards, body retroverted and mobile. The lower border of the abdominal tumor could be touched per vaginam. The uterus was not affected by the movement of the tumor. *Diagnosis:* Ovarian cystoma. Immediate removal advised. *Operation:* Assisted by Drs. Walls, Hayes, and Lichtenthaler, in the presence of Drs. Watson and Ball. Incision two and a half inches, fat in abdominal wall at least an inch in thickness. Tapped the cyst, which contained a bucketful of a thick fluid the color of pus. Removed the collapsed tumor through the small incision—there were no adhesions—ligatured the short pedicle and dropped it. The left ovary was found to be as large as a walnut and undergoing polycystic degeneration; it was also removed. The incision was closed

with six silk sutures. The patient recovered without an untoward symptom.

The rapidity of the development of this tumor was remarkable, and justified me in bringing it before you. The other ovary is a beautiful specimen of beginning polycystic disease. It is a curious fact that of my last six ovariotomies in not one of them did the period of development extend over nine months from the time the disease was first discovered. One of them only three months, as just reported, from the time it was found by Dr. Walls to be the size of an orange. They were all good-sized tumors, two of them weighing nearly forty pounds each.

THE BROMIDE OF ETHYL AS AN ANÆSTHETIC IN LABOR.

DR. MONTGOMERY reviewing the various anæsthetics, said chloroform is objectionable in that it causes inertia uteri and tedious labor, and increases the danger of post-partum hemorrhage. The relatively infrequent fatal cases under its use in surgical practice and the still more rarely serious results from its use in obstetrics, forbid its habitual use. The use of ether in natural labor is infrequent, because to relieve pain the patient must be profoundly etherized. Partial etherization destroys the ability to bear pain without obtunding sensation. Besides, Tait has demonstrated that ether passes rapidly into the circulation of the fœtus, endangering its existence. The mixture of nitrous oxide and air, advocated by Klikowitsch, requires a special apparatus and is unwieldy. The ideal anæsthetic is one that is safe for mother and child, certain in its effects, rapid in relieving pain without producing loss of consciousness, and whose effects pass off quickly. All these demands are met by the bromide of ethyl. He enumerated 112 cases in which it had been used, twenty-nine of which were in his own practice; none of the mothers died, and but three of the children. In none of the latter could death be attributed to its use. It was administered during the second stage of labor by placing a napkin, wet with a few drops of the ethyl, over the face of the patient at the advent of each pain and withdrawing it as the pain subsided. Unless a drachm was used, the sensation of pain was obtunded without arresting consciousness. The process of labor was carried forward, vigorously, and quietly, the patient ready to exert or withhold voluntary aid as her attendant might direct, and the expulsion of the head was attended by no greater pain than accompanies the evacuation of obstinately constipated bowels. His experience did not lead him to believe that its use would induce inertia uteri or increase the tendency to post-partum hemorrhage.

DR. D. M. BARR is much interested in this subject, and thinks, from this report, that the indications for the usefulness of bromide of ethyl are favorable. He would like to know to what degree the patient returned to consciousness between pains. He will use bromide of ethyl as an experiment, but he will say here that his old combination still gives him the very best effects with perfect safety. He has continued to use it in almost every case of labor since his report on anæsthetics in labor, see *Medical and Surgical Reporter*, March 13, 1880. He would feel some hesitation in using the bromide of ethyl, as it is dangerous, even if not so much so as chloroform. How would it act if mixed with ether? The objectionable qualities of chloroform and ether balance and overcome each other, and the addition of alcohol to the mixture prevents their explosive action, so to say; that is, the sudden effect of a full and deep inspiration of the strong vapor of the anæsthetic is prevented by the admixture of alcohol in the proportion of: Chloroform, one part, by measure; ether, three parts; and alcohol, two parts. If a portion of this mixture be placed in a saucer and heated, it will all evaporate together; the ether does not pass off from the alcohol. This mixture soothes the pain and makes the patient happy. The excited or drunken stage of ether is avoided; the danger of chloroform is avoided; unconsciousness is unnecessary, and is not produced. If bromide of ethyl has any of the dangers of chloroform, they are unchecked by admixture with correcting agents. Dr. Barr related the particulars of a case in which he had employed this mixture to show how kindly it acted in presence of suspected functional heart disease. In this case its administration was continued for nine hours; the pain was relieved, there was no vomiting, no effect upon the pulse.

DR. R. P. HARRIS remarked that chloroform was considered perfectly safe as an anæsthetic in labor. Playfair, in his last book, advocates it on this ground; but there have been fatal cases. The danger of an anæsthetic can only be ascertained after it has been used and reported by many observers, so as to get an average. Some men are careful and cautious, but all are not. The use of mixed anæsthetics is becoming more general in England.

DR. W. M. WELSH, upon invitation, remarked that he had had no exprience with bromide of ethyl and but very little with other anæsthetics. He had given ether in one case, and a troublesome condition of intoxication had been developed. He was applying the forceps, and the patient suddenly seized one blade and wrenching it out of the vagina tore the vulva. He prefers to get along without the use of anæsthetics.

DR. HENRY LEAMAN, upon invitation, said that he also had no experience with the bromide of ethyl. He does not hesitate to use ether in bad cases of labor, but he does not employ it when he can avoid it. He is not yet convinced that the use of anæsthetics in natural labor is advisable. There has not yet been formulated a satisfactory definition of natural labor. He is now engaged in studying that subject. He has observed in private practice most of the positions described by Engelmann in his papers on primitive obstetric practice. The sympathetic system in labor reacts upon the cerebro-spinal system and produces the condition of nervous excitement which is seen in the patient, and which often extends to the friends of the patient and even to the doctor in charge of the case. After a close observation of over six hundred cases, he thinks labor can be as natural a physiological operation as respiration or the circulation of the blood, or any other function of the body, with this one difference, that whereas the ordinary performance of function is pleasurable, in labor pleasure is replaced by pain. He is not in favor of the use of anæsthetics merely to remove or obtund this pain, as it is natural; and anæsthetics may interfere with the natural process and cause relaxation or retard involution, resulting in that root of endless misery, a subinvoluted uterus.

Dr. Leaman has been making careful studies with a dynamometer, which measures the available pressure. He believes that it gives the sum of the pressure applied to the ovum expressed in the projection of the advancing part, against which it rests. He will continue these studies, which are not yet complete. The force of the accessory muscles, as the diaphragm and abdominal muscles, takes no real part in the expulsion of the fœtus, but merely embraces the uterus, preventing any rebound or loss of force when the ovum impinges against the pelvic walls or perineum, their action being to sustain or hold the uterus closely to its work. The entire force exerted is not nearly so great as is usually supposed. The force of labor does not exceed that of arterial pressure, which, I think, is about six pounds. The exit of the child is not violent, but gradual. It is a popular belief that a majority of labors occur at night, but, of his six hundred carefully recorded cases, an equal number were born between 6 A.M. and 6 P.M. and between 6 P.M. and 6 A.M. There are, however, two acmes, one at 11 P.M. and another between 7 and 8 A.M. These two periods correspond to the times of greatest blood-pressure. He ranges himself on the side of those who believe in the non-necessity of the use of anæsthetics in natural labor.

Dr. W. H. Parish would like to hear more particularly from Dr. Montgomery in his closing remarks respecting the safety of bromide of ethyl as an anæsthetic. A few years ago it was introduced into surgical practice in this city, and was abandoned in consequence of its dangerous character. If it is dangerous in surgery, why should it not be so also in obstetrics? Chloroform which was at one time considered perfectly harmless in the latter class, has been found to be no safer there than in ordinary cases.

He has established for himself three rules respecting the use af anæsthetics in obstetric cases:

1st. In easy normal cases no anæsthetic is required.

2d. If the patient is nervous, excited, and uncontrollable, he gives chloroform at the incipiency of each pain, to quit the excitability of the patient and take off the sharpness of the pain without producing unconsciousness; during the intervals between pains the chloroform is withheld.

3d. Whenever he considers that unconsciousness, full anæsthesia, is necessary, he employs ether, so as to avoid the depressing effects of chloroform. Bromide of ethyl might be used in place of chloroform, as indicated in his second rule, if shown to be equally safe; but he would not consider it proper to use it to produce complete relaxation as required for version or the application of the forceps. Prof. Wood, in his experiments, found bromide of ethyl more dangerous than chloroform. Dr. Parish does not now use it, and he fears it would go hard with any physician before our courts if he had a fatal accident occur during its use.

Dr. Barr thought Dr. Leaman's estimate of the force required to extrude a full term fœtus far below the mark. A child weighing seven pounds or over is pushed through a curved, horizontal, resisting passage, with irresistible power, and sometimes rapidity. A force of six pounds would not lacerate a perineum. In some cases there is but slight resistance, and the force required is small and the pain not severe. He has seen cows moaning from the severity of their pains during parturition. In one case recently, a cat was delivered of its first kitten after severe and prolonged pain, and the second kitten required three hours for its extrusion. The pains of labor are more easily alleviated than the pains of surgery by anæsthetics, and with no increase, if not a diminution, of danger.

Dr. Montgomery, in closing, said that as to danger from the use of bromide of ethyl, he thought there was no danger if a pure article was carefully used. The patient is not completely narcotized, consciousness is not lost, the administration of the drug is interrupted. The patient can coöperate, although relieved of suffering. She can answer questions. Prof. Müller is the only one who has failed in obtaining good effects, and this was probably due to impurity in the drug. Bromide of ethyl does not take the place of chloroform, nor does it produce muscular relaxation, nor relaxation of the uterus as required in version. It can be pushed to complete unconsciousness, but that is not necessary, as pain will be relieved without, while the contractions of the uterus and respiratory muscles are fully as effective as without it. Labor is undoubtedly a physiological process as much so as respiration or defecation, but it does hurt. It is the type of the most severe and agonizing suffering, and we as physicians are called on to relieve that suffering and prevent the waste of vital force to the extent that we can by preventing pain, long-continued pain. Bromide of ethyl is apparently entirely safe when given as I have used it. Experimental physiologists do not all agree with Prof. Wood as to the comparative danger of this and other anæsthetics.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 24, 1885.

The President, R. F. Weir, M.D., in the Chair.

NECROSIS OF THE LOWER PORTION OF THE FEMUR; EPITHELIOMA; AMPUTATION.

Dr. McBurney presented a specimen removed by amputation from a man thirty-five years of age, who had his first periostitis twenty-eight years previously. The bone was the seat of necrosis, as shown by the presence of a sequestrum projecting from the inner side of the thigh, and for a period of nine and a half years he had escaped surgical treatment. Sinuses had formed at different points, and finally an epitheliomatous mass developed at the inner side of the thigh, some four or five inches in diameter, through which the sequestrum protruded. There was great dislocation of the leg backwards, and the limb was useless. On dissection the artery was found lying in absolute contact with the specimen of dead bone. Fortunately no one had made sufficient strain upon it to cause hemorrhage.

Dr. Post remarked that probably if the sequestrum had been discovered and removed, the epithelioma would not have developed. Several years ago he saw a case of epithelioma, the result of a wound of the leg which had been received in the war, and which had remained unhealed.

The President remarked that he thought all had seen instances of epitheliomatous growth from long-continued bone injuries at the lower or middle portion of the tibia, but Dr. McBurney's specimen was the first

which he had seen where epithelioma under such circumstances had invaded the thigh.

FRACTURE OF THE PATELLA.

DR. SANDS was called in consultation three days ago to see a lady who had received, ten days previously, an injury while getting off a railroad car in the Grand Central Depot. She stepped from the car to the platform, which, she says, was an unusual distance, and alighted upon the right foot. She was aware that she had received some injury by feeling a sharp pain which almost caused fainting, and by hearing and feeling something snap. She did not fall, and was certain that she did not strike her knee. She was able to walk a considerable distance—nearly the length of the depot—where she was met by a relative who escorted her to her carriage, in which she was driven home. She was able to ascend the steps without much assistance, and was helped upstairs to her bedroom in a similar way. On the following day, she sent for her physician, who found a great deal of swelling in the lower part of the thigh, from extravasation of blood, and also a considerable effusion into the knee-joint. Ten days afterward the effusion into the knee-joint had subsided, the ecchymosis had disappeared, and a fracture of the patella was discovered. Dr. Sands saw the patient, and found that the fragments were separated to the extent of half an inch. A singular feature of the case was that the fracture, which ran through the middle of the bone, was not transverse, but diagonal, running from above downward and inward.

This was the only case in Dr. Sands's experience in which he had ever known a person to fracture the patell a completely and to be able to walk immediately afterward, and he would like to know the observations of the members of the Society on that point.

The other fact which was interesting was that the fracture was evidently produced by muscular violence, and that it should show the obliquity noticed in the present case.

DR. L. A. STIMSON had a case, three or four years ago, in which oblique fracture of the patella took place, as in Dr. Sands's case, and in which, also, the fracture was produced by muscular action. He did not remember that the patient was able to walk. The line of fracture ran from the outer upper angle downward to a point below the equator. Dr. Stimson remarked that it had been stated in text-books that patients with fracture of the patella could walk backward.

THE PRESIDENT remembered one case in which a man fractured the upper portion of the patella, and who walked upstairs; whether the fracture was transverse or not, he was unable to recall.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, March 25, 1885.

T. G. RODDICK, M.D., IN THE CHAIR.

DR. FRANCIS I. SHEPHERD read a paper on

THE MUSCULUS STERNALIS AND ITS OCCURRENCE IN ANENCEPHALOUS MONSTERS.

He stated that the musculus sternalis was a supernumerary muscle which has always excited a great deal of interest among anatomists, and that its proper morphological significance was not yet fully determined. It was seen in about three or four per cent. of ordinary individuals, and its fibres generally ran at right angles and superficial to the great pectoral. It was often bilateral but most frequently unilateral, and was subject to many variations. Frequently it had no attachment to bone, but lay superficial to the great pectoral and was attached at either end to fascia. It often was inserted into the costal cartilages. It might be continuous above with the sternal origin of the sterno-mastoid, and below with the fascia of the external abdominal oblique. Again, it might be continuous with the pectoralis major and be associated with deficiency of that muscle. It was often of small size, but occasionally it was quite a strong muscle, and could be seen under the skin in the living. Dr. Shepherd had seen it measuring five inches long, two and a half inches broad, and two a half inches thick. For years it was considered to be a remnant of the rectus abdominis, which in many animals extends from the pubis to the top of the sternum, and was called the "*sternalis brutorum*." This view had long ago been given up because the rectus abdominis lies in a plane deeper than the great pectoral, and is never superficial to it. Bourienne many years ago held that it was a prolongation downwards of the sterno-mastoid, a view still held by Henle and others. Hallett and Wilde regarded it as belonging to the same group of muscles as the platysma, and Prof. Turner, of Edinburgh, considered it to be one of the representatives in man of the great panniculus group which exists in most mammals. Darwin also held this view in his work on the *Descent of Man*, after referring to the views of Prof. Halbertsma, M. Testut, and Prof. Bardeleben.

Dr. Shepherd stated that Prof. Cunningham, of Dublin, had lately in five cases traced the nerve supply of the musculus sternalis to the anterior thoracic nerve, and that he, believing that the nerve supply was the best indication for the proper classification of muscles considered that the musculus sternalis belonged to the pectoral group. Prof. Cunningham also suggested that this was a new inspiratory muscle appearing in man, and that it was his impression that it occurred more frequently in females, due posibly to costal inspiration being more pronounced in them. Mr. Abraham, of Dublin, first pointed out, last year, that this muscle was very common in anencephalous monsters, as he had found it in six out of eleven specimens examined. Mr. Abraham looked upon it as probably an aberrant portion of the great pectoral muscle.

Dr. Shepherd said he had examined six anencephalous monsters which were in the Museum of the Medical School of McGill University, and wished to place the results of his dissection before the Society.[1] In each monster he had found a well-developed musculus sternalis. In three the muscle was double. In two continuous above with the sterno-mastoid, and in several it arose from the manubrium sterni and was inserted into the costal cartilages. In all the cases there was a deficiency of the great pectoral muscle on the side where the supernumerary muscle was found, the abnormal muscle apparently taking the place of the absent portion of the pectoral In several the muscle was of

[1] The specimens were exhibited to the Society after the reading of the paper.

large size, and in part continuous with the fibres of the great pectoral. Nine muscles, in all, were found in six monsters, as three had double muscles. Dr. Shepherd had successfully traced the nerve supply of these muscles in all but two, that is, seven of the muscles were supplied by the anterior thoracic nerve, the nerve entered the muscle in its deep surface and could be traced back over the lesser pectoral through the costo-coracoid membrane to the internal anterior thoracic nerve.

Dr. Shepherd remarked that it was a curious fact that this muscle should be supplied by a nerve which is at so great a distance from it, and not by the intercostal nerve, which in several cases pierced the abnormal muscle without giving any branches to it. He also stated that he had formerly held that the *musculus sternalis* belonged to the panniculus group, but that these dissections had caused him to alter entirely his previous views as to its homology, and that now he had little doubt that this muscle belonged to the pectoral group because: 1. Its nerve supply. 2. When present the great pectoral is generally deficient. 3. Its continuity in many cases with the great pectoral. 4. That it was in the same muscular plane as the great pectoral. Dr. Shepherd said that it was his belief that the nerve supply was the best guide we possessed for determining the homology of a muscle.

Dr. Shepherd was unable to explain why this muscle should be so common in anencephalous monsters, except that in these undeveloped beings there was a greater tendency to revert to previous conditions; but he said it was difficult to reconcile the fact that this muscle was an aberrant portion of the great pectoral and a reversion to some preëxisting muscle, as no known existing arrangement of the pectoral group in the lower animals at all resembles the condition found in these monsters. He also stated that if this muscle was an aberrant portion of the great pectoral which had no animal representative, then Prof. Cunningham's theory that it was a new muscle appearing in man had some degree of probability. Dr. Shepherd said he was not prepared to accept this explanation, but awaited further light and further knowledge of comparative anatomy before pronouncing definitely on the morphological significance of the musculus sternalis.

CORRESPONDENCE.

ON THE STAMPING OUT OF EPIDEMIC CHOLERA IN THE CITY OF NEW YORK IN 1866 AND 1867.

To the Editor of The Medical News.

Sir: In 1866 and 1867 epidemic cholera in the city of New York was effectually stamped out by disinfecting and other measures employed to prevent the diffusion of the disease. These measures were adopted by the Metropolitan Board of Health, which had recently been organized. They were carried out under the direction of the late lamented Edward B. Dalton, who had been appointed by the Board Sanitary Superintendent. With regard to their success, I quote a paragraph from a paper which I read at a meeting of the New York County Medical Association in October last, as follows: "My belief is that never before nor since, in any other part of this or in any other country, have measures for the prevention of epidemic cholera been devised so scientifically, so thoroughly carried out, and so successful in their results as those employed by the Metropolitan Board of Health in 1866 and 1867. They should be cited throughout the world as evidence that epidemic cholera is a disease which may be stamped out by efficient sanitary measures efficiently employed. I believe firmly that, should the disease be again introduced into this country, to decide whether or not it shall prevail as an epidemic, lies within the power of preventive medicine."

The results of the preventive measures in 1866 were stated by the late Elisha Harris in his report as Registrar of Vital Statistics, as follows:

"In houses and localities where well-marked first cases were not promptly treated by local cleansing and specific disinfection, cholera soon gained a foothold as a local epidemic, and we have found no large group of fatal cases in which this was not true; while in a great number of instances where the disinfection was prompt and adequate, *the arrest of cholera in the very worst localities and the worst houses and population was immediate and final.*"

"*In three hundred and sixty-two houses* where individuals or families were smitten with cholera, but which were promptly brought under full sanitary control by disinfection and sanitary purification, the pestilence *did not extend beyond the family in which the first case occurred.*"

Certainly no facts could demonstrate more conclusively than these that epidemic cholera was stamped out in the city of New York in 1866.

In 1867, cases of cholera again occurred in the city of New York. With regard to the stamping out of the disease in that year, I quote the following from the report of Jackson S. Schultz, President of the Board of Health: "Twenty-seven deaths from cholera have occurred during the past year in the city of New York, five in the city of Brooklyn, and eighteen at the military post in the harbor. The disease has not excited public alarm, and never approached the character of a general epidemic. The means used to combat it were the same as those employed in the year 1866. Wherever a case occurred the Disinfecting Corps cleansed the buildings, or fumigated them with sulphur, and destroyed the clothing, if it could not be disinfected by boiling water, or the permanganate of potash. The experience of another year has confirmed the opinion that active interference by means of disinfectants is the surest way to control and arrest this terrible disease."

The foregoing quotations from the reports of Dr. Harris and Mr. Schultz are contained in the volumes entitled "Report of the Metropolitan Board of Health" for 1866 and 1867. These volumes were published by the State of New York at Albany.

On the basis of the facts contained in these volumes, may it not be claimed, in behalf of the means employed in 1866 and 1867, that, if carried out with equal efficiency, they will prove equally efficacious whenever and wherever epidemic cholera may again appear? Entertaining the conviction that this question may be answered in the affirmative, it seems to me very desirable that a full account of these measures should be available for the medical profession. The volumes of

not be accessible to many, and, therefore, I am led to suggest the publication of extracts from the report of the Board of Health by Dr. Dalton, embracing a detailed account of the measures, which, under his admirable direction, were carried out faithfully, and the success of which renders them immensely important in view of the probability that they may soon be called into requisition. Yours truly,

Austin Flint, M.D.

New York, April 14, 1885.

Extract from the report of the late Edward B. Dalton, Sanitary Superintendent to the Metropolitan Board of Health, November 1, 1866.

"A large quantity of chloride of lime, sulphate of iron, and permanganate of potassa, was, therefore, purchased, articles which abundant experience in hospitals, civil, and military, had proved to be most efficient for ordinary disinfection, and the recent use of which abroad had given evidence of a probable efficiency in arresting the progress of cholera. Measures were at once adopted for the constant use of these agents, and a plan was put in force by which every case of cholera, which could be discovered, should be promptly investigated, the patient cared for, and every possible advantage derived from disinfection. All persons were called upon to give intelligence, at once, at the nearest police station, of any case of supposed cholera coming under their notice. The officer in charge of the station-house was to notify the nearest sanitary inspector, and it became the duty of the latter to investigate the case immediately, report its true character by telegraph to the central office, and render such professional aid, and in cases proving to be cholera, direct such measures for preventing the spread of the disease as might be necessary.[1] The office of the Superintendent was now constantly open, and for this purpose four inspectors were detailed for extra duty at night and on Sunday, two of them being on duty at the office on alternate nights and Sundays. It was the duty of these officers to attend to any case which might become known directly to them, or which might be referred to them from a precinct station-house, in case the officer in charge there had failed to find an inspector close at hand.

"Under the direction of the Board, a disinfecting depot and laboratory was established in a building, No. 308 Mulberry St., immediately adjacent to the central office. This depot was placed under the immediate charge of Mr. James A. Christie, late a lieutenant in the army, and who had before the war a practical education as a druggist, assisted by Mr. I. B. Gardner, also a practical druggist. There were employed a number of assistants, all men who had served honorably in the army and navy. A sufficient number of horses and light covered wagons were purchased and kept in a neighboring stable, ready for immediate use.

"The laboratory was constantly used for experiments in the use and combination of various disinfectants, and the men for the proper and faithful application of the same. Both Mr. Christie and his men lodged in the building, and the latter were organized into various squads, or reliefs, for the performance of duty in successive portions of the twenty-four hours. This duty, as the season advanced, became of a most laborious and often hazardous character. The men were constantly visiting infected districts, entering the houses there, and handling bedding and clothes soiled by the dejections of cholera patients. They were obliged to disinfect all bodies dead of cholera, and frequently to place them in coffins and remove them to the morgue. To the judgment and devotion of Mr. Christie, and the fidelity of his men, is due the satisfaction which this branch of the business has given."

The process of disinfection consisted in putting sulphate of iron, either in saturated solution, or dry, if used in wet places, where dejections had been deposited. An ordinary privy, six feet in diameter and twelve feet deep, required twenty pounds of the sulphate of iron for its thorough disinfection. All bedding and clothing, soiled or used by the patient, was boiled in a solution of the permanganate of potassa, of the strength of one ounce to five gallons of water, for two hours, and then removed and reboiled in pure water. For purifying the atmosphere of the room without incommoding the patient, chlorine was gradually set free by adding sulphuric acid to a mixture of binoxide of manganese and chloride of sodium (common salt). In addition to these measures, chloride of lime, or Labarraque's solution of chlorinated soda, was scattered freely about the floors of the rooms and halls of the house. Dead bodies were washed in a solution of chloride of lime or chlorinated soda, and then packed in the coffin with chloride of lime.

A large quantity of common lime and charcoal dust was purchased and placed in the branch at the "Five Points," to be used in the general disinfection of filthy localities, without reference to the occurrence of cholera. A number of horses and carts were hired, and a sufficient number of men to furnish each cart with one helper, beside the driver, to distribute the material. This force was placed under the immediate charge of officer Ezekiel Palmer, of the Sanitary Corps of Police, who has conducted this branch of the business throughout the season with great judgment and fidelity. The plan adopted was to pass through each street in the filthy portions of the city once, and in some instances twice, in each week, and sprinkle the disinfectants freely along the gutters and throughout the alleys and yards, and deposit a certain amount in each garbage box, privy, and filthy cellar. Now and then a few loads of sulphate of iron and chloride of lime were used in the worst places. At first the inhabitants misunderstood the operation, but it soon became popular and received their hearty cöoperation.

Additional instructions were issued to the sanitary inspectors and assistants in the following order:

"Sanitary inspectors and assistant inspectors will immediately investigate any case of supposed cholera reported at any hour by any officer of the Metropolitan Police. They will do what may be immediately necessary, professionally, and will give instructions as to the proper method of obtaining medical attendance from the dispensaries, or, if the case require it, of giving admission to hospital, and furnish the necessary certificate. They will at once decide what is necessary in the way of disinfection; and, if the parties be able to procure and employ the necessary articles themselves, the in-

the Reports of the Metropolitan Board of Health may

[1] Twenty-nine medical inspectors were appointed for the city of New York, and eight for the city of Brooklyn.

spector will give them detailed instructions regarding the same, and make a reinspection of the premises six hours later, to ascertain if his instructions have been carried out. In any case where the parties are unable to procure and employ the necessary articles, the inspector will at once apply at the nearest police station, and through the officer in charge telegraph to this office that disinfection is necessary at said premises, giving accurately street, number, room, etc. He will then reinspect after six hours, and ascertain whether the proper action has been taken. Every inspector will promptly report his action at the office in person, by telegraph, or in writing."

"Sanitary inspectors and assistant inspectors will keep notes of every case of cholera investigated by them until either recovery or death takes place, and will then promptly report the result to this office in writing if recovery, by telegraph, if death." The inspectors in the country districts were instructed to "forward to this office a written report upon each case of supposed cholera investigated by them, whether proved to be genuine or not, within twenty-four hours subsequent to said investigation."

The inspectors were also called together at the office of the Superintendent once a week, and a more full understanding of their duties and responsibilities obtained, especially from various practical suggestions which occurred to them while in the performance of their duty. They were especially instructed to make thorough inspection of premises where any case of cholera occurred, to visit every family residing on or near said premises, and inquire carefully for any premonitory symptoms resembling those of cholera, and on finding such, to give advice; and, if necessary, treatment—to extend such investigation throughout a block, or as much further as, in their judgment, the situation and circumstances required; to repeat these visits from time to time during the week or two following the occurrence of a case, so as either to be sure that no second case was to appear, or, in case of such appearance, to meet it promptly.

. . . . . .

The practical application of disinfectants was soon reduced to a simple system, which was followed in every case and with apparently satisfactory results. Whenever a dispatch was received at the central office that disinfection was needed at any house, Mr. Christie was notified, a wagon loaded with the requisite material, and the men at once sent to the spot. The officers and men of the police force were most prompt in their coöperation, and the disinfecting men were usually at work on the premises within an hour from the time at which the dispatch was forwarded from the station-house.

. . . . . .

The plan of disinfection already described has given entire satisfaction as regards the dejections, clothing, and other immediate surroundings of the patient; but frequently the recurrence of successive cases in tenement houses showed that the power of such measures was too limited, and, at an early date, general fumigation of such buildings was resorted to either with chlorine, or sulphurous acid gas. The process was this: All tenants were removed from the house, being allowed to take out nothing more than the clothing then upon them. All the windows and chimneys were closed. The gas was then set free in quantity—if chlorine, by the addition of sulphuric acid to chloride of lime; if sulphurous acid, by the burning of sulphur in large open pans supported by long iron legs. The men employed commenced the process on the upper floors, and descended, leaving the pans in operation on the different floors, and finally closed the street door. The house thus filled with the gas was left undisturbed for from eight to twelve hours. It was then opened and freely aired, and finally the tenants allowed to reoccupy.

The first house treated in this manner was an emigrant hotel in the lower part of State Street. Three cases of cholera occurred in this house within a period of thirty-six hours, and a large number of boarders were attacked about the same time with severe diarrhœa. The proprietors were notified that all guests must leave, and the hotel be closed. This was promptly done. The house was then thoroughly fumigated with chlorine, and kept so for twenty-four hours, when it was opened and aired. It was then cleaned throughout, and the walls freely whitewashed. At the end of ten days, the hotel was reopened, and very soon crowded with lodgers. No case of cholera or other disease of any moment has occurred there since.

Subsequently a large number of houses were fumigated after cholera had occurred in them. Sometimes chlorine was the agent, and at others sulphurous acid. They have proved equally satisfactory, though in far the larger number the latter was used. In the great majority of instances, fumigation has been followed by immunity from the disease. In a few, however, cases have occurred subsequently to the process, but they have seemed the result of renewed exciting causes. The evidence is strong that the adjuvants of cholera, such as impure air and improper food, which encourage the development into actual disease of the prevailing disposition; and, second, those direct agents in its propagation, such as the dejections of patients, can be controlled and even destroyed by a strict enforcement of cleanliness and the prompt use of disinfectants; and the mortality may be restricted to the minimum, which is due to the presence of the cholera poison proper. If these conclusions are just, it must be inferred that while the cases of cholera, which have occurred the past season, have been of the severest and most unyielding type, yet the infection has not been largely present. That the epidemic, if such it may be called (which might, if left unrestrained, have grown indefinitely), has had comparatively but a feeble foundation, and so has been more readily controlled.

. . . . . .

Throughout the whole season not an officer nor an employé of any of the four hospitals has had the disease, A few have had severe attacks of diarrhœa, which have yielded readily to ordinary treatment, and, finally, every one who has been employed, has left the hospital in as good health as when they came. The most rigid cleanliness, and constant and careful use of disinfectants, have been enforced. All dejections were either received at once into vessels containing a sufficient amount of disinfectant (sulphate of iron), or the latter was immediately added. Soiled bedding, or clothes were at once removed and put in soak in a solution of permanganate of potassa—one ounce to five gallons of water. The walls of the wards were always kept freshly

whitewashed, the wash containing a small proportion of the chloride of lime, and the floors were frequently scrubbed with the latter, and some of the same placed in various parts of the rooms and halls. For further details I refer to the reports of the officers in charge.

NEWS ITEMS.

NEW YORK.

(From our Special Correspondent.)

THE NEW BOSTON "MENTAL CURE" has reached New York, and those "cranks" who have exhausted the virtue of hot water and spectacles, are now submitting to the laying on of hands.

A STATE EXAMINING BOARD.—There seems to be a strong probability that the new law, which requires a State examination by the Regents, will be passed, in spite of the fact that the eclectics and homœopathics claim that they will not be properly represented in the Board.

THE CABLE ROAD AND UNDERGROUND WIRES.—Much discussion has arisen in regard to the new cable road that it is feared may be built, and the laying of telegraph wires beneath the street surface. Many affidavits of medical men have been presented by the counsel opposed to these enterprises. There is an almost general opposition to the tearing up of the streets this summer in face of the approach of cholera. The Board of Health have come out with a protest, and it now looks as if the pavements of the city would not be disturbed.

GENERAL GRANT.—The papers are filled with the case of General Grant, and some of the reports, despite the sad nature of the subject, are ludicrous in the extreme, and the active mind of the reporter has found vent in glowing descriptions of the doctors, the visitors, and the family of the illustrious sufferer. The bulletins recall the death of the late President Garfield, and many of them are as grandiloquent and meaningless.

MONTREAL.

(From our Special Correspondent.)

MEDICAL ARRANGEMENTS IN CONNECTION WITH THE NORTHWEST REBELLION.—There has been great activity lately in military circles owing to the half-breed rebellion in the northwest. Regiments have been hurried off to the scene of action rapidly, and hence not thoroughly equipped. The medical department was found very inefficient, and needed thorough reorganization. Dr. Bergin, M.P., has been appointed Surgeon-General, and Dr. T. G. Roddick, Prof. of Clinical Surgery in McGill University, is to proceed to the northwest immediately as Deputy Surgeon-General, and to have complete control of the hospital arrangements. He takes up with him materials for the equipment of base and field hospitals, and also a large staff of medical men and dressers. It is expected that a force of 10,000 men will be needed to put down the uprising. Most of these men being unaccustomed to campaigning, the season of the year being unfavorable, and the distance so enormous, it is expected that a large number will require treatment in hospital. The appointment of Prof. Roddick as principal medical officer to the expedition is a guarantee that the sick and wounded will be well cared for, and has given great satisfaction to the profession.

CONVERSAZIONE AT THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.—A conversazione was given at the College of Physicians on Thursday evening. The guests were received by the President, Dr. Da Costa.

Drs. Weir Mitchell and E. T. Reichert exhibited specimens of snake poisons and drawings showing their effects. Drs. Shakespeare and Formad exhibited apparatus for sterilizing organic infusions, various cultures of bacilli, and the bacillus of tuberculosis and of cholera. The circulation of the blood, and the various forms of bacilli were also shown by the lantern microscope.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.—Dr. George M. Sternberg, U.S.A., delivered an address before this Society last night on "The Pneumoniacoccus of Friedlander," which constituted one of the most important contributions which has yet been made to the subject of "disease germs."

MEDICAL SOCIETY MEETINGS.—The thirty-sixth annual meeting of the American Medical Association will convene at New Orleans on Tuesday, April 21st, under the presidency of Dr. Henry F. Campbell, of Georgia.

The Louisiana State Medical Society will meet at New Orleans, and the South Carolina Medical Association at Charleston, on Tuesday, the 21st instant.

The Arkansas State Medical Society will hold its annual session at Little Rock on Wednesday, the 22d instant.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 7 TO APRIL 13, 1885.

BROWN, HARVEY E., *Major and Surgeon.*—Leave of absence extended two months.—*S. O. 83, A. G. O.*, April 11, 1885.

BIART, VICTOR, *Captain and Assistant Surgeon.*—Leave of absence extended six months on surgeon's certificate of disability.—*S. O. 77, A. G. O.*, April 4, 1885.

COWDREY, STEVENS G., *Captain and Assistant Surgeon.*—From Department of the East to Department of Missouri.—*S. O. 77, A. G. O.*, April 4, 1885.

DE LOFERE, AUGUSTUS A., *Captain and Assistant Surgeon.*—From Department of the East to Department of Dakota.—*S. O. 77, A. G. O.*, April 4, 1885.

CRAMPTON, LOUIS W., *Captain and Assistan Surgeon.*—From Department of the East to Department of the Platte.—*S. O. 77, A. G. O.*, April 4, 1885.

TORNEY, GEORGE H., *Captain and Assistant urgeon.*—From Department of Missouri to Department of the East.—*S. O. 77, A. G. O.*, April 4, 1885.

ARTHUR, WM. H., *First Lieutenant and Assistant Surgeon.*—From Department of the Platte to Department of the East.—*S. O. 77, A. G. O.*, April 4, 1885.

WYETH, M. C., *First Lieutenant and Assistant Surgeon.*—From Department of Dakota to Department of the East.—*S. O. 77, A. G. O.*, April 4, 1885.

ORIGINAL LECTURES.

ON SCROFULA.

A Clinical Lecture delivered at the Good Samaritan Hospital, Cincinnati.

BY F. FORCHHEIMER, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL DISEASES OF CHILDREN AT THE MEDICAL COLLEGE OF OHIO.

(Reported by JAMES M. FRENCH, M.D.)

GENTLEMEN: I bring before you this afternoon a little negro child suffering from a disease that is very common to its race. What it is, I shall ask you to tell me after you have heard the history of the case.

The child is now fourteen months old. You observe that it is somewhat emaciated; and, although a negro, you can see that it is anæmic, its head is of the type which we call the square head, and the fontanelle is still large and somewhat depressed. You see further that the child has a flat nose, from which there comes a bloody seropurulent discharge. The upper lip is very much swollen; the lower lip is also somewhat thickened, and at the corners of the mouth we see fissures with infiltrated edges. Continuing the examination, we find that there is a tendency to a chicken-breast, and that the child has a "frog's belly." The epiphyses are enlarged, especially those of the wrist-joint and of the lower extremities. The lymphatics about the neck are very much enlarged. There is no enlargement of the epitrochlear glands, but the axillary glands are infiltrated. The genitals, the soles of the feet, and the palms of the hands are perfectly free from signs of disease. Examining the mouth, we find that upon the tongue and upon the sides of the cheeks there are whitish patches, which, when removed, leave a bleeding surface.

The case is now ready for diagnosis. What is it? Among the answers that I receive I hear the word "scrofula;" and that is what I expected. This is a typical case of scrofula; you could not desire anything more perfect. Here is a child that has a skin-disease; it has enlargement of all the lymphatic glands; it is troubled with its mucous membranes; what more would you wish? Now let us see what the disease really is. We have here all the symptoms of a rickets that has probably about completed its course. So far as I know, it has now no symptoms of the disease. The child has other manifestations, however, which were *formerly* classed under the head of scrofula—a *great many years ago*, we like to say—yet it is not many years; and some prominent members of the profession still use the term.

The eruption to which I have called your attention is best seen about the angles of the mouth. It is best described as a fissure with extensive infiltration of the surrounding tissue. There is, further, an eruption behind the ear—rather an unusual place for it to appear—an eruption that is also surrounded by an infiltration. In addition to this the child has, as I have told you, a flattened nose, and there comes from it a discharge which has an exceedingly offensive odor, and consists of blood, pus, and serum. It is also very irritating, and it is to this irritation that we must attribute the eruption and swelling of the upper lip. You have heard, also, that the child has universally enlarged glands. With this condition of things there is but one disease to be thought of. The fissure about the angle of the lips is, in fact, sufficient for us to make our diagnosis. When I first saw the eruption behind the ear, day before yesterday, it appeared as two discrete infiltrated spots, each the size of an old-fashioned silver half-dime, but they have since blended into one.

There is but one disease to be named, I say, that is hereditary syphilis. If, on the other hand, we had only this peculiar nose, characterized not only by a flatness of the bridge (not always present), but also by a seropurulent discharge, very thin, and of an exceedingly offensive odor, and streaked with blood, we should have to consider *two* diseases before deciding upon our diagnosis. We should have to consider a catarrh arising from tubercular deposits, and a syphilitic catarrh. We have here a disease known as ozæna, so-called because of the offensive odor of the discharge; and when in the presence of this disease, we are always justified in thinking of but two things, namely, a catarrh due to tuberculosis, and a catarrh due to syphilis.

In this regard recent investigations agree in every particular with the theories that have been held for a number of years. When I speak to you to-day of these troubles, I speak to you with authoritative knowledge, and not theoretically, as I formerly had to do. If, now, you take a large number of these cases of ozæna and examine the discharge from the nose for the bacillus tuberculosis, you will find them present in the great majority of instances. One of the most interesting cases of this kind was reported by Démme. A child was brought to him with an affection which he pronounced nasal catarrh of tubercular origin. The tuberculosis ultimately extended to the meninges, and the child died of tubercular meningitis. We have all hitherto been underestimating the importance of these local manifestations of tuberculosis. It has been my custom for years to point out to you the relation which I believed to exist between these local troubles and general tuberculosis.

You are justified in calling every case of ozæna a tubercular catarrh, or a syphilitic catarrh. Examine for the bacillus tuberculosis; if you find it, you know that you are dealing with a tubercular affection; if you do not find it, you are justified in pronouncing the disease one of syphilitic origin.

We have in this child a late manifestation of syphilis. There can now be no question about the case, except in regard to the possibility of the existence of tuberculosis in addition to the syphilitic trouble. It is not uncommon to have both these processes going on at the same time in the general system, or in the lungs alone. If you were to find in this child, in addition to its syphilis, a

tubercular process, your prognosis would of necessity be pitched at a much lower grade than otherwise. The child has at best a strong enemy to fight.

[Subsequent examination failed to discover the bacillus tuberculosis in this case.—Rep.]

Looked at from this standpoint, the whole subject of scrofulosis becomes very plain and simple. Looked at from the standpoint that it is either tuberculosis or syphilis, and that in probably ninety-nine cases out of a hundred it is tuberculosis, the subject of scrofulosis becomes very simple; but if you look through the literature of the subject for several hundred years in French, German, and English, you will be surprised to see how much of vague conjecture has been written upon it. Before his discovery of the bacillus, Koch claimed that tuberculosis and scrofulosis were identical in origin but he had no proof of the identity. It had been claimed that scrofula was simply a clinical picture, of really little importance—that it was, in fact, only a convenient name for the peculiar combination of symptoms that are presented in this case. The great objection to this term is, that while it is sufficiently applicable as long as it is used in a scientific way, it has, by a too general use, become degraded so as to be but little more than a mask for ignorance.

Let me give you an example of this. I have, within the last few weeks been called to see two cases in different families. In the one case the child had a profuse eruption covering its face, its neck, and its buttocks. I looked at the eruption carefully and found that it was an eczema. Of course the lymphatic glands were all enlarged. Upon inquiring into the history of the child, I found that Dr. So-and-so had treated it—that is, he had been giving it medicine internally—but the child had gotten no better. They tell me also that Dr. So-and-so, another physician, had not only given the child medicine, but had also put the mother upon a special diet, not permitting her to eat certain articles of food of which she is very fond,—probably the reason for his dismissal—but the eczema has gotten no better. Finally, under proper treatment, based upon a correct diagnosis, the child improved, and is now practically well. Here is a practical illustration. The physician who was called before me either thought that the child had hereditary syphilis, which would have been a mistake, indicating that he did not know his business, or, to be more charitable, he called the case one of scrofula and treated it for—he knew not what. Now he has by this mistake done harm both to the case and to himself, for the child could have been well long ago. Such practitioners reason, that because the child has an eruption and enlarged glands, it must have scrofula. Now all of you know that where there is an eruption of the skin, the neighboring glands are all enlarged. I do not deny that these glands that are enlarged from the irritation of an eruption in the skin are more likely to have developed in them the bacillus of tuberculosis than are healthy glands; but these gentlemen make an incorrect diagnosis and treat the child accordingly, with no results.

The second case to which I refer was a child about eight weeks old, in an excellent family. When the child was about four weeks old, an eruption appeared about the nose and corners of the mouth. It appeared also on the forehead and on the soles of the feet. This child had been treated by a physician who called the affection scrofula. I had no hesitation at all in going one step further and giving to the disease its proper name, "infantile syphilis." I put the child upon proper treatment and it recovered. These are simply examples of numerous cases that I could mention.

What now is there to be gained by using the term scrofula? Nothing. It is simply a term which, like a great many others, we use to cover over our ignorance. It has no actual value, and in that respect resembles paper money. I want you to fix this point in your minds, that scrofula is either tuberculosis or syphilis. Some cases however are called scrofula by many practitioners that are neither the one nor the other. Some are called scrofula which, like the first case that I narrated to you, are nothing but eczema. Any rational physician would not call such a case as that scrofula, for he would certainly know that the lymphatics which take away from the affected part its lymph, or supply lymph to it, must be enlarged. So, whatever be your views as to the origin of the eczema, whether you be a "localist" or a "constitutionalist," you have no right to call a case scrofula simply because the lymphatic glands are enlarged. As I told you before, we do more than theorize in regard to this subject; we make our diagnosis positive by examining for the bacillus tuberculosis. Not one of you should go out from this College until he knows how to examine for this bacillus, so important is such knowledge not only for the scientific investigation of disease, but also for diagnostic purposes. The process for its detection is not at all difficult, and when it is made, we have something that is positive. Wherever we find these bacilli, we know that the tubercular process is going on. It is true that it has taken away a good deal of the dread that we formerly had for the disease. We know now that it may be local, and not only that, but that it may be for a long time localized. Yet we know also that, from this local focus, there may come general tuberculosis, and hence the great importance of it to you as practitioners of medicine is that you may be able to detect the primary local focus and then endeavor to remove it. In cases in which there is incipient phthisis, you may sometimes detect the disease long before there is any positive physical evidence that would warrant you in making any great change in the habits of the individual, or advise a change of climate. I feel very sure that I have saved a number of lives as a result of this brilliant discovery of Koch, simply by having the patients secure at an early period of the disease the benefits of a change of climate.

Now, to return to this case. What shall we do for it? These large sores, these papules are to have applied to them *unguentum hydrargyri fortior*—the stronger ointment of mercury. This is put upon pledgets of lint, retained by a cap over the head. I do not know of any dressing that works with greater rapidity or with more certainty than does this stronger ointment of mercury, especially in the softer or papular forms of eruption wherever we find them.

What do we give this child internally? We give the iodide of potassium, especially for its effects upon the nose. I shall have this child brought before you at our next meeting, in order to show you the improvement we shall have obtained in the case by that time. You

will find that the iodide works wonderfully in these cases of ozæna. The first improvement is that the discharge becomes less offensive in odor, the next that it becomes less in quantity. If the child becomes thoroughly under the effects of the iodide, the discharge becomes greater in quantity again, but it is a different kind of discharge.

Having, now, this form of eruption in the mouth, having made the diagnosis of syphilis, you would intuitively come to the conclusion that the eruption was due either to the syphilitic infection or to long-continued mercurial treatment received before coming to us. In regard to treatment, we know that the child has not been treated by mercurials for the simple reason that we do not find here a mercurial stomatitis. We have not the characteristic eruption of mercury. We have not the red line about the gums, we do not have the salivation, or the offensive odor from the mouth. Neither is this a syphilitic stomatitis, and why? In the first place it is not localized as a syphilitic stomatitis ought to be; it does not appear where a syphilitic stomatitis generally occurs; that is, about the posterior segment of the mouth. This alone would not be sufficient to exclude syphilitic stomatitis, but if you look at one of these small spots carefully, you will see that it is made up of a layer of necrotic tissue beneath which there seems to be perfectly healthy mucous membrane. If you strip up this layer, you turn back a mass of dead epithelium, and you find that in the centre it leaves a healthy mucous membrane, while at the periphery it leaves a bleeding surface. What then is it? I have no hesitation in saying that it is simply a case of stomatitis aphthosa, aphthous stomatitis. What shall we do for this? Nothing beyond keeping the mouth clean and having it washed out freely with the best disinfectant for the mouth, namely, the chlorate of potash in solution. By the time the child comes before you next week, this trouble will be entirely relieved. And the chances are that before that time the papules about the mouth and behind the ear will have begun to heal, and you will find, I hope, that the child's nose will be in a much improved condition.

The leading truth which I desire to impress upon you to-day and the lesson which I wish every one of you to carry away with you is the relation that exists between so-called scrofula and syphilis.

ORIGINAL ARTICLES.

CASES BEARING UPON CERTAIN MOOTED POINTS IN SYPHILOLOGY.[1]

By E. L. KEYES, M.D.,
PROFESSOR OF CUTANEOUS AND GENITO-URINARY DISEASES IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

The Excision of Syphilitic Chancre.

Case I.—In 1884, a medical gentleman from a neighboring State called at my office to show me a small pimple situated upon the middle portion of the integument of the dorsum of the penis. This lesion was an acuminated papule, not capped by a pustule. The epidermis was unbroken. The color was slightly livid, the size about three-sixteenths of an inch at the base. There was no appreciable induration, indeed the lesion had no pronounced specific character. It was not painful. There was no inguinal glandular engorgement. The lesion had appeared during the afternoon of the day before I saw it. It was less than twenty-four hours old, and the patient ascribed it to suspicious sexual contact dating back two weeks. The integument of the penis and of the rest of the body was normal, the general health good.

A diagnosis was impossible, although the general appearance of the lesion suggested an accidental papule, and would have justified a favorable prognosis as to syphilis. Yet the patient was solicitous that something should be done.

Cocaine as a local anæsthetic was just coming into use, and I proposed to him excision with the aid of this agent. He gladly accepted the test. I washed the unbroken surface with a powerful solution of bichloride of mercury, one in two and a half, dried it, injected five minims of a four per cent. solution of cocaine under the skin, caught up the little papule with a full margin of the ample soft integument around and with scissors curved on the flat excised an abundant fold, including the lesion and considerable healthy tissue around.

Two catgut ligatures upon bleeding veins and three catgut sutures promptly finished the operation and left the wound absolutely dry. The patient had not experienced a particle of pain.

On his return home the doctor visited the suspected party and found that she had a syphilitic eruption.

The wound healed promptly by first intention. On the sixty-second day, after three or four days of premonitory fever, no medicine having been taken, the patient observed a mild roseola, which promptly disappeared. Fourteen days later he visited me. He had lost eight pounds in weight. In one groin were two indolent indurated glands, one in the other groin. The site of the excised chancre was soft and perfectly well, showing only a faint linear white scar. There was intense rheumatism, worse at night. There were scabs in the scalp, and the hair was falling. A profuse general papular syphilide covered the entire trunk, the face, and both the palms. Mucous patches abounded in the mouth. The eruption was brilliant and abundant, the patient pallid.

The disease had not been interfered with by any medical treatment, and was a plain instance of a sharp attack of syphilis which had not seemingly been in any degree modified by the excision of the initial lesion, although executed under unusually favorable circumstances.

This case I consider worthy of record because it fulfils the most exacting conditions for testing the question, still under consideration in the profession, as to whether syphilis is or is not already a constitutional disease when the chancre appears.

I do not care to tabulate statistics of the excisions practised by various operators. The résumé of Dr. Morrow,[1] in December, 1882, covered enough cases to allow generalization, and nothing which I have seen since that date has modified the conclusion he seemed justified in drawing; namely, that the ex-

[1] Read before the New York Surgical Society, April 14, 1885.

[1] Journal of Cutaneous and Venereal Diseases.

cision of chancre does not attenuate the poison of syphilis or modify the general symptoms.

Berkeley Hill's case,[1] it appears to me, carries more weight than any other reported before or since. A man tore his frænum during intercourse, at 4 A. M. At 3.30 P. M. on the same day—less than twelve hours after exposure—Hill destroyed the entire raw surface with fuming nitric acid. An eschar separated and the wound healed. A month later the cicatrix indurated and general syphilis followed.

My own opinion has been strongly opposed to the belief that local excision of chancre would prevent or modify general syphilis. I have offered the treatment to many, but as I never felt conscientiously at liberty to promise any advantage as a result of the operation my proposition has been declined. I would not have operated in this case except to test the cocaine, and because the patient, being a physician, earnestly desired it.

My case is quite analogous in its history and result to one reported by T. W. Taylor, in which[2] a papule was excised upon the day on which it appeared—with no advantage to the patient, whose general symptoms came out in two weeks. It is on a par with others in which early excision was practised in vain (Mauriac, forty-eight hours).[3]

I have recently also encountered another case in point (unpublished).

Case II.—X., aged 37, came to me in January, 1885, stating that in November, 1883, he noticed a small chancre on the penis. This was excised on the first day and the wound promptly healed. In six weeks he had a general roseola. He is now in his second year, having had numerous eruptions and been plentifully treated in various ways, including forty-five grain doses of the iodide of potassium three times a day, and a course of eight weeks at the Hot Springs, during which time ten ounces of blue ointment were rubbed into him. He came to me for some small gummatous tubercles upon the face, and is still under treatment. In this instance surely the excision did not favorably modify the intensity of the disease.

A medical friend, who wishes to be nameless, has recently reported to me a case of excision within twenty-four hours of the appearance of the lesion, in which general symptoms (roseola) appeared upon the thirty-second day. In other words, it has not been my good fortune to meet any case in which excision was practised with a favorable result.

I think it not difficult to understand how apparent success may follow excision, when we remember the multiple sources of possible error in diagnosis, and particularly is this the case in Germany, where the best results are claimed (thirty to fifty per cent.), for here the advocates of excision are all unicists (notably Anspitz and Kaposi), and are doing their best to return all primary venereal sores into that chaos from which Bassereau and the French School have endeavored to deliver them.

[1] Venereal Diseases, 1883, p. 310.

[2] Syphilis and Local Contagious Disorders, Hill & Cooper, 1881, p. 76.

[3] Ann. de Derm. et de Syph, July, 1881, p. 523.

The sources of error to which I refer are:

1. Inflammatory induration of lesions not syphilitic.
2. The small ulcerated gumma of the penis.
3. Non-specific sores which resemble the infecting chancre.
4. Cases of delayed syphilis.

I need not cite instances of the first two classes mentioned above. We are all familiar with the local sore of unknown incubation, with a hardness so nearly typical that we cannot ignore its peculiar quality, yet where observation without treatment has proved the absence of any true venereal taint.

The localized gumma commences as a tubercle under the skin, has all the essential hardness and sometimes the inguinal indolent adenopathy. Its physical characters might deceive any one. It may come upon one in seemingly vigorous health and be the only lesion present. The patient may have forgotten his old syphilis, the last symptoms of which occurred perhaps ten years before. I have had more than one such case.

If now this individual has had suspicious sexual contact a month before the sore appears, he is very apt to be considered a case of reinfection. These localized gummata (pseudo-chancres) have a marked partiality for occupying the site of the original chancre, but this is not an invariable rule.

Of the third class—a sore resembling, but not being a specific ulcer in any poisonous sense—I have seen a number of examples. The most striking is the following. I have no theory upon which to explain it, but can affirm that I have never seen a more typical excoriated induration as a starting point of syphilis than was this simple inflammatory hardening.

Case III.—A young man came to me about two years ago with a tight foreskin and a contracted preputial orifice, from which a moderate amount of pus exuded. In the substance of the prepuce at about its right lateral centre, was a hard disk with clearly defined margins, insensitive, giving to the fingers about the feel one would expect to get from a disk of gutta-percha set into the foreskin. The patient could retract the foreskin formerly, and assured me that he had seen an ulcer on the inner surface of the hard spot so long as he could expose it to view, which of late had become impossible. The sore had appeared one month after intercourse. There were two or three indolent indurated glands in each groin.

This boy had consorted only with one female. She would not allow herself to be examined. She shared her favors among a set of young men, of whom several had been patients of mine for various disorders not syphilitic. These young men continued to consort with this woman before, during, and after the date of the alleged exposure in this case. All remained well excepting one, who acquired mild urethritis from intercourse too near the menstrual epoch. After a local treatment of several weeks I was enabled to retract the foreskin and inspect the lesion. It proved to be a simple livid excoriation upon a sharply defined induration. There had been no true ulcer. The whole physical appearance of the lesion was that of infecting chancre. I concluded that it must be due to mediate contagion.

No internal treatment was ever given. I watched

the case several months. The excoriation healed; the induration disappeared. No symptoms of syphilis followed.

This case is unique in my experience. I believe it to have been an unusual form of simple inflammation, traumatic in origin, due primarily to the tightness of the foreskin.

If it was syphilis, it was delayed syphilis.

I have seen a number of other traumatic lesions which might have been mistaken for the starting-point of syphilis, but nothing so seemingly typical as this case. In any event such cases are not common.

Delayed Syphilis.

Case IV.—A gentleman of 37 called upon me in September, 1883. He stated that he had had an ulcer on the penis in August, 1880, which appeared three months after exposure. This was the first venereal symptom he had ever observed. The sore was treated locally. It healed within two weeks. No symptoms followed.

In April, 1883—more than two and a half years after the alleged chancre—he fell into a sort of stupor, with fever and rheumatic pains, especially of the feet. After three weeks a spotted eruption came out upon his palms, which was pronounced to be syphilitic. Then his throat got sore, ulcers appeared in the mouth, the hair fell out freely, and, having been taking antisyphilitic treatment already for a few weeks, he became alarmed, and went to the Hot Springs. There he was treated actively. In July he had some ocular trouble, which improved at the Hot Springs. At my examination I found two characteristic palmar desquamating spots, and some mucous patches in the mouth.

This case, of course, allows a suspicion of a new infection in March, 1883; but the patient, who was absolutely free in giving his history, disclaimed it.

Case V.—X. aged 30, visited in November, 1883, stating that five years previously he had a local set of lesions on the penis for which he received no internal treatment. He remained well for one year. Then painful lumps appeared under the scalp, the throat ulcerated, the bones of the nose came away, the middle ear suppurated, rupial eruptions, scaling spots and papulo-squamous patches came out upon various parts of the body, then he got heart-flutterings, dyspnœa, vertigo, dyspepsia. The patient denied any venereal malady up to the time of the sores first mentioned above.

Anything so irregular as these two cases, of course, is a matter of suspicion, but the unexpected element in syphilis is so common, and irregularities from the normal type so constant, that I think it possible to accept them as instances of irregular or delayed syphilis.

These last described forms of disease capable of causing error in the diagnosis of syphilitic chancre are very uncommon, the first two inflammatory hardening of chancroid and local cutaneous gumma resembling chancre, are very common. Whether it is possible that observers so renowned as the German advocates of the excision theory could be mistaken in their diagnosis in such a large percentage of cases I cannot affirm. It seems improbable, yet it is more improbable that success should follow an excision practised upon a chancre several days old with the inguinal glands already involved, and, as has been claimed, that failure should occur in cases like those I have narrated at the beginning of this article.

Mediate Contagion of Chancroid.

The mediate contagion of true syphilis is notoriously not impossible, several authentic instances of it being recorded. I do not remember to have seen the report of any case of the mediate contagion of chancroid, and therefore bring forward the following:

Case VI.—X. aged 20, visited me in August, 1883, with an ulcer upon the penis behind the corona glandis having a hard base. There was one hard gland in the groin, slightly sensitive. His history was as follows: After two months of continence he had cohabited with a woman who had formerly been syphilitic, but had remained free from symptoms for five years. This woman was the mistress of a friend.

On the morning following intercourse the patient noticed an excoriation, which, on the third day, swelled up and discharged. It was then burned by a physician, whereupon the base hardened, and the ulcer began to grow larger. I saw it on the twentieth day, when it had all the appearance of chancroid with an inflamed base.

Five days after exposure the patient had the woman examined. She was declared sound, except as to leucorrhœa. I pronounced the sore a probable chancroid, and urged a further search as to cause. The search developed the following facts: On the night before the day on which my patient had cohabited with the woman she had had intercourse with another person and had remained partly intoxicated, and lying quiet thereafter until my patient had cohabited with her. The man in question was followed up and found to have a well-marked chancroid under treatment. This sore he had possessed at the date of intercourse with the woman. My patient's ulcer healed after six weeks. No syphilis followed. The woman did not acquire any sore, nor did the man who habitually lived with her.

The Hutchinsonian Teeth.

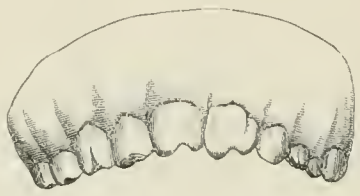
The test-teeth of inherited syphilis are the two central, permanent incisors, in the upper jaw. They are known as the Hutchinsonian teeth, after the distinguished Englishman who first accurately described them.[1] The broad, rather shallow groove in the cutting-surface is the feature which distinguishes them. These teeth are often convergent or divergent, but may be straight, and they are often narrowed on the cutting-edge, but not necessarily so.

I have here two casts of the upper set of teeth, showing the characters usually believed to indicate inherited syphilitic disease (Figs. 1 and 2). I present with them Hutchinson's original plate, and a photograph of the woman whose teeth are pictured in Fig. 2, showing the macular syphilide which was

[1] Illustrations of Clinical Surgery, London, 1876. Fascicules III., Plate XI.

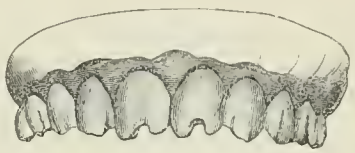
upon her when I first saw her. The patient whose teeth are represented in Fig. 1, had inherited syphilis.

Fig. 1.



The patient possessing the teeth represented in Fig. 2 showed no sign of ever having had inherited dis-

Fig. 2.



ease, and came to me with fully marked secondary syphilis, which she had acquired from her husband. I think the case is interesting, as illustrating the fact that teeth very closely, if not identically, resembling the test-teeth of Hutchinson, may be possessed by a patient who has not inherited the disease. The cases are briefly as follows:

Case VII.—To this case belong the teeth of Fig. 1. One of the outer incisors was crowded out of line by the contraction of the jaw, and appeared behind the alveolar border. It is not represented in the cast, which was taken by the husband of the patient, a plasterer by trade.

In 1878 I first saw this patient, 14 years old, with a large gumma in the right axilla, then ten years old. Her mother, who brought her, had an old syphilitic ulcer on the leg, at the bottom of which was a necrosed portion of the tibia. The child had also a large node on the left tibia. She had strabismus and bad headache, with some scabs in the scalp. When five weeks old an eruption came out over the entire body, nose, and the feet, and she has suffered from mottled, livid, scaling spots, and rheumatic pains ever since. Her treatment had been more or less constant since birth. The child was plainly a victim of inherited disease. The mother was frankly syphilitic, and had miscarried once and produced two dead children before the birth of this child. The father was also syphilitic (ulcers and nodes).

This patient had a variety of disorders, among which was sudden blindness for half an hour at a time; but she recovered of everything, even her strabismus, under treatment; married at the age of 17; produced a healthy child; then took to drink; developed a well-marked tubercular syphilide on the arms, with ulcers on the scalp; miscarried five times in succession, and finally died.

Case VIII.—To this case belong the teeth of Fig. 2. Mrs. X., aged 31, visited me in February, 1884, showing flat, mottled patches of a recent papulo-erythematous syphilide, covering the trunk and extremities, with a few spots on the face. She related that her husband had a sore upon his penis, and had given her a similar ulcer upon the vulva some weeks previously. The sore was well at the date of her visit to me. She showed also mucous patches in the mouth, indurated glands, fall of hair, etc., and the teeth as seen in the cast.

Her father and mother are alive and well, she says. She herself has always been healthy. She has no scars, no syphilitic countenance, no history, and no evidence of any inherited disease. She is robust and well-formed; has had five healthy children, and laughs at the idea of having suffered from any inherited malady. Actually she has recent syphilis.

In March, 1885, one year later, she returned—still under treatment at the hands of her own physician—and presenting well-marked clusters of tuberculo-squamous syphilide in patches upon various parts of the body. The photograph shows the appearance of the first eruption on the chest.

The Administration of Iodide of Potassium in Milk.

I wish to add a word in favor of milk as a most suitable vehicle in which to administer the iodide of potassium, notably in cases in which large quantities of the drug have to be used.

Several years ago a patient first called my attention to the fact that he could take his dose of iodide of potassium in milk without minding the taste, which otherwise was very offensive to him.

I adopted the suggestion at once, and found it of great service in many cases. Ten grains or more of the iodide in a gill of milk (cold) make a very palatable drink, and impart only a mild, metallic taste to the fluid, which most patients find not at all disagreeable. I have used this method in a routine way with the happiest result in several instances in those desperate cases in which some portion of the nervous system gives out, food is unpalatable, or cannot be taken, and the indication is, disregarding all else, to push the iodide rapidly to the point of tolerance. In such a case no time can be lost, and a fixed routine system, which shall accomplish all the needs of nourishment, as well as medication, is a very valuable factor in the treatment. I shall cite one illustrative case out of a number in which I have used the method:

Case IX.—In the summer of 1883, a gentleman was referred to me from another city, with precocious malignant syphilis (rupial in type), and a feeble stomach. He could not digest the iodides well, as they deranged his stomach, and caused disfiguring acne, a twenty grain dose of the iodide of sodium being too much for him.

His symptoms gradually disappeared and he returned home, and for about a year did more or less well and badly, until his physician, one of the most thoroughly competent gentlemen in the profession, concluded that the antisyphilitic treatment was keeping his stomach so constantly deranged, that he was suffering more from treatment than the disease. He

therefore omitted medication for a time, and again sent the patient to New York to see me.

He came to the city, and remained in his hotel two days, not calling upon me and feeling rather better, but being much excited at night and sleepless. His only active symptom was one ulcer on the arm. On a given day at noon, while lying quietly on a lounge in his room, he got up to cross the floor. Having accomplished his object upon the other side of the room he turned to go back, but when half-way across the floor, without warning or pain, he suddenly fell in a heap upon the floor (his age was 36), without loss of conciousness, and found himself unable to get up or to speak. I saw him shortly afterward, and found him totally paralyzed upon the right side, and aphasic. He had no heart disease of any kind, and the only premonition of the attack had been a certain recurring numbness of the fingers and toes of the *left* side during each of several days before the attack. I procured a day and night nurse and ordered quiet, the cessation of all habitual food, drink, and medicine, and instructed the nurses to give him each hour, night and day, ten grains of the iodide of potassium in a claret glass of milk. He took it all, nearly three quarts of milk and 240 grains of the iodide of potassium in the first twenty-four hours. A laxative was the only other thing allowed. Increased the daily dose two drachms each second day, and after a week employed also inunctions of mercurial ointment which I pushed rapidly until the gums were mildly touched.

During the second week his daily dose reached ℥iss of the iodide. He took no food whatsoever except the milk in which his medicine was given, and he took also an occasional laxative. His tongue cleared, the acne disappeared from his face, early in the second week he began to move his arm and leg spontaneously. Electricity and massage were now added, and in one month from date of the attack he left the city walking with a cane and dragging his foot slightly, but talking about as naturally as ever, and looking exceedingly well. The daily dose was then ten drachms taken in four separate portions, for as he got better I gave up the hourly medications, and allowed him to eat.

The patient is still under observation, doing well, taking ten drachms of the iodide a day which he has been continuing for several months, and promising nearly, if not quite, a perfect recovery.

1 Park Avenue, New York, April 14, 1885.

COCAINE IN DIPHTHERIA.

By HOWARD A. KELLY, M D.,
of Philadelphia

The following results, which I have obtained from the use of cocaine in diphtheria and diphtheritic sore-throat, are uniform and remarkable:

Case I.—Jan. 21st, Emily C., age 11, complained of feverishness for two days, and for one day of sore-throat. She has anorexia and slight prostration. The fauces are red and engorged; the tonsils enlarged, nearly touching; they are both covered with a thick, pultaceous, gray mass. A diaphoretic mixture was given, and a four per cent. solution of hydrochlorate of cocaine applied to the throat every two hours. The false membrane began to melt immediately, and in five days she was well, and the throat normal.

Case II.—George T., age 13, has had a headache for several days. This morning his throat began to pain him, and in the afternoon he was feverish. Both tonsils are enlarged and red; on the right tonsil is an elongated, oval patch of ulceration, one-half inch long.

Cocaine was applied as in preceding case, and in two days the throat was well; and the prostration, which had been marked, disappeared gradually after.

Case III.—Mary F., age 19, hump-back, has felt weak and prostrate for two days. She has a rapid, feeble pulse; fever, and an enlarged tender gland under the right ear and sore-throat. The pharynx is engorged, and of an angry-red color. The tonsils are both enlarged, and on the right tonsil is an oval patch of ulceration a half inch long.

Cocaine, applied as in the preceding cases, cured the inflammation in twenty-four hours, and completely removed all trace of ulceration, except a thin, crescentic ring, which formed the anterior border of the ulcer.

Case IV.—Mr. O'C., a very intelligent druggist, came into my office, a few evenings since, looking very wretched with a stiff neck, and in a hoarse voice informed me he was "all broken-up." The pulse was quickened; temperature 102°; the pharynx and fauces very red. On the left tonsil was an elongated, whitish ulcer, half an inch in length. The secretions were constantly accumulating in the throat, and he suffered severe pain in clearing it. Cocaine, used as in the other cases, relieved the pain in hawking, cured the ulcer in one day, and on the second day the patient was feeling perfectly well.

In each of these cases, except the third, in which cocaine alone was used, some constitutional measures were employed, as I have found that they always add greatly to the patient's comfort, although apparently exerting no control over the duration of the disease. For this purpose I give morphine in small doses, or bromide of potassium, or nitrate of potassium, with sweet spirits of nitre, concentrated tincture of gelsemium, or liquor potassæ citratis.

Dr. Schools, of this city, informs me that he has had a similar experience with the drug in a case like the first I have detailed.

In the so-called cases of diphtheritic sore-throat with erosion I feel confident the cocaine is of signal value.

MEDICAL PROGRESS.

Rheumatic Phlebitis.—Dr. Letulle, in the *Gazette Médicale de Paris*, reaches the following conclusion relative to rheumatic phlebitis:

1. Rheumatic phlebitis is one of the rare complications of acute articular rheumatism.

2. It affects by preference the veins of the lower extremities, and more particularly those of the left leg.

3. Stasis of the blood (the same as for phlegmasia alba dolens) seems to be one of the most active of de-

termining conditions which favor the formation of phlebitic clots.

4. The coexistence of cardiac complications and anterior pleuro-pulmonary disease (conditions often met) seems to play an important part, though secondary in increasing the intravenous blood-pressure.

5. The pathogenic influence of primitive inflammatory lesions (antecedent endophlebitis) appears disputable.—*Revue Médicale*, March 14, 1885.

Hydrochlorate of Cocaine as an Adjuvant to Catheterization.—Dr. De Larabrie, in the *Gazette Médicale de Nantes* of March 9, 1885, says: Since the discovery of the anæsthetic effects of hydrochlorate of cocaine upon the ocular conjunctiva, its field of usefulness has constantly extended. Besides the well-known effects upon the pharynx, stomach, and vagina, it also can be used with great advantage in operations upon the urethra. Knopp, by experimentations upon animals, first demonstrated this fact. The following clinical evidence justifies the conclusions reached, and gives foundation, in fact, to recommend its use in urethral surgery. The case is the following: A young man, afflicted from infancy with nocturnal incontinence of urine to the present time, has resisted all means employed to remedy the condition. Galvanization was at last resorted to according to Guyon's method.

The patient was constitutionally weak, and presented at the same time some constriction of the urethra along with unusual sensitiveness of the canal. When catheterization was practised the first time, the procedure was accompanied by extreme pain, which seemed greatest when the instrument reached that portion of the urethra midway between the glans penis and the scrotum. Urethral spasm also was produced, and was followed by oozing of blood for twenty-four hours. Urination during the following days was frequent and painful.

All efforts at treatment were alike painful, and finally resort was had to cocaine, and previous to each attempt to introduce the sound a one per cent. solution of the drug was injected into the urethra.

On first trial the injection was repeated after a few minutes, and the sound was tolerated without the least pain. There existed, in fact, absolute insensibility, which lasted for about two minutes, a short but sufficient time to permit the introduction of the sound and exactly locate the constricted portion of the urethra. Since this time each application of electricity has been preceded by injection of cocaine, and subsequently the bladder has been entered without pain.

It is worthy of remark that while a five per cent. solution is required to anæsthetize the conjunctiva, and though Schrotter, of Vienna, uses a twenty per cent. solution for operations upon the larynx, yet for the urethra a one per cent. solution is sufficient to produce complete anæsthesia.

Iodoform Dressings.—Dr. V. Mosetig-Moorhof, in a paper read at the International Congress at Copenhagen, on the efficiency of iodoform dressings, reaches the following conclusions:

1. Iodoform is applicable as an antiseptic and aseptic dressing to all wounds, whether old or recent, deep or superficial. It is specially to be recommended in those wounds which, for any reason, cannot be carefully kept under observation, or in which the extensive apparatus necessary for antiseptic precautions is wanting.

2. Pure iodoform is also applicable to all such wounds as will heal by first intention. For this purpose the fine powder, lightly strewn over the wound, is the best form for use, and will exercise no opposition to the prompt healing of the wound.

3. Iodoform is specially to be recommended in the treatment of fungous or recent wounds attributable to local tuberculosis, and for such purposes far excels all other antiseptics hitherto recommended.

4. The application of the iodoform dressing is simple and cheap. Within reasonable limits it is not as dangerous as are some methods of antiseptic dressing.—*Medicinische Chirurg. Centralbl.*, March 27, 1885.

Antiseptic Treatment of Erysipelas.—M. Verneuil, in a communication to the Académie de Médecine de Paris, after giving statistics in proof of the efficiency of the antiseptic treatment of erysipelas, concludes his observations as follows:

1. Erysipelas is an infectious, contagious, and auto-inoculable disease, which, for various reasons, it will be difficult for a long time to suppress.

2. In great centres erysipelas, essentially endemic, is propagated from two sources—externally from the city, internally from the hospital—which reciprocally infest each other.

3. It is possible to prevent, to a great extent, the appearance and extension of the disease by precautions against auto-inoculation, by antiseptic dressings, by isolation when it is possible; and, in default of this, by creating about the patient a circumscribed antiseptic atmosphere.

4. The diminution of erysipelas in the surgical wards not only has for its effect the sanitation of these wards, but conduces to an improved sanitary condition of the entire hospital, and of the quarters tributary to the hospital, as is shown by the considerable diminution of erysipelatous admissions from without.

5. If the prophylactic and curative resources against erysipelas, of which science has proved the efficiency, are rigorously and generally applied in city and hospitals, it is possible that erysipelas may become as rare as pyæmia, and, perhaps, disappear as completely as hospital gangrene.—*L'Abeille Médicale*, March 2, 1885.

Pseudo-paralysis produced by Carbonic Oxide Gas.—At a meeting of the Royal Academy of Medicine of Torino, lately held, Professor Morselli presented a communication from Dr. Giuseppe Musso, on a new form of general pseudo-paralysis by slow poisoning by carbonic oxide.

All the forms of pseudo-paralysis hitherto recognized are due to the effect of alcohol, lead, or syphilis, but Dr. Musso now shows that general pseudo-paralysis may be developed by the incomplete combustion of carbonaceous substances in confined and illy ventilated apartments.

At the same meeting of the Society was reported a case in which trephining was performed on January 1, 1885, for epilepsy occasioned by a depression of the skull, produced four years ago by a blow. Cure resulted in a few days, and the general, as well as the mental, condition of the patient improved noticeably

after the operation.—*Gazzetta degli Ospitali*, March 15, 1885.

Osseous and Articular Tuberculosis.—Dr. Ferrari, in a recent study of osseous and articular tuberculosis, has reached the following conclusions as to this special manifestation of tubercular disease:

1. The slowly developing fungous processes of the bones and articulations—generally designated as white swellings, etc., are manifestations of tubercular periostitis, osteitis, osteomyelitis, or synovitis.

2. Tuberculosis of the bones is manifested under two different forms: *a*, the circumscribed, *b*, the infiltrated, variety.

3. Both these forms are distinct from tubercular osteitis and osteomyelitis.

4. In the infiltrated variety, designated *acute tubercular osteitis*, the rapid destruction of the osseous tissue is histologically distinct from the rapid development of tubercular follicles which, without passing through the different stages of the development of tubercle, undergo a rapid, cheesy degeneration.

5. In fungous synovitis tuberculosis is manifested under two forms, one of which is distinct from the development of tubercular follicles; the other from the diffuse infiltration of lymphoid cells, in the midst of which giant cells appear.

6. In the fungous, osseous, or synovial growth the specific bacilli tuberculosis are frequently found, but not in such abundance as in other parts affected with tubercular disease.—*Gazzetta degli Ospitali*, March 22, 1885.

The Transplantation of Muscle and Regeneration of Muscular Fibre.—Dr. Eduardo Salvia, in an experimental study upon the transplantation of muscle, and the regeneration of muscular fibre, sums up the results obtained as follows:

1. It is possible to transplant a portion of the muscular tissue of one animal into that of another, difference of species having no effect upon the result.

2. The transplanted portion of muscle may unite completely with the muscle with which it is brought into relation by first intention. To obtain this result, it is necessary that the transplanted muscle completely fills up the void made by the retraction of the excised muscle, and that the operation be conducted under strictly antiseptic conditions.

3. The union between the transplanted muscle and that of the animal upon which the operation is performed takes place from the formation of new muscular fibre, which is produced without leaving trace of the original points of separation.

4. The muscular fibre which is introduced gradually loses its own special anatomical peculiarities, and acquires those of the living animal, to the degree that after a time the most careful microscopic examination is unable to detect a difference between the original and acquired muscular tissue.

5. The function of the muscle after its introduction in a relatively short period is perfectly restored, without the slightest tendency to weakness or stiffness.—*Gazzetta degli Ospitali*, March 22, 1885.

Nephrectomy for Encephaloid Tumor of the Kidney.—At a meeting of the Académie de Médecine de Paris, held March 30, 1885, M. Pèan presented a patient upon whom he had performed the operation of nephrectomy for encephaloid disease of the kidney. The patient, previous to the operation, was cachectic in the extreme, and, though advised against undergoing operation, insisted upon its performance.

M. Pèan proceeded as follows: The tumor was exposed by an incision in the median line, extending from the epigastrium to the pubis. The mesentery was incised, and the numerous dilated veins treated by compression.

The tumor was then found to be surrounded by a capsule, which was, to a certain extent, removable by the fingers. Before continuing the removal of the capsule further, the tumor was taken away by degrees in small portions, partially with the fingers and partially with a spatula. This necessitated the compression of numerous arterial and venous trunks.

The operation was continued till the whole mass was removed. The diseased tissue was darkish green in color, ecchymosed in spots, and contained throughout its mass granular calcareous nodules. It was adherent, moreover, to portions of the small intestine—the mesentery, and to some of the vascular trunks—to separate it from which required great care.

Sufficient progress had now been made to discover that the growth had its origin in the right kidney, of which the pelvis and the ureters were in a state of fatty degeneration. The kidney and its appendages were then removed, the vessels and ureters having been cut between two ligatures.

The mesentery was then united by three ligatures, which were left in the abdominal cavity. The operation lasted one hour. The tumor weighed more than twelve pounds. In three weeks the woman was convalescent.

A microscopic examination, by M. Robin, showed the tumor to be an epithelioma of the kidney.—*L'Union Médicale*, April 2, 1885.

Naphthalin in the Intestinal Catarrh of Children.—Dr. Ph. Pauli, in the *Berliner klin. Wochenschr.*, of March 9, 1885, publishes an account of his clinical observations concerning the use of naphthalin in the intestinal catarrh of children.

The ages of the children—a history of whose cases is given—vary from one and a half to five years, and in all the drug seems to have been very successfully used.

The quantity of naphthalin administered varied with the age of the patient, and ranged from a grain and a half to fifteen grains daily. In one case, in which the remedy seemed not so prompt as in the others, increasing the dose until the feces had a strong odor of naphthalin had the desired effect. Dr. Pauli remarks that, for prompt action, doses that can be so recognized are necessary.

In the cases treated, with one exception, there was no return of the disease, and in this instance it was insignificant. In two cases of the diarrhœa of phthisis the administration of naphthalin had the effect of diminishing the number of stools, but, on discontinuing the remedy, the diarrhœa returned and persisted.

Bromohydrate of Quinine and Valerianate of Caffeine in Malarial Infection.—Dr. Martinez Cerecedo, in the *Gaceta de los Hospitales*, Anno III.

N. 55, publishes the results obtained by him in the treatment of serious forms of intermittent fever by the association of the bromohydrate of quinine and valerianate of caffeine. He claims, as a result of comparative trials of the sulphate and bromohydrate of quinine, the superiority of the latter in the following respects:

a. A greater activity in smaller doses.

b. A gradual sedative action upon the nervous system.

c. The power of abating, and finally of removing, all tendency to vomiting, — a property worthy of special consideration.

d. In the ease with which it gains mastery over the malarial infection.

e. In that the ill-effects of the drug are less marked, or indeed imperceptible.

f. In that it does not irritate the stomach, or produce diarrhœa.

g. In that hypodermatic injections are less frequently required.

h. In that relapses and returns of the fever are less frequent under its use.

i. Because, by associating the bromohydrate of quinia and the valerianate of caffeine (fifteen grains of the former to eight of the latter), many quotidian forms of the disease may be subdued which do not yield to the sulphate in much larger doses.

j. Because the comparative cheapness of these drugs renders their employment less onerous to patients in moderate circumstances.

Ovariotomy.—Prof. Giovanni Calderini recently performed two difficult operations for ovariotomy at the Obstetrical and Gynecological Institute of Parma. In the first case there was an enormous left tubo-ovarian cyst, which presented extensive peritoneal adhesions.

In the second a bilateral ovariotomy was performed. The left ovary contained a cyst largely adherent to the peritoneum, parietes, and pelvis. The right ovary also had undergone cystic degeneration, and was the size of a hen's egg. Notwithstanding the difficulty and extent of the operation in each case, they were successfully concluded, and both patients are convalescent.—*Gazzetta degli Ospitali*, March 25, 1885.

Nephrectomy.—Dr. Vincenzo Dattilo, on the 8th of March, 1885, performed a difficult operation of nephrectomy for suppurative pyelo-nephritis. The walls of the cyst could not be removed, owing to extensive adhesions to the lumbar muscles, the diaphragm, and peritoneum. They were accordingly secured to the edges of the external wound by interrupted sutures. The cyst was previously evacuated eight times with Potin's apparatus, four pints of a purulent fluid being obtained at each evacuation. The operation, which was preceded by a ninth puncture with Potin's aspirator, and by free exsection of the twelfth rib, lasted forty minutes, and was conducted under strict antiseptic precautions. The highest temperature recorded subsequent to the operation was 100.4° F. The patient is rapidly recovering.—*Gazzetta degli Ospitali*, March 25, 1885.

Resection and Suture of the Median Nerve.—M. Surmay has recently published an interesting case of resection and suture of the median nerve, in which immediate union resulted in the reëstablishment of the function of the nerve, except sensibility to pain and temperature. From the result he draws the following conclusions.

1. That simple hypertrophy of the neurilemmar tissue between the primitive nerve fascicles may determine the abolition of the functions of the nerve.

2. That after resection the union of the two ends of the nerve may be followed by immediate reunion.

3. That this reunion may be accompanied by the immediate reëstablishment of the functions of the nerve.

4. That in the restoration of the function of the nerve general sensibility, tactile sensibility, and sensibility to pain and temperature do not return simultaneously, but in the following order: sense of touch, general sensibility, ability to appreciate pain, and, finally, to distinguish temperature.—*Revue Thérapeutique*, April 1, 1885.

Cholecystotomy in the Treatment of Biliary Calculi.—Prof. Jules Bœckel, in a paper read before the French Surgical Congress, held April 6 to 12, 1885, reaches the following conclusions as to cholecystotomy as a method of treatment of biliary calculi:

Cholecystotomy is or is not grave as depends upon (A) the presence or (B) absence of biliary fistulæ.

A I. In the first case (existence of a fistula having demonstrated or given cause to suspect the presence of one or several calculi), operative interference is demanded.

II. Although cure is sometimes spontaneously effected, there is great advantage in operating opportunely.

III. Early intervention assures and hastens the cure by preventing accidents due to incessant draining of the bile.

IV. The operation is one of great simplicity and remarkable benignity, owing to the adhesions which unite the gall-bladder to the abdominal wall; even when it is necessary to open the peritoneum, cholecystotomy, practised under these conditions, may be considered harmless when done under antiseptic precautions.

B I. In the second case (absence of fistula and adhesions), the operation is much graver, and its indications are much more difficult to grasp.

II. Primarily, the diagnosis must be established and the cause of obstruction fully ascertained, in order to avoid an operation of doubtful utility.

III. When the history, progress of the disease, examination of the patient, and, above all, *the presence of a biliary tumor*, and *exploratory puncture*, reveal the presence of biliary calculi, cholecystotomy, opportunely performed, seems to be indicated.

IV. When the diagnosis is well established the operation should be done as early as possible, to obviate the serious, or even fatal, complications which may result from delay.

V. In all other cases the operation is in itself too grave, and its results too uncertain to justify its performance.

VI. At present our knowledge is not sufficiently definite to decide as to the relative merits of cholecystotomy or cholecystectomy. To solve the problem, additional data must be collected.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, APRIL 25, 1885.

NEPHROLITHOTOMY.

MR. CHIENE, of Edinburgh, narrates, in the *British Medical Journal* for February 7, 1885, a successful removal of a calculus, weighing forty-eight grains, from the otherwise healthy kidney of a man twenty-nine years of age. The chief symptoms were long standing, intermittent, and severe pain in the loin, and bloody urine. As soon as the kidney was reached by the ordinary incision, an elevation was detected in the substance of its lower half, which proved, on exploration with a needle, to be a stone. The parenchyma of the organ was scratched through with the finger-nail until the concretion was reached, the wound enlarged with dressing forceps, and extraction effected. There was considerable oozing of blood; two drainage tubes were inserted, and antiseptic dressings were applied. At the expiration of rather more than three months, the relief was complete.

DR. SYMONDS and MR. HENRY MORRIS have each recorded in the *Lancet* for March 7, 1885, an equally gratifying result; and on last Wednesday, at the meeting of the American Surgical Association, Dr. Tiffany, of Baltimore, read a paper on renal lithotomy, in which he gave the details of a successful removal of a stone weighing five hundred and fifty-six grains, it being the largest on record.

In 1869 Mr. Annandale advocated nephrolithotomy. Simon, in 1871, suggested acupuncture of the exposed organ, with a view to detect the concretion; and Dr. Gunn, of Chicago, and Mr. Durham, in 1872, were the first to cut down upon the kidney in the expectation of finding a stone. It was, however, reserved for Mr. Henry Morris, in 1880, at the suggestion of Dr. Coupland, to perform the first formal nephrolithotomy, and, in the five years which have elapsed since its successful introduction, it has established for itself the reputation of being an eminently safe and rational procedure.

In connection with the cases of Chiene, Symonds, Morris, and Tiffany, and an able and instructive address on "Some Points in the Surgery of the Kidneys," recently delivered by MR. MORRIS at the Medical Society of London, and published in the *British Medical Journal* for February 14, 1885, we propose to discuss the operation of nephrolithotomy, and briefly compare its results with those attained by nephrectomy for calculus alone, and with those secured by nephrectomy and nephrotomy for calculus associated with other lesions.

At the outset it should be stated that by nephrolithotomy is meant, as declared by Morris in his original paper on the operation, which may be found in the *Transactions of the Clinical Society of London*, vol. xiv., incision of the kidney simply and solely for the removal of a renal calculus, the organ not being dilated by pus or urine. For these reasons, we omit the cases of Haward, Golding-Bird, and Jones, of Manchester, which are usually referred to as examples of the procedure, as pus was present in all. The statistics are derived from a paper read at the recent meeting of the American Surgical Association by Dr. S. W. Gross, many having been gleaned by him from private sources of information.

Nephrolithotomy has been resorted to in 21 cases, the operators having been Thornton in 3, Morris and Beck, each in 2, and Butlin, Bardenheuer, May, Howse, Hill, Symonds, Anderson, Godlee, Elder, Cullingworth, Pepper, Chiene, Rouse, and Tiffany, each in 1. Of the entire number, 2, or 9.52 per cent., died; the patient of Cullingworth from the blocking of the opposite ureter by a stone near its vesical orifice, while the patient of Pepper expired suddenly, some days after, from causes which were not connected with the operation. Thornton's cases were by the combined ventral and lumbar incision, the kidney having been reached in the remainder through the loin. In the cases of Butlin, Anderson, and Cullingworth, the stone was removed through an incision in the pelvis of the kidney; in the others, it was extracted through an opening in the substance of the organ. In the case of Bennett May, the calculus weighed nearly an ounce, and its extraction was followed by profuse venous bleeding, which was, however, speedily arrested by pressure. In only two other instances was this accident met with, but the loss of blood was readily and easily controlled.

From existing experience it appears that the extraction of a calculus from an otherwise healthy kidney is an operation almost without danger to life. All of the recoveries were prompt and perfect, except

in the first case of Morris, in which a suppurating sinus still persists five years subsequently. In three of the cases, the stone was removed through the pelvis of the kidney, on which account Mr. Anderson suggests the term pyelolithotomy, to distinguish the operation from the ordinary one in which the concretion is removed through an opening in the parenchyma of the organ. This, however, is an unnecessary complication of nomenclature, and no special stress need be placed upon any supposed advantages to be derived from the site of the opening, as the surgeon will cut or scrape through the tissues which cover the stone. Under no circumstances should any but the lumbar incision be resorted to, unless there be doubt as to which kidney is involved. Under these circumstances, laparotomy is proper, and the kidney and ureter should be examined on both sides. Had Mr. Cullingworth suspected the presence of a stone in the opposite ureter, an exploratory median incision and intraperitoneal ureterotomy would probably have saved his patient.

With such an excellent record, it is remarkable that the operation has not been more frequently resorted to, and it is odd that only two cases have occurred outside of Great Britain. The uncertainty of the diagnosis in the earlier stages of renal calculus has, however, probably deterred many surgeons from performing it, since the symptoms are almost identical with those met with in commencing strumous kidney, and with those observed in persons with an abnormally acid urine, or of a gouty tendency, or who lead sedentary and indulgent lives. Hence, Mr. Morris is emphatic in stating that before a surgical exploration of the kidney, with a view to nephrolithotomy, is undertaken, symptoms which are regarded as characteristic of renal calculus shall have existed for some months, and still persist; and, secondly, that these symptoms have not yielded to ordinary treatment. As a rule, recurring attacks of renal colic, the presence of blood or pus in the urine, frequency of micturition, and the absence of prostatic or vesical lesions which can explain these phenomena, are held to be sufficiently characteristic symptoms. Experience has, however, demonstrated that they are not positively characteristic, since surgical exploration of the kidney has frequently failed to detect a calculus when these signs were pronounced.

With these symptoms before him, however, the surgeon is justified in making an exploratory operation. If a calculus be removed, the integrity of the organ is saved, and advancing suppuration prevented. If, on the other hand, a stone is not found, our present knowledge warrants us in stating that no danger will have been incurred. Thus, of 22 exploratory operations, of which 3 were done by Marcus Beck, 2 each by Morris, Lucas, and Annandale, and 1 each by Gunn, Durham, Lente, Golding-Bird, Barker, Barbour, Norton, Anderson, Fowler, Powell, Thornton, Hulke, and Lawson, all recovered, the kidney having been actually incised in three. More than this, the mere digital exploration of the organ has in some instances been followed by prolonged relief: first, by the securing of a mobile kidney in its proper place through the contraction which followed cicatrization; secondly, by causing cessation of the pain and renal irritation through division and stretching of the nerves of the lumbar region; thirdly, by taking off tension from a perinephritic inflammation; and, fourthly, by giving vent to a little pus after puncturing a scrofulous kidney.

In some of the failures, a stone was doubtless overlooked. Even when supplemented by acupuncture, the detection of a calculus is not always easy, as is shown by a case in which Mr. Morris recently removed an otherwise healthy kidney containing a concretion, which the repeated use of the needle had failed to discover. Hence, he concludes, and as we think very justly, that ordinary exploration with the finger and needle should not be considered a complete exploration, but that the kidney should be incised, after the failure of these measures, in order that its pelvis and calices may be thoroughly examined with the finger. This procedure will doubtless add to the risks of the procedure, and, it may be, subject the patient to the annoyance of a sinus or a urinary fistula, a contingency which is to be feared, if we may base an opinion upon the frequency of the formation of such a sinus or fistula after nephrotomy for calculous pyonephrosis, ordinary and strumous suppuration, and hydronephrosis, as they are met with in one-third of the recoveries.

Nephrectomy for calculus uncomplicated by other lesions has been done by Czerny, Kosinski, and Morris. Two of the operations were by the lumbar incision, and one by the ventral incision. Despite the fact that the patients recovered, the organ should never be removed for this condition. It may happen, however, that, even after incision, a stone cannot be detected, and that the patient's sufferings demand that extirpation be resorted to. Under these circumstances, a stone may be present, but the surgeon has the satisfaction of knowing that a useful organ was not sacrificed until all the means for the detection of the stone had been employed and failed.

That nephrolithotomy is a most judicious procedure in the early stage of renal calculus, is shown not only by the favorable results of the operation, but by a comparison with other operations performed after the concretion has given rise to more or less advanced disorganization of the kidney. Thus, of 20 nephrotomies for calculous pyonephrosis 9, or 45 per cent., were fatal, while of 23 nephrectomies for a similar condition, 10, or 43.47 per cent.,

perished. For calculous hydronephrosis, 4 nephrectomies indicate 1 death. These facts are suggestive, since they indicate the great necessity of framing an accurate diagnosis of a renal concretion before it has occasioned destructive changes which are liable to terminate in the death of the patient, whether he be abandoned to nature's efforts, or be afforded a chance by a resort to the knife. They also show the great importance of increasing our knowledge of the symptoms of renal calculus, in order that its early removal may be more frequently practised.

ANTIPYRETICS IN PUERPERAL SEPTICÆMIA.

One of the most important and frequent indications in the treatment of puerperal septicæmia is the reduction of the high temperature. But there is a difference of opinion as to the best means for causing this reduction. Thus Dr. Charles, of Liege, in the *Journal d' Accouchements*, February 28, recommends thirty-four grains of quinine and one-tenth of a grain of aconitia made into twenty pills, and if a patient's temperature be 102° F., or more, gives one of these pills every hour, or once every two or three hours, as the temperature may require. The quinine treatment is probably that which is followed by most practitioners, and a preparation of aconite may be added, though probably few use aconitia, because of the uncertain strength of this form of the drug. Siredey, though advising quinine in that form of septicæmia which he calls lymphoperitonitis, claiming that the medicine is marvellously appropriate to the morbid state, being antipyretic, sedative, and antiseptic, prefers in infectious phlebitis, alcohol associated with extract of cinchona. He gives about two ounces, of alcohol in the twenty-four hours. It certainly seems to us better in this disease, if alcohol is to be used, to give it thus in a known quantity, than to give it as is usually done in the form of whiskey or brandy. Moreover, when a definite quantity of alcohol is directed, the nurse will be very careful not to give more or less than the amount prescribed, and thus a blunder that may cause death be prevented.

Dr. Barbier, of the Maternity of Liege, after trying antipyrin in a case of puerperal metritis associated with phlegmon of the iliac fossa, states that it caused a reduction of temperature when aconitia, quinine, sodium salicylate, muriate of quinine hypodermatically, and carbolic acid had failed. Barbier, referring to Henocque's assertion that antipyrin acts upon the bloodvessels and causes contraction of the capillaries, suggests that it may prevent absorption of septic matter by causing contraction of the uterine vessels.

A case of phlebitic puerperal septicæmia now under treatment confirms the statement as to the very prompt reduction of temperature caused by antipyrin. A single dose of nine to fifteen grains will cause within two hours a reduction of temperature of between 2° and 3° F. Very profuse sweating follows the administration of the remedy, and the patient is somewhat prostrated. Unfortunately, the temperature usually begins to rise in about three hours.

REMOVAL OF TUMORS OF THE BLADDER.

In *The Medical Record* for March 15th may be found the results of 100 operations for the removal of neoplasms of the bladder of both sexes, collated by Dr. Stein, of which 54 occurred in males and 46 in females. In view of the recent impetus given by Sir Henry Thompson and Mr. Whitehead to the surgery of vesical neoplasms, these statistics are of more than ordinary interest.

The operations on males include external perineal urethrotomy, perineal cystotomy, hypogastric cystotomy, combined hypogastric and perineal cystotomy, and combined epicystotomy and perineal urethrotomy. Of the 31 external perineal urethrotomies 14 terminated fatally. Of the 17 recoveries, in 5 the growth was only partially removed, so that permanent relief was not to be expected; in some cases the relief was decided, but temporary; while in others the reports were too recent to determine the final result. Of the 10 perineal cystotomies, of which the majority were by the lateral method, 6 recovered, 3 died, and 1 was of recent date. Of the 11 epicystotomies, 2 recovered and 9 died, and further data are required in the recoveries to admit of any positive statement as to the ultimate issue. In at least five of the cases the growths were malignant, and a decided amelioration of the symptoms was noted in four. One combined suprapubic cystotomy and lateral perineal cystotomy recovered, while one combined epicystotomy and median urethrotomy perished.

Of the 46 operations on females 37 were by urethral dilatation, 8 by incision of the urethra, or by colpocystotomy, and 1 by resection of the bladder. Of the 37 in which the growths were removed through the urethra, 24 recovered, 3 were much improved, and 10 died. Of the 8 cutting operations, 5 recovered, and 3 died. The operation of resection of nearly the entire bladder for sarcoma, done by Sonnenberg, was doing well nearly four weeks subsequently.

In his comments upon these several procedures Dr. Stein very justly concludes that each will have to rest upon its own merits, and that a disposition to routine practice is manifested, especially in favor of median urethrotomy. As a result of this practice, not a few sessile neoplasms, particularly when seated at other points than the lower fundus, have been incompletely removed, and thus served to swell the list of deaths. Hence, we agree with him in advising

that in all cases an exploratory median cystotomy in the male, or dilatation of the urethra in the female, should be resorted to, when, if accessible and removable, the growth can be gotten rid of. If, on the other hand, it is inaccessible or too broadly attached, the bladder can be opened above the pubes, and removal be effected. The recorded failures should not militate against its performance, since in nearly one-half of the cases the disease was malignant, while in others the operation was too long deferred.

GENERAL GRANT'S CASE.

Since Sunday, April 12th, General Grant's condition has undergone uninterrupted improvement. He has been free from pain, has eaten with relish, and has slept naturally. His strength has so far returned that he has left his room, has joined the family at table, and has driven in Central Park. This great improvement has, apparently, coincided with a partial or complete abandonment of the use of morphine, digitalis, and alcohol, which had become no longer needed; but it cannot be safely taken to indicate an advance toward a certain, or even probable, recovery. If the disease is epithelioma, recovery is so improbable that it cannot be predicted or even anticipated; it can only be recognized after it has taken place.

But, is it epithelioma? Of that the physicians in charge are best able to judge, although others, knowing the recognized difficulty and uncertainty of a diagnosis in any such case, may, properly, entertain a doubt. It is highly improbable that individual difference of opinion should not exist among four consultants;—indeed, if there were no doubt, why should there be a consultation? Moreover a sentence in a late bulletin, significant in what it leaves unsaid rather than in what it says, seems to point to differences in this case. "The physicians in attendance are, and have been, in entire agreement concerning the management of this case"—not the diagnosis, only the "management," is what the bulletin says; and yet the phrase was plainly written to meet the criticisms of the diagnosis, with which the daily press has of late been filled. A positive diagnosis has been published by only two of the professional attendants, and to those who are acquainted with the large experience, calm judgment, and wise prudence of the others, it would not be surprising if it should appear that they had refused to say that there could be no doubt concerning it.

It is particularly unfortunate, under the present circumstances, that the microscopical examination was not made by a pathologist of wide reputation. It is not to the discredit of the gentleman who did make it that he is not widely known, for he has been but a short time in the ranks of the profession. The demonstration may have been complete, but in such an important case, if an opinion on the microscopic appearances of the diseased tissue was to be published, it would have been better if the report had been made by such recognized authority as would have carried conviction with it to the mind of every one.

The disease appears to have made no progress locally; the slough on the back of the pharynx has in great part fallen, leaving a slightly elevated surface; the right half of the soft palate is destroyed, and the lump behind the angle of the jaw is larger and more diffuse.

CARE OF POOR WOMEN DURING THE LYING-IN PERIOD.

Dr. John P. Gray, the distinguished Superintendent of the Utica Institution for the Insane, has recently delivered a very interesting address upon insanity, and some of the means for its prevention. Among these he mentions want of proper care during maternity, especially during the lying-in period. He takes the just ground that a woman for a month after labor should be free from toil, worry, and anxiety, and that she should have suitable food. In order to secure these most desirable ends for poor women, he suggests the employment of women of the same social class to do the housework, and to be paid for it by an association. This association should be under the care of a physician, and, of course, must depend upon private beneficence for its support. In support of his views he observes: "If women knew they would have all needed care, not in a hospital with its necessary publicity and separation from home, but in their own homes and among their families, and without the notoriety of their condition, what a burden would be lifted, what health saved, and what insanity prevented."

Dr. Gray has had most favorable and extensive opportunities for studying the causes of insanity, and whatever he may say upon the subject is entitled to consideration. Certainly the observation of every practitioner of obstetrics among the poor, will offer instances confirming Dr. Gray's views as to insanity often resulting from neglect and want of proper care after labor. The suggestion made for the prevention of this evil seems to us wise, just, and practicable. In all our great cities there are multitudes of mothers whose condition cries aloud for the very protection proposed. And in all our large cities too, there are men and women of wealth and generous hearts, who, if properly appealed to, would be willing to give liberally for the purpose indicated. We hope the day will soon come when such associations as Dr. Gray proposes will be in active operation wherever needed.

SOCIETY PROCEEDINGS.

AMERICAN SURGICAL ASSOCIATION.

Sixth Annual Session held in Washington, D. C., April 21, 22, 23, 24, 1885.

(Specially reported for The Medical News.)

Tuesday, April 21st.—Morning Session.

The Sixth Annual Session of the American Surgical Association assembled in the Hall of the Army Medical Museum, at Washington, and was called to order at 11 A.M., by The President, W. T. Briggs, M.D., of Nashville, who then delivered the

ADDRESS OF THE PRESIDENT.

After expressing his profound appreciation of the exalted honor conferred upon him by his election to the Presidency of the Association, he said:

We may safely indulge the confident expectation that this meeting will be characterized by the spirit in which the Association had its origin, and will be pervaded by the same united purpose, the same harmonious and agreeable intercourse and similar valuable work to that which has edified and instructed us in previous meetings, and which, in the brief period of its existence, has so illustrated the usefulness of the Association that its permanency as an exponent of the status of American surgery, and as a factor in the true advancement of its science and art, is fully assured.

Notwithstanding these just and bright anticipations on the threshold of this session, we feel oppressed and saddened by the notable absence of a Fellow who, when among us, stood, like Saul, "a head and shoulders taller than his brethren;" an absence which deprives us of the light of remarkable genius and learning upon our discussions, and, at the same time, bows our heads in sorrow for the loss of one whom we had come to venerate as the Nestor of American surgery. While we sat a year ago, his noble form lay prostrate, and his spirit was then near passing, though we had hope that he might be spared. To-day we realize that he whose fertile brain conceived, and whose indomitable effort brought this Association into existence, and developed it to its present proud position among the scientific bodies of the country, has gone from us forever. The death of Prof. Samuel David Gross orphaned the surgical profession of America, and removed from its ranks one who, as pathologist, surgeon, and medical philosopher, was the acknowledged peer of any one in the world. He no longer lives in the flesh, but his labors in the domain of science, for a period of nearly sixty years, has secured an immortality of fame, and his utterances and achievements will descend to further generations of the profession as a precious heritage. Though endowed with brilliant intellectual qualities, his life and example are truly great, in that he conspicuously illustrated the value and dignity of enthusiastic labor and devotion to his profession.

He was the father of this Association. It is the child of his old age, and was to him a deeply cherished offspring. He has left it to us, his Fellows and successors, to nurture and maintain in all the vigor and power with which he would have invested it. Let us then be animated by the same lofty spirit which moved him in its organization, and vow to each other, as in the Temple, that we will devote ourselves to the duty of making it as great and shining as the fame of its founder, and as enduring as the science to which he consecrated his life.

At the close of this address, the Association went into

EXECUTIVE SESSION.

The reading of the minutes of the previous session being dispensed with, the reports of the Treasurer and of the Committe on Publication were read, and the following

COMMITTEE ON NOMINATIONS

was appointed: Drs. C. T. Parkes, of Chicago; A. B. Watson, of Jersey City; E. M. Moore, of Rochester; W. F. Peck, of Davenport, Iowa; N. Senn and S. W. Gross, of Philadelphia; and N. P. Dandridge, of Cincinnati.

Dr. David Prince, of Illinois, then read a short paper on

ATMOSPHERIC PURIFICATION.

After dwelling briefly upon the importance of measures adopted to rid the air of its deleterious impurities, and recounting the more successful of the methods that have been and are now employed, the author introduced a pamphlet describing and illustrating a new device of his own invention, for atmospheric purification by the use of steam. The method he considered preferable to the use of the douche or spray, in that it acted upon a larger scale, and he thought it an important adjuvant to other prophylactic measures.

The report of the Committee on

RESECTIONS OF THE ANKLE-JOINT

being called, Dr. P. S. Conner reported progress, and requested a continuation of the Committee until the next annual session of the Association.

The Association then adjourned until 2 P.M.

Afternoon Session.

Dr. John B. Roberts, of Philadelphia, read a contribution on

THE FIELD AND LIMITATION OF THE OPERATIVE SURGERY OF THE HUMAN BRAIN.

The study of this subject, he remarked in opening, was suggested to him by the observation, while a resident hospital surgeon, of the death of a man from a traumatic cerebral abscess, and the inactive conservative surgery which was then in vogue. "Do we," he asked, "know no better now than to allow a man to die from acute encephalitis without even an attempt at his relief?"

He then introduced nine conclusions which, he remarked, embodied his creed on the subject of traumatic brain injuries:

1. The complexus of symptoms called "compression of the brain," is not due so much to displacing pressure exerted on the brain-substance as it is to some form or degree of intracranial inflammation.

Let the profession repudiate the idea, he urged, that displacement of brain-substance is the cause of the trouble, and they will then discard many of the erroneous

theories in regard to the use of the trephine. There are no definite symptoms by which we can distinguish between an inflammation from laceration and compression of the brain-substance. It would be well if the expression, "traumatic compression of the brain," were always translated "traumatic inflammation of the brain."

2. The conversion of a closed (simple) fracture of the cranium into an open (compound) fracture by incision of the scalp is, with the improved methods of treating wounds, attended with very little increased risk to life.

In this respect, the dangers of open fractures over closed fractures of the skull do not correspond to the corresponding fractures of other bones.

3. The removal of portions of the cranium by the trephine or other cutting instruments is, if properly done, attended with but little more risk to life than amputation of a finger through the shaft of the metacarpal bone.

It remains for the opponents of trephining to show that the cause of death, when it occurs, is due to the trephine. President Briggs and some others consider the operation one of the simplest in surgery; but other authorities oppose that view. The comparison between fractures of the skull and amputation of a metacarpal bone, the speaker considered appropriate, because in each case there was exposed a small amount of cancellous bone tissue. Amputation of the finger may be followed by septicæmia and death, and so may the operation of trephining the skull, but neither is to be expected. According to Amidon, the mortality of trephining (3.6 per cent.) is less than that of amputation through the shaft of the metacarpal bone (4 to 5 per cent).

4. In the majority of cranial fractures the inner table is more extensively shattered than the outer table. The element of danger in fractures is due solely to the splintering of the internal table. Necrosis of the splintered bone fragments is looked upon by some as the element of danger, but in the opinion of the speaker necrosis is of rare occurrence, and the true element of danger is the acute encephalitis that is excited by the splintering.

5. Perforation of the cranium is to be adopted as an exploratory measure almost as often as it is demanded for therapeutic reasons.

This measure the speaker considered justifiable in all cases in which the injury was of sufficient severity to justify the belief that spiculation had occurred.

6. Drainage is more essential in wounds of the brain than in wounds of the other structures.

This method, the author believed, had been greatly neglected, for surgeons who would be loath to permit an accumulation of pus to remain for an hour after its discovery in any other part of the body, would quietly allow a case to die from an abscess in the brain without an attempt at relief by operative procedure. Several cases were reported illustrative of this proposition.

7. Many regions of the cerebral hemispheres of man may be incised and excised with comparative impunity.

The timidity of surgeons with regard to injuring the brain-substance by operative means, the speaker attributed to the prevalent ignorance on the subject of cerebral localizations. Deaths are not due to the exposure of the cerebral convolutions.

8. Accidental or operative injuries to the cerebral membranes, meningeal arteries, or venous sinuses should be treated as are similar lesions of similar structures in other localities.

Numerous cases have been reported in support of this proposition.

9. The results of the study of cerebral localization are more necessary to the conscientious surgeon than to the neurologist.

The time has come when a man, if he assume the role of a surgeon, must make the study of cerebral localizations a special feature of his education. When called upon to operate in cases of head-injury, he must in many cases be the only one to decide what shall or shall not be done.

The principles thus set down were next applied to cranial fractures, to intracranial hemorrhage, to intracranial suppuration, to epilepsy following cranial injury, to insanity following cranial injury, and to cerebral tumors.

The following are the rules adduced by the author:

A. Cranial Fractures.

Closed (Simple) Fissured Fractures.

1. Where there is no evident depression, and no brain symptoms, no operation should be made.

2. In case of no evident depression, with brain symptoms, incise the scalp and trephine.

3. With evident depression, but no brain symptoms, incise the scalp and possibly trephine.

4. With evident depression and brain symptoms, incise the scalp and trephine.

Closed (Simple) Comminuted Fractures.

5. Where there is no evident depression, and no brain symptoms, it is advised to incise the scalp and probably trephine.

6. In cases of no evident depression, with brain symptoms, incise scalp and trephine.

7. With evident depression, but no brain symptoms, incise scalp and trephine.

8. With evident depression and brain symptoms, incise scalp and trephine.

Open (Compound) Fissured Fractures.

9. In cases with no evident depression, no brain symptoms, no operation is advised, but treat the wound.

10. Cases presenting no evident depression, with brain symptoms, should be trephined.

11. With evident depression, no brain symptoms, possibly trephine.

12. With evident depression and brain symptoms, trephine.

Open (Compound) Comminuted Fractures.

13. If there is no evident depression, and no brain symptoms, it is probably proper to trephine.

14. In case of no evident depression, with brain symptoms, trephine.

15. With evident depression and no brain symptoms, trephine.

16. With evident depression and brain symptoms, trephine.

As a working rule for surgeons the speaker believed that these conclusions would be found reliable and

correct. Trephining has become an operation of so little danger that every case of doubt should be treated by it.

B. Intracranial Hemorrhage.

Trephine for the removal of a clot and the arrest of bleeding when the probable seat of hemorrhage is ascertainable, and the clot is believed to be a localized one. The speaker then discussed briefly the symptoms which rendered the operation advisable and those which contraindicated it.

C. Intracranial Suppuration.

Trephine and make, if necessary, exploratory punctures in all cases of abscess. This is rendered more compulsory because of the fact that the spontaneous evacuation or other removal of an abscess in the brain practically never occurs. Early symptoms of pus mean, as a rule, "Do not operate;" later appearances of pus indicate, however, the propriety of an early operation. If the pus is not discovered beneath the dura, then incise the dura, and if the pus is not then discovered aspiration should be performed, unless the symptoms disappear upon the removal of tension by the perforation of the dura.

D. Epilepsy following Cranial Injury.

Remove a portion of the cranium in selected cases. Abscesses are usually situated in the anterior half of the cerebrum. The symptoms indicating the propriety of trephining in these cases are, a painful or sensitive cicatrix, and symptoms indicating brain irritation in the vicinity of the scar, especially if this be in the anterior half of the cranium. The temperature test was then referred to and the statement of a modern writer that the temperature may be taken by placing a thermometer in the auditory meatus. The symptoms contraindicating operative procedure are the presence of signs indicative of inflammatory processes at other portions of the brain, the history of epilepsy or insanity in other members of the family.

In these cases, Dr. Roberts added, several months must elapse before the case can be pronounced one of failure. The operation should be done as promptly as possible.

After a brief review of the last divisions of the application, the author passed to a demonstration upon a chart of the leading cerebral localizations. The rules for these last cases were.

E. For Insanity following Cranial Injury.

Remove a portion of the cranium in selected cases.

F. For Cerebral Tumor.

If it can be localized, and if it is probably superficial, remove the bone and excise the growth, if it is found.

Dr. Hunter McGuire, of Richmond, remarked that in reviewing the paper that had just been read, he could find but two instances in which an operation was not advised. This advice, he continued, takes us back one hundred years, to the time when men used to boast of the number of holes they carried in their heads, and when surgeons boasted of the number of heads they had trephined. There are no set rules that can be laid down for the government of all cases; each case must be a law to itself. There are no two injuries of the skull that are the same any more than there are two faces exactly alike. Referring to the first proposition, he asked how the author could account for the almost immediate appearance of symptoms of compression of the brain in so many cases. A man receives a blow upon the head. The bone is depressed, the brain is compressed, and almost immediately, within a few minutes, or even within a few seconds, symptoms of depression are manifested. Is it possible that an inflammatory exudation could have developed so rapidly? Such, to the speaker, seemed almost impossible. The author has compared the use of the trephine to the amputation of the metacarpal bone. It was either Cooper or Hunter who said that there was to the patient between the trephine and eternity a little thin sheet of paper. How the author came to the conclusion that the application of the trephine was so simple a matter the speaker could not comprehend. He asserts that a man may even be trephined and immediately go to his home. With no disrespect, the speaker wished to know to which home Dr. Roberts referred, and whether it would not, in a great many cases, be the "long home." With regard to the importance of drainage in cerebral difficulties, he agreed with Dr. Roberts. In the last case of trephining which he had performed, he had taken out a piece of the scalp of a size to correspond to the size of the trephine, in order to secure thorough drainage. He then narrated several cases in which he had made use of the trephine. In one case, in which an individual had been insane for nine years, the day following the operation he spoke of events as occurring yesterday which had occurred nine years before, and uttered the first coherent words for that period of time.

Dr. Moses Gunn, of Chicago, recalled the position he had taken in a discussion of the same ground covered by this paper three years ago, when he had advocated the early operation in cases of cranial fracture with symptoms of depression, and had endeavored to advocate the rule that in simple or closed fracture the bone should be elevated as in compound fractures, taking the ground that aseptic measures as now practised avert the danger that would otherwise exist in the conversion of a simple into a compound fracture. This rule, he thought, if properly applied could be employed not only with safety, but with benefit to the human race.

With regard to the first proposition laid down by Dr. Roberts, he agreed, and believed that in many cases the symptoms arise not from depression but from irritation and inflammation. Mere mechanical compression of the brain is not a symptom of importance. As stated by Dr. Briggs in the discussion referred to as occurring three years ago, if compression of the brain was all that is to be feared, he would never use the trephine, because the brain would soon accommodate itself to the new pressure. The danger is in the changes of nutrition that follow. He did not go so far as Dr. Roberts, however, and say that there are no such symptoms as those of compression. These symptoms, he thought, were too distinctive in their character, and came on too soon after the accident to be due to any other cause. There is then mechanical compression, and not irritation or inflammation. But that mechanical compression does not require the application of the trephine. The danger of permitting the pressure to remain is that it may become permanent and excite irritation and in-

flammation that may do injury, in giving rise to secondary symptoms.

Dr. C. B. Nancrede, of Philadelphia, agreed with the writer of the paper in many points, but differed from him in a number of others. As to the first proposition, he agreed with the previous speaker. If Dr. Roberts were to call it secondary compression he would agree with him in the conclusion: that it is due to some form of inflammation. Compression of the brain produces sudden and violent contraction of the vessels of the brain in the vicinity of the compression. It is an error to associate in our minds the dangers of compound fractures of the cranium and compound fracture of other bones. They are not to be compared. In considering any operation we must consider the complications that may arise from it in the most skilled hands. He could hardly conceive how a serious complication could arise from an amputation of the metacarpal bone, but he could very easily understand how serious complications could arise from operative procedures upon the skull.

In referring to the fifth conclusion, he remarked that he would be very sorry to have his cranium perforated as an exploratory measure. The importance of drainage he considered well established. On the seventh proposition he differed from Dr. Roberts. Nearly all the cases of operative procedure for brain-tumor have terminated fatally. The treatment of wounds of large arteries and veins, he said, is manifest, but, he added, in all cases where there is reason to suspect that a coronal sinus has been wounded, we should act as though that sinus had been wounded. He was cognizant of one or two cases in which the patient perished before the eyes of the operator because that assumption was not made. In one case which he had seen with Dr. Hopkins, this assumption was made, with the gratifying result of averting what would have been a fatal hemorrhage. As soon as the button of bone was detached, there was a most appalling gush of blood. This was controlled by pressure and the vessel secured by suture, but great difficulty was encountered in the removal of the forceps by which the vessel was secured. Finally a piece of lint dusted with iodoform, was placed over the ligature and the case went on to recovery.

With regard to the study of cerebral localization, he agreed with Dr. Roberts, and believed that we are now fairly acquainted with the motor centres. There are few of them so well located, however, that we can be sure of the point that should be uncovered. As for the reasons for the application of the trephine he agreed in some of them with the author and differed in others, but considered the subject one that should be given more deliberate investigation. How Dr. Amidon could have obtained such a number of cases with so low a mortality as 3.6 per cent. from trephining, he could not understand. From his investigations, he would place the mortality at about 10 per cent.

As to the importance of drainage he agreed with Dr. Roberts, but not to such a degree as asserted in the paper. In regard to the temperature test, the speaker referred to its importance if it could be confirmed. In every case of which he could learn in which a record was taken, where the inflammation was confined to the brain-substance itself, the temperature was normal or subnormal. He further cautioned against waiting until inflammation had developed before applying the trephine. After inflammation has developed, there is no good that can be done by operative procedures, unless there was a mass of pus to evacuate. The symptoms of intracranial irritation can be recognized long before there is any change but an effusion of serum.

Dr. W. F. Peck, of Davenport, Iowa, said that he coincided, in the majority of instances, with the opinions expressed in the paper. The first thing to decide in accidents to the skull was whether any injury had been done to the brain, and then whether pressure was being exerted upon the intracranial contents. The secondary consequences certainly call for other interference than therapeutic. Several cases were then narrated to illustrate his views on this subject. He had had about six cases, and in their treatment he had endeavored chiefly to remove pressure and to establish drainage, which being secured, the result was, as a rule, favorable.

Dr. T. F. Prewitt, of St. Louis, considered the propositions of Dr. Roberts so sweeping that they should be thoroughly discussed, and clearly defined views as to the conditions which demand trephining and those which do not demand it, laid down. He did not consider the injury in a simple case of fracture as of great importance. The danger is from the injury that may have been done to the brain. There is, however, undoubted danger in the too free use of the trephine. Some fractures of the skull are unaccompanied by symptoms, and are recovered from without leaving any permanent ill-effects, hence it is not proper to use the trephine in all cases. Those cases in which there are very sharp, needle-like spicula, are those in which the trephine should be used. Where, then, it is believed from the nature of the injury that the spicula are of this kind, as in perforating wounds, it is proper to trephine, even in the absence of very severe symptoms. Where there were no symptoms and no external wound, the speaker thought it proper to wait.

Dr. C. T. Parkes, of Chicago, differed from Dr. Roberts in regard to the symptoms of compression, but admitted that it is difficult to determine to what these symptoms are due.

Dr. S. W. Gross, of Philadelphia, requested that Dr. Roberts explain, before the discussion was permitted to go further, exactly what he meant by the expression "brain symptoms."

Dr. Roberts explained that by the term he meant the manifestations which are generally believed to come from lesions; in cases of fracture the term symptoms is generally employed to designate the coma, the hemiplegia, etc., which are usually attributed to depression of bone, or a clot upon the cerebral cortex. But in his first proposition he had tried to make clear that when we say compression we mean irritation, which is the first symptom of inflammation.

Dr. Prewitt then continued his remarks by a review of the propositions of the author, and a statement of his views upon them. Referring to the location of the centre of sensation as given by Dr. Roberts, he narrated a case that had occurred in his practice. A man was struck upon the upper and outer portion of the parietal and anterior portion of the occipital bone, with the end of a pistol. There was a complete fracture. He trephined, and noticed that before the operation as

well as during it, a large amount of brain-substance was removed. After trephining, he introduced his finger and found upon the tentorium cerebri, the "sight" of the pistol. In this case the seat of sensation must have been lacerated, and in part at least removed, and yet there was not a symptom of the trouble that would be expected to follow. Two weeks later, however, the man had a chill, and became hemiplegic. This was found due to the removal of the drainage-tube, and when this was replaced the symptoms soon subsided.

Dr. J. Collins Warren, of Boston, referred to the difficulty of obtaining such thorough drainage as that referred to. This is chiefly on account of the intracranial tension with which we have to contend. We do not find usually large collections of pus, but get rather the symptoms of irritation from brain-inflammation without much accumulation of its products. Another difficulty in deciding the question of interference in any given case lies in the difficulties of diagnosis. We may also have brain symptoms, from lesions external to the brain, as from periostitis and cellulitis. He reported a case of fracture at the upper and anterior portion of the parietal bone, that was treated at the Massachusetts General Hospital, which had been thoroughly analyzed by Dr. Walton, the neurologist of that institution. In that case paralysis of the leg first appeared, then paralysis of the arm, and finally a paralysis of the lower portion of the face. After some time had elapsed, the symptoms began to disappear in the order of their invasion.

Dr. L. McLane Tiffany, of Baltimore, differed from Dr. Roberts as to the insignificance of open wounds of the cranium, and remarked that most surgeons prefer to have their wounds, whether of the cranium or of other parts, remain closed. Certain monkeys, he continued, have been cited as having had their heads opened without damage, but it has yet to be shown that any man has had his head opened with as great impunity. In regard to the shattering of the inner table of the skull, he referred to the fact that it only depended upon which direction the missile took which table was shattered. He further called attention to the difference which exists between grown persons and children with regard to operative procedure, and remarked that he had seen a number of fractures in children which had gotten well without any bad symptoms, and in which the groove in the skull could be felt after the individual had reached maturity, but where a similar injury to an adult would have certainly called for operative interference. Attention was also called to a difference between the negro and the white race in regard to these operations. The negro, he said, will tolerate operations involving the brain with much less shock than the white man. He thought that the diagnosis where there were no symptoms and no depression was an impossibility Lastly, in referring to the rules laid down by Dr. Roberts, he called attention to the direction, "brain symptoms, but no depression," and asked, "How would you know where to trephine?" There might be counter and not direct injury, and for this reason there should be a distinction made.

Dr. S. W. Gross agreed with Dr. Roberts that there might be brain symptoms with no evidence of a fracture. Such an occurrence is of extraordinary frequency in army practice, as he remembered stating in a paper which he had prepared a few years ago on the subject of fractures of the brain in military practice. The dura mater may be so much stripped from the internal table of the skull as to give rise to an effusion of blood, and in such a case the symptoms of compression come on much more slowly than in case of the rupture of a branch of the middle meningeal artery. In regard to the simplicity of open fractures of the skull he differed from the author of the paper chiefly for the reason that the carrying out of antiseptic precautions in skull injuries is an exceedingly difficult matter. He did not consider trephining as safe as amputation of the metacarpal bone. The tables of Amidon, he stated, will not bear a critical inspection, for he has made a theory and has made his facts fit his theory, so that his paper is unreliable.

In regard to drainage, he agreed with Dr. Roberts, but added that the drainage of the brain is an exceeding difficult thing to accomplish. In regard to the rules that are laid down, he thought it proper to make further investigation before such measures are adopted. In the case of gunshot injuries, he thought it proper to enlarge the opening and to follow the ball with a large probe until its location is established, and then, if possible, to remove it. The popular sentiment with regard to the interference by the surgeon in cases of cranial injuries was also strongly denounced.

Dr. E. M. Moore, of Rochester, considered the subject one upon which the Association should give a very decided opinion. Accidents to the head are cases that are occuring to us constantly, especially in cases of suicide. What is to be done? With regard to popular sentiment, he did not think that the scientific surgeon should trouble himself about the silliness of juries, or the folly of judges. The idea of using a drainage-tube in the brain is modern, but the good results that have followed its introduction are gratifying. He has been accustomed of late to use a large probe as recommended by the last speaker, for the exploration of these wounds. In the last case in which he had used it he was able to follow the bullet down to the occipital bone, and then to trephine down upon it and remove it. He did not persevere sufficiently to carry the drainage-tube entirely through the track of the wound, as he now regretted that he did not do. The recovery in many cases is clearly attributable to the free drainage that is established by the wound, or by operation. As for the statistics of trephining, he considered them of no value whatever.

The further discussion of this paper was postponed until Wednesday morning.

MISCELLANEOUS BUSINESS.

A motion was passed inviting the Surgeon-General of the Army, the Navy, and the Marine Hospital Service, to be present, and to participate in the discussions.

Dr. J. S. Billings then invited the Association to take an excursion to the Johns Hopkins College and Hospital in Baltimore on Wednesday afternoon. The invitation was accepted and sufficient time set aside for the purpose.

MEDICAL SOCIETY OF THE STATE OF TENNESSEE.

Fifty-first Annual Session, held at Nashville, April 14, 15, and 16, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE Society was called to order in the House of Representatives, State Capitol, in Nashville, April 14th, and had a three day's session, The President, DR. D. D. SAUNDERS, of Memphis, in the Chair. There were a number of valuable papers read.

DR. R. F. EVANS, of Shelbyville, presented a paper on

MALARIAL REMITTENT FEVER,

in which he did not undertake to settle the dispute as to the name *typho-malarial*, but stated that there was a class of cases in which quinine failed to control the paroxysms. He held that in such cases it was useless to continue the use of quinine, and it was advisable to look mainly to the support of the patient. He referred to the use of tr. gelsemium and potassium bromide for the restlessness and pain, and of opium and quinine in small doses to sustain the vital functions. The paper gave rise to an animated discussion.

DR. D. D. SAUNDERS, of Memphis, attacked vigorously the hybrid term *typho-malarial*, claiming that the fever cases were either maltreated or neglected malarial fever or pure typhoid.

DR. C. C. FITE, of Nashville, stated that it was a very troublesome question but he believed that there was a malarial fever caused by a malarial germ, a typhoid fever caused by its proper *materies morbi*, and a different, distinct fever caused by decayed vegetable matter and this fever was the one under discussion. He instanced some cases in his practice in which a cistern was found to contain rotten poplar planks and also referred to the experience of Dr. Hoff, of the army; a regiment contracted this fever (called then mountain fever) from the soldiers drinking water which after leaving the snow line trickled through a bed of decaying pine-needles. He stated that some of these cases could not be called either malarial or typhoid fever, but he not only objected to the word *typho-malarial*, but believed that it was a separate and distinct disease due to vegetable decay, and held that in less than twenty years it would be so decided.

DR. O. H. MENEES, of Nashville, said that he believed in the term typho-malarial and instanced the ulceration of Peyer's patches and hemorrhage, stating, however, that ulcerative changes might occur from any protracted fever.

DR. G. W. DRAKE, of Chattanooga, held that the two fevers did coexist and the proper plan was to state that the case was typhoid *and* malarial fever combined in the same case. After the discussion had been continued further a committee was appointed to make a report on this subject at the next meeting of the Society, Dr. Deering J. Roberts, of Nashville, being made chairman.

DR. J. W. SHARBER, of Spring Hill, exhibited a specimen of

EXTRAUTERINE PREGNANCY,

in which the patient carried an eight months' child for twenty-nine years, and finally died from other causes.

DR. J. W. PENN, of Humboldt, read a paper on

THE CAUSES OF CHOLERA,

in which he held that people never had cholera who used pure cistern or freestone water.

DR. THOMAS L. MADDIN, of Nashville, said that the experience of Nashville proved this, for in the epidemics which had visited Nashville, and it never failed to come early and linger long there, there was always a heavy mortality for we use a strong and impure limestone water, whilst just across the river, in Edgefield, everybody uses cistern water, and they never had a case. He did not hold that impure water caused cholera, but that it prepared the system to receive the poison. Impure limestone water so impaired the vital forces that they do not resist the *materies morbi* when introduced.

A resolution was unanimously adopted memoralizing the President to place the

EPIDEMIC CONTINGENT FUND

in the hands of the National Board of Health, stating that it was the proper body to attend to such matters.

DR. D. D. SAUNDERS, of Memphis, Chairman of

THE COMMITTEE ON LEGISLATION,

made a report in which he severely overhauled members of the profession who by their indifference had allowed the proposed medical bill to fail before the recent General Assembly. Tennessee has no medical law whatever, and is overrun with travelling harpies, and the profession will not unite and put a stop to it. The bill was prepared by the Committee, and afterwards rewritten and introduced by the Hon. Ernest Caldwell, of Shelbyville, and it would have become a law, but some medical men in the Legislature opposing, and not being sustained by members of the Society in the State, it failed for the lack of a constitutional majority.

DR. W. W. TAYLOR, of Memphis, Chairman of

THE COMMITTEE ON COUNTY MEDICAL ORGANIZATION,

made a report in much the same strain. Another Committee was appointed, with Dr. Taylor as Chairman, to report next year.

There was a good attendance, and the meeting proved to be one of more than usual interest. The Society will meet next year, the first Tuesday in April, in Memphis, being invited to do so by the retiring President, Dr. D. D. Saunders.

Dr. Thomas L. Maddin, of Nashville, was elected *President*, Dr. C. C. Fite, of Nashville, *Secretary*, and Dr. Deering J. Roberts, of Nashville, *Treasurer*.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 16, 1885.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

THE ANNIVERSARY ADDRESS.

THE PRESIDENT announced that the Council had appointed Dr. E. G. Janeway to deliver the anniversary address before the Academy in November next.

PRESENTATION OF THE PORTRAIT OF LATE PRESIDENT, FORDYCE BARKER, M.D., LL.D.

DR. THOMAS M. MARKOE, on behalf of Mr. and Mrs. John Jacob Astor, presented to the Academy

a large and admirable portrait of Dr. Fordyce Barker, painted by Lazarus. In the course of his remarks he referred to the kindly esteem in which Dr. Barker was held, as indicated by this generous gift from those who had previously testified their appreciation of the Academy of Medicine by presenting it with its "loving cup," and adding materially to its library fund.

The President made an appropriate address in accepting the portrait on behalf of the Academy, in which he said that he was glad that it came from the midst of the public, and especially from those who held such an influential position in the community. It showed, as Dr. Markoe had said, that the public was beginning to take an interest in the medical profession, and to recognize the value of the services rendered by it. In the case of Dr. Barker this was certainly a well-merited homage.

Dr. James B. Hunter then read a paper on

ENDOMETRITIS FUNGOSA; ITS PATHOLOGY, DIAGNOSIS, AND TREATMENT.

The attention of the profession was first called to this condition, he said, in 1846, by Robert, a pupil of Récamier, who himself wrote of it in 1850. He then mentioned the labors of Récamier, Nélaton, Aran, Courty, Ferrier, Goldschmidt, Gallard, Winchel, Mundé, and other authorities in regard to the subject. The affection was one the importance of which had never been fully appreciated in England, but which had long been recognized in this country.

According to his own experience, Dr. Hunter said, fungosities proper were never found in the cervical canal, though they might be found immediately beyond this. They resembled small polypi, and while seldom exceeding five millimetres in diameter, were usually much smaller than this. Neither the number of the growths nor their size seemed to have any proportion whatever to the amount of hemorrhage resulting from their presence. They were of a pale pink color, had an abundant vascular supply, and there was always a distinct fibrous element in their structure. They constituted a truly inflammatory tissue, and were characterized by no process at all akin to degeneration, although Dr. Thomas, in his work on diseases of women, alluded to the condition as fungous degeneration of the lining membrane of the uterus. It had often excited remark that such profuse hemorrhage should result from such an apparently slight cause; but this was in reality not to be wondered at when the great extent of surface presented by the cavity of the uterus when studded with these growths was taken into consideration. The superficial area of the endometrium was enormously increased by the presence of even a few of them. The question of the true cause of the hemorrhage resulting from them, however, had been avoided by all writers on the subject, with whose works he was acquainted.

In making a diagnosis of endometritis fungosa, it was sometimes quite difficult to exclude sarcoma and epithelioma from the examination of a single specimen, and, hence, it was very desirable that repeated examinations should be made. Great care and perseverance were, therefore, often necessary in order to arrive positively at a correct diagnosis.

As to the symptomatology, the principal, and, indeed, only symptom of importance was menorrhagia; pain being quite rare, as a rule. In this condition the menstrual period was likely to be increased; while in carcinoma there was a metrorrhagia, rather than a menorrhagia. Sarcoma usually did not appear until after the thirty-fifth year; but endometritis fungosa might occur at any time during the childbearing period as well as (though more rarely) both before and after the latter. The affection had no connection whatever with syphilis or gonorrhœa; but was often associated with uterine fibroids. Dr. Hunter then called attention to the differential diagnosis on the one hand between endometritis fungosa and such foreign growths as polypi, adenomata, retained decidual remains, papillomata (which were believed to be always a friend to the cervical canal, and thus occupying a distinctly different position), and the so-called villous degeneration of the endometritis referred to by Goodell; and, on the other, from malignant affections. Among the latter, round-celled sarcoma is most liable to be mistaken for it, and is not so uncommon as Dr. Mundé, in his paper sent to the Edinburgh Obstetrical Society, in 1878, and other authors had stated. In addition to microscopical differences, there are certain points by which a differential diagnosis may be made, and among these are the following: In endometritis fungosa there is little pain, while in sarcoma the pain is apt to be a prominent feature. In the one there is, as a rule, menorrhagia; in the other, metrorrhagia. In the one the discharge is odorless; in the other it is often offensive. In the one the growths are of a pale pink, and firm in consistence; in the other they are grayish-white, amorphous, and very friable. In the one there is no infiltration of the surrounding tissue; in the other there is marked infiltration and the surrounding mucous membrane is destroyed. In the one the pathological changes are confined exclusively to the mucous membrane; in the other they involve the body of the uterus also.

The treatment of the fungous growths themselves is very simple, consisting merely of their removal from the endometrium by means of the curette. The treatment of the condition which gives rise to them, however, is generally a more difficult matter, and on the success of this depends the prospect of a return of the fungosities. In his own experience he had never found it necessary to produce dilatation of the cervical canal before using the curette, as the mouth of the uterus was always sufficiently patulous for the purpose. He thought it better to etherize the patient, as the growth can be more thoroughly and satisfactorily removed when this was done. Sims's speculum is placed in the vagina, and the instrument employed is the Thomas blunt copper wire curette. After the curetting Churchill's tincture of iodine is thoroughly applied to the whole endometrium, and a light tampon having been inserted, the patient is put to bed for two days.

The use of the curette has an excellent effect on the congested mucous membrane of the cavity of the uterus, even when no fungosities are present. The contra-indications for resorting to the curette are recent pelvic inflammation or the existence of any degree of parametritis. Récamier's original curette was undoubtedly a cutting instrument. It has recently been claimed in England that it is blunt; but there is in reality no evidence that such is the case.

Both Sims's and Simon's curettes are also cutting steel instruments. In the curette of Dr. Thomas, which he devised about 1870, the bluntness is the important factor, and it was the first one of the kind. Two sizes of the instrument are used. Emmet's curette-forceps is an entirely different instrument. The blunt curette is perfectly safe, and as it is thoroughly efficacious in removing fungous growths, he thinks that it is greatly to be preferred in this class of cases.

Dr. W. Gill Wylie said that the pathology of the affection had been well stated, and that he was willing to accept the greater part of the paper, though he would object to Dr. Hunter's treatment in some respects. He agreed with him in the statement that the use of the curette was seldom followed by hemorrhage; and he was, therefore, somewhat surprised when he heard him say that he was in the habit of employing a light tampon after cutting. For himself, he never used a tampon if he could possibly avoid it, because he considers it a violation of one of the first laws of surgery—thorough drainage. Even in cases of cancer he prefers to stop hemorrhage in some other way. If the circular artery had been injured he would twist it with a silver wire, and under any circumstances would apply lint and cold water, styptics or pure carbolic acid, and even wait an hour before resorting to the tampon. Before antiseptics were used it was well known how offensive the tampon became, and although this may to a great extent be avoided by the use of the bichloride of mercury and iodoform, he believes there is always a liability of irritating fluid being forced up into the Fallopian tubes. He is in the habit of practising dilatation in all cases, and principally for the purpose of securing more proper drainage. In addition, though the os were quite patulous, there is always danger of injuring the cervical tissues with the curette unless further dilatation is made. He is, of course, strongly opposed to the use of sponge tents on account of the danger of septic absorption, and always uses Sims's steel dilators. He also uses Sims's steel curette, and in regard to this instrument he thought great injustice had been done Dr. Sims. The so-called sharp Sims's curette is not in reality a sharp curette, although it is true that it is made of steel. At first it was made with a flexible shank, but afterwards it was found advisable to have it constructed with an universal curve. If a tenaculum is employed in connection with the curette, any uterus can be straightened to such an extent as to admit of having the instrument satisfactorily applied to every portion of its cavity. The advantage of the steel curette over the dull copper one is, that it does the work desired more thoroughly, while at the same time it does not injure the normal tissue. In many cases he believes that the dull curette is not sufficient, because it can not remove the fungosities perfectly. Sarcoma could also be removed very thoroughly with the steel instrument.

Dr. P. F. Mundé said that since his paper read seven years ago before the Edinburgh Obstetrical Society, to which Dr. Hunter had alluded, had been written, cases of sarcoma have accumulated; the disease having of late become much better known than formerly. He thought that Dr. Hunter ought to have given attention to the influence of laceration of the cervix upon the causation of endometritis fungosa. He believed that it constitutes a very important element in the etiology. This is the first link in the pathological chain which finally results in the fungous growths in the cavity of the uterus; and in restoring the organ to its normal condition it is inconsistent in the gynecologist to proceed in an inverse order. The first thing to do is to scrape away all the fungosities with the curette, and the next to apply strong tincture of iodine thoroughly to the inflamed endometrium; after which, if he repaired the laceration of the cervix there would be little danger of a return of the trouble.

Though menorrhagia was the rule with fungous endometritis, there were occasional exceptions. Dr. Wylie had mentioned amenorrhœa as being present in certain instances, and he had himself observed it in one case. The lady consulted him for amenorrhœa, telling him that she would go five or six months without any appearance of the menses, and then there would be a profuse flow. Yet, on making an examination, he found the uterus full of fungous growths. In this case, he did not employ iodine, but applied carbolic acid instead. In the paper before referred to, he had advocated the use of the short curette, and he believed that it had in reality been the means of practically introducing this instrument into Great Britain. Since the time that it had been written, however, he had modified his views, in regard to it, to some extent. While he is still an advocate of its use in many cases, he now agrees with Dr. Wylie that there are also many cases in which the blunt curette is not sufficient; the sharp instrument being required in order to eradicate the growths. In such cases it is necessary to scrape down the mucous membrane almost to the substratum. Still, he does not think it advisable to run a stiff curette, or one with which we could scrape through the uterine wall. A fairly flexible shank is preferable. The dull curette is very useful for diagnostic purposes, and if in any instance no fungosities are brought away with this, he concludes that the case is not suitable for curetting.

In regard to the after-treatment, he disagreed with Dr. Wylie and accepted the position of Dr. Hunter. When there is subinvolution there is very apt to be partly free hemorrhage, and he is often glad to plug both the uterus and the vagina. He does not believe it a good plan to curette a patient except at her own home and under the influence of an anæsthetic, and does not think it is safe to leave the house without having placed a tampon in position. After using the curette he makes an application of either tincture of iodine or of a mixture of equal parts of solution of persulphate of iron and glycerine, after which he places a tampon in the vagina. He regards this procedure in the light of an operation, and always calls within forty-eight hours to remove the tampon. Applications of iodine to the endometrium ought to be made twice a week at first, and later once a week; and he regards it as very important that the after-treatment be maintained for a sufficient length of time.

Dr. C. C. Lee said he concurred, in the main, in the views expressed by Dr. Hunter. In regard to the symptomatology, however, he thought that the condition was not necessarily characterized by menorrhagia. Metrorrhagia, he believed, is a well-marked symptom in quite a large minority of typical cases; the condition of the uterus being, as a rule, one of general passive congestion. In treating endometritis fungosa he always

prepares the case carefully before operating, and when using the curette prefers to give ether. In the choice of instruments he has no hesitation in declaring himself strongly in favor of the blunt curette, as he believes the sharp curette quite as likely to do injury as good, even when employed by the most skilful hand. One of the worst cases of pelvic peritonitis, which he had ever seen, had been directly caused by the employment of the sharp curette by a gynecologist of high reputation.

He does not find it necessary to practise dilatation, as the cervical canal is always sufficiently patulous in these cases. He makes it a rule always to wash out the cavity of the uterus both before and immediately after using the curette with a weak carbolic acid solution. In addition, after curetting he applies a solution of strong tincture of iodine to which is added a small quantity of chromic acid, and he had found that this combination has a much more permanent effect upon the uterine mucous membrane than any other with which he is acquainted. One part of saturated solution of chromic acid is added to four parts each of alcohol and tincture of iodine. He objected to persulphate of iron on account of the hard coagula which result from its use. The Thomas curette is the one he always employs.

Dr. Mundé explained that when glycerine is used with the persulphate of iron solution, as he had recommended, these hard coagula are not formed.

Dr. B. F. Dawson expressed himself as being heartily in accord with the sentiments of the author of the paper. The mildness of the dull curette constitutes its great advantage. Dr. Mundé had said that if he is unable to extract any granulations from the cavity of the uterus with the blunt curette, he does not use the sharp instrument; and if such be the case, he could not see why he should ever use the sharp one at all. Only recently he had seen a very aggravated case of pelvic cellulitis which followed the application of the sharp curette. He did not think it necessary to practise dilatation, because the whole cavity of the uterus is enlarged by the growth. Uterine catarrh is a constant concomitant of the condition of fungous granulations, and whenever uterine catarrh exists there is sure to be a patulous os. He thought that ferocity was too apt to characterize the modern gynecologist.

Dr. Wylie said that the Sims's curette is not a sharp instrument in the sense of a cutting knife, and he thought that some of the gentlemen who had spoken were not familiar with it, or they would not have expressed themselves so strongly in opposition to its employment.

Dr. Lee thought it strange that Dr. Wylie should make such a statement, as he himself is, and, he believed, all the other gynecologists present are perfectly familiar with the Sims's curette.

Dr. Hunter brought the discussion to a close. He said he is in the habit of using a light tampon for antiseptic purposes, and that he had not, like Dr. Mundé, found it necessary to employ it for the controlling of severe hemorrhage. Unlike Dr. Wylie, he does not believe it necessary to dilate the cervix, and this dilatation, he thought, is much more likely to do injury than the use of the curette without dilatation. He had been personally taught the use of the Sims's curette by Dr. Sims himself, so that he is well acquainted with the instrument. He had mentioned laceration of the cervix as one of the causes of endometritis fungosa; but as it was not his intention to make his paper an exhaustive one, he had not had time to dwell upon it at length. When there is very great hemorrhage following the use of the curette in any case, he was inclined to think that it is due to the fact that all of the growth has not been removed. Like Drs. Lee and Dawson, he also had some instances in which serious consequences had resulted from the use of the sharp curette, and, at the present time, he is treating such a case in which the instrument had been handled by a skilful operator. The blunt curette should always be employed, he believed, in the condition in question; though the sharp curette also has its use, as, for instance, in the removal of carcinoma.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 14, 1885.

The Vice-President, Charles McBurney, M.D., in the Chair.

Dr. E. L. Keyes read a paper entitled

CASES BEARING UPON CERTAIN MOOTED POINTS IN SYPHILOLOGY.

(See page 451.)

Dr. Post asked if any irritation of the kidneys was produced by the large doses of iodide of potassium.

Dr. Keyes replied, not a particle.

Dr. Hall asked if the percentage in Dr. Keyes's statistics included chancroids or only indurated chancres.

Dr. Keyes said that they included only chancres which had initial sclerosis; he did not think it had ever reached quite fifty per cent.

Dr. Gerster asked Dr. Keyes with regard to selection of cases by the Vienna men, if among the unicists excision is not practised indiscriminately.

Dr. Keyes replied that it was. He thought the first statistics given were based on the fact that only initial sclerosis was excised.

Dr. Gerster believed that the position taken by the unicists was rational and logical, inasmuch as they admit that there is something, with reference to venereal sores, which they do not know, but which dualists claim to know and do not know. It is frequently the case that a soft chancre occurs which remains soft and yet is followed by syphilis, and one such well-authenticated observation was sufficient to overthrow the whole doctrine of dualism.

Dr Keyes said that one such authenticated case was sufficient to overthrow the entire theory of dualism if syphilis was always ushered in by hard chancre, a view which no dualist at the present time, so far as he knew, entertained. The induration of a primary chancre is very constant, but it may be entirely simulated by conditions which are not induration, so that all dualists have dropped the view that the initial lesion of syphilis is always indurated—in other words, that a given lesion is syphilitic simply because it is hard, and it is not syphilitic simply because it is soft, was not held to-day by any dualists. But that the initial lesion is generally hard, is what the dualists uphold. The absence of inguinal engorgement might as well be claimed by the

unicists as one of the irregularities in the expression of syphilis, nor did the dualists believe that the indurated chancre was necessarily a syphilitic chancre, but that it is very frequently so. The sore may be soft, the inguinal glands may be suppurating, and still the patient have syphilis. It had not been Dr. Keyes's experience to encounter a sore occurring within ten or twelve days after exposure which had turned out to be a syphilitic sore. The incubation period is one which requires great care in deciding its exact limit, and is, as Dr. Keyes thinks, a more valuable symptom of syphilis than the induration of a given sore.

DR. GERSTER said that his remarks did not refer so much to the practical study of the question as to the statement made by Dr. Keyes that the dualistic theory had brought order out of chaos. He thought that chaos had been much more firmly established by the doctrine of dualism, and that the dualistic theory is artificial and not based upon the natural history of the disease, and that it is unphilosophical. It is practically useful in most cases, to be sure, but it does not give a real and satisfactory explanation of the relation of the initial sore to the subsequent phases of the disease.

DR. KEYES said that it certainly produced practical cure, and he should be very glad to put the word practical before the words which he had used in his paper. Practically it reduces the matter to a chaotic state, to say, that all sores, whether soft or hard, are syphilitic, and reduces the surgeon logically to the necessity of treating the patient with mercury because of the fear of the development of syphilis. This is much less philosophical and less useful than the dualistic theory, which involves the use of mercury in the treatment of only one class of cases.

DR. GERSTER believed that inasmuch as it had been taught by Sigmund that syphilis should be treated symptomatically, that is, not until it manifested itself unmistakably, the objection set forth by Dr. Keyes fell away.

DR. KEYES said that it would fall away except that the natural sequence of the statement that all chancres are syphilitic would be to treat them as for syphilis. The logical conclusion of unicism, as it seemed to him, was that all sores should be treated as if they were to be followed by syphilis, which would be an error, and would have a deplorable effect upon patients in general.

DR. GERSTER: That is an error, certainly, but what we are after is the truth, and not the effect which it will produce upon the community.

DR. A. C. POST presented a specimen of

THROMBOSIS OF THE BRACHIAL ARTERY, OCCURRING FROM PRESSURE OF THE WEIGHT OF THE BODY.

The patient was a feeble man, 58 years of age, who had been bedridden for nine months with myelitis and paralysis, and loss of power over the urine and feces. Two days before death he slept with his right arm under the back, and awakened with pain and a feeling of tingling and numbness, and about an hour later the arm was seen to be white and was cold and pulseless. On the next day there was discoloration about the elbow, which in the evening had extended to the shoulder. The specimen was presented to him by Dr. Waitzfelder, and showed the upper third of the brachial artery distended with a firm clot.

FIXATION OF THE BONES AFTER RESECTION OF THE KNEE-JOINT.

DR. C. K. BRIDDON described a method which he had used, consisting in the driving in of four nails, each about three inches in length, two in the sides of the lower end of the femur, and two in the sides of the upper end of the tibia, and suturing them with copper wire. The nails should be driven in about half an inch from the cut surface, and should be left projecting about an inch and a half to prevent the copper wire from becoming buried in the integument. It was also important to approximate the skin flaps before driving in the nails. The nails were held firmly in position by making a figure of eight loop around them close to their heads, and in the two cases in which he had employed this method immobilization was complete.

DR. MCBURNEY said that the method seemed to do away with one objection which had been urged against nails, as it seemed applicable to cases in which the ends of the bones had been largely excavated by abscesses.

CORRESPONDENCE.

CHOLECYSTOTOMY AND CHOLECYSTECTOMY.

To the Editor of THE MEDICAL NEWS.

SIR: I have just read an article in your valuable paper upon cholecystotomy and cholecystectomy, in which you compare the relative advantages of the two proceedings upon figures which I think are erroneous. Thus, you give six cholecystectomies with one death, or a mortality of 16.66 per cent., whereas the fact is, according to Langenbuch himself, that there have been six cases performed, with three deaths, giving a mortality of 50 per cent. I do not think it is fair at all to estimate the value of any operation by a heterogeneous collection of cases from a number of operators, the majority of whose experience is limited to one or, at most, two cases. It is much more fair to judge of the value of the operation from the experience of one man who has had a fairly large number of cases. I have now performed cholecystotomy fifteen times without a death, and I think that that is an argument sufficient to justify me in saying that it contrasts very favorably with Langenbuch's operations in his own hands. Also that I am entitled to emphasize my previous opinion that cholecystectomy is an "intrinsically absurd operation." I am, sir,

Yours very truly,

LAWSON TAIT.

7 THE CRESCENT, BIRMINGHAM.
April, 1885.

[In the article referred to by our esteemed correspondent the figures are correct, and we invite Mr. Tait to refer us to any published or private statement in which "according to Langenbuch himself there have been six cases performed, with three deaths, giving a mortality of 50 per cent." The truth is that Langenbuch has recorded in the *Berliner klinische Wochenschrift*, Nos. 51 and 52, 1884, five cases, of which one proved fatal, in which he excised the gall-bladder. The sixth case is recorded by Courvoisier in the *Correspondenzenblatt für Schweizer Aerzte*, No. 15, 1884, so that 6 examples of cholecystectomy indicate 1 death, or a

mortality of 16.66 per cent. That this is a very fair result is shown by the fact that 36 cholecystectomies have furnished 8 deaths, or a fatality of 22.22 per cent., so that we still entertain the view that cholecystectomy is not so "intrinsically absurd" an operation as Mr. Tait still insists that it is.

As Mr. Tait has fully tested incision and drainage, we trust, in view of these correct statistics, and of the unequalled opportunities that he has in this class of cases, that he may be induced to give excision of the gall-bladder an equally fair test. When this has been done, his views, based upon actual experience, and not upon theoretical objections, will be entitled to serious consideration.—Ed.]

NEWS ITEMS.

NEW ORLEANS.

(From our Special Correspondent.)

The American Medical Association Meeting.—The Local Committee of Arrangements have secured the Tulane Hall and the whole of the Medical Department for the General Meetings and the Sessions of the Sections.

The General Meetings will be held on Tuesday, April 28th, at 11 A.M., and on Wednesday, Thursday, and Friday at 10 A.M. The Sessions of the Sections will be held in the seven rooms selected for the purposes at 3.30 P.M.

Registration will be attended to on the lower floor of the College building. There will be three rooms, the largest of which will be divided into four departments. The Committee will require four registry clerks, four cash clerks, one doorkeeper, one messenger, one card clerk, one postmaster, one hotel clerk. The registration office will be open on Monday from 10 A.M. to 12.30 P.M., and from 4 to 6 P.M. On Tuesday, Wednesday, and Thursday from 9 A.M. to 12 M. and from 4 to 6 P.M. On Friday from 9 to 10 A.M. On Friday, perhaps earlier, a member of the Transportation Committee will be on hand to give information as to railroads, depots, etc.

The Transportation Committee announced that the rates now in force for Exposition visitors are the best obtainable.

Exhibitors before the Association have been assigned spaces in the College building convenient to the members.

The following programme has been prepared:

Tuesday, April 28th.—*The General Session* meets at Tulane Hall, Dryades St., between Canal and Common Sts. The Association will be called to order by Dr. Samuel Logan, Chairman of the Committee of Arrangements. After prayer, the President, Henry F. Campbell, M.D., of Augusta, Georgia, will be introduced. An Address of Welcome will then be delivered by Samuel Logan, M.D., after which the President will deliver his *Annual Address*. Austin Flint, M.D., Chairman of the Special Committee to take action in regard to the death of Prof. S. D. Gross, M.D., LL.D., will then report. New and miscellaneous business will then be in order.

The Section on Practice of Medicine, Materia Medica, and Physiology, will meet at Tulane Hall at 3.30 P.M. Dr. H. D. Didama, of Syracuse, N. Y., Chairman. The following papers will be read:

The Treatment of Carbuncle without Incision, by L. Duncan Bulkley, M.D., of New York.

Syphilis as it appears among Negroes, by Thomas F. Wood, M.D., of Wilmington, N. C.

Practical Suggestions in the Administration of Iodide of Potassium in the Treatment of Syphilis, by Morris H. Henry, M.D., of New York.

The Percuteur: Its use in Diseases of the Nervous System, by A. F. Potter, M.D., of Boston.

Hydatid Tumors of the Brain, by N. Harvey Reed, M.D., of Mansfield, Ohio.

Ulcer of Rectum, by A. Atkinson, M.D., of Baltimore.

Some Inquiry Concerning the Resources of Non-medicinal Therapeutics, by Samuel S. Wallian, M.D., of Bloomingdale, N. Y.

Section on Obstetrics and Diseases of Women and Children, Dr. R. S. Sutton, of Pittsburg, Pa., Chairman. The following papers will be read:

The Treatment of the Secundines in Abortion and Labor, by W. H. Wathens, M.D., of Louisville.

Pelvic Peritonitis: Suggestions as to Cause, Recognition, and Treatment, by W. M. Polk, M.D., of New York City.

Chronic Periuterine Abscess, its Treatment by Laparotomy, by Christian Fenger, M.D., of Chicago.

Parametric Abscess, by W. W. Potter, M.D., of Buffalo.

How soon after Exposure to Sepsis may the Accoucheur resume Practice? By George F. French, M.D., of Minneapolis.

Section on Surgery and Anatomy, Dr. Duncan Eve, of Nashville, Chairman. The following papers will be read:

False Doctrine in the Treatment of Fractures, by John B. Roberts, M.D., of Philadelphia.

Clinical Observation on the Treatment of Varicocele, by Morris H. Henry, M.D., of New York.

Section on Ophthalmology, Otology, and Laryngology, Dr. J. A. White, of Richmond, Va., Chairman. The following papers are announced to be read:

Two New Forms of Spray Apparatus: A New Electro-cautery and New Electric Lamp, by W. C. Wile, M.D., of Sandy Hook, Ct.

Ossification of the Choroid with Sympathetic Ophthalmia, illustrated by sections of an enucleated eye, by H. B. Tiffany, M.D., of Kansas City.

Section on Diseases of Children, Dr. J. H. Pope, of Marshall, Texas, Chairman. Papers will be presented on:

Acute Inflammation of the Bones During Period of Growth, by Edward Boeck, M.D., of St. Louis.

Repeated Doses of Castor Oil in Certain Skin Diseases in Children, by L. Duncan Bulkley, M.D., of New York.

Section on Oral and Dental Surgery, Dr. W. W. Allport, of Chicago, Ill., Chairman. The following papers will be read:

Cocaine, by John S. Marshall, M.D., of Chicago, Ill.

The Alternation of Rest with Effort, by Jacob L. Williams, M.D., of Boston.

On Wednesday, April 29th, in the *General Session*, the *Address in Medicine* will be delivered by H. D. Didama, M.D., of Syracuse, Chairman of the Section on Practical Medicine, and the *Address in Obstetrics*

and Gynecology by R. S. Sutton, M.D., of Pennsylvania, Chairman of the Section of Obstetrics.

Dr. W. C. Van Bibber, of Maryland, will then make some suggestions in regard to the construction of a Health City in Florida, or, Peninsular and Sub-peninsular Air and Climate.

In the *Section on Practice of Medicine*, the following papers will be read:

A Uniform Nomenclature of the Physical Signs which Occur in Connection with the Respiratory System, by Austin Flint, M.D., of New York.

The Relation of Clinical Facts to the Question of Contagiousness of Phthisis Pulmonalis, by N. S. Davis, M.D., of Chicago.

Fever as a Neurosis, by H. C. Wood, M.D., of Philadelphia.

Mineral Foods, and how to give them, by R. J. Nunn, M.D., of Savannah.

The Treatment of Diseases by Hypodermatic Injections of Oils, by J. V. Shoemaker, M.D., of Philadelphia.

The Specific Treatment of Enteric Fever, by James C. Wilson, M.D., of Philadelphia.

Cardiography, by A. T. Keyt, M.D., of Cincinnati.

In the *Section on Obstetrics and Diseases of Women*, the following papers will be read:

A paper, the title of which is to be announced hereafter, by George J. Englemann, M.D., of St. Louis.

A New Speculum and a New Vaginal Irrigator, by T. M. Healey, M.D., of Cumberland, Md.

The Role of Bacteria in Parturition, by Henry O. Marcy, M.D., of Boston.

Vaginal Hysterectomy for Cancer, by A. Reeves Jackson, M.D., of Chicago.

The Ring of Bandl, by W. W. Jaggard, M.D., of Chicago.

A New Wire Speculum, by C. W. Wile, M.D., of Sandy Hook, Conn.

The Multiple Speculum Uteri and an Improved Dressing Forceps, by R. J. Nunn, M.D., of Savannah.

In the *Section on Surgery and Anatomy*, the papers announced are:

The Surgical Treatment of Cysts of the Pancreas, by N. Senn, M.D., of Milwaukee.

Two Successful Laparotomies on the same Patient, by Joseph Ransohoff, M.D., of Cincinnati.

In the *Section on Ophthalmology, Otology, and Laryngology*, papers will be read on

Determining Errors of Refraction by Double Images and by Parallax, by T. E. Morrell, M.D., of Little Rock.

A Case of Hereditary Glaucoma, by Herbert Harlan, M.D., of Baltimore.

In the *Section on Diseases of Children* the following papers are announced:

Successful Results of a New Treatment of Diphtheria, by R. J. Nunn, M.D., of Savannah.

The Treatment of Diphtheria in Children, by H. R. Kelly, M.D., of Gallion, Ohio.

In the *Section on Oral and Dental Surgery* papers will be read on

Epulis Tumors, by Truman W. Brophy, M.D., of Chicago.

A Case of Sarcoma of the Lower Jaw, with Successful Removal, by Oscar J. Coskery, M.D., of Baltimore.

THURSDAY, APRIL 30TH.—In the *General Session* reports will be made by the Committee of Arrangements, Committee on Nominations, and the Standing Committee on Meteorological Conditions and Their Relation to the Prevalence of Diseases. Also concerning the subject of Collective Investigations of Disease in coöperation with the Committee of the British Medical Association, by N. S. Davis, M.D., of Illinois, Chairman.

The *Address in Surgery* will be delivered by Duncan Eve, M.D., of Tennessee, and that in *State Medicine* by E. W. Schauffer, M.D., of Missouri.

The reports of the Treasurer, Librarian, and Committee on Publication will then be in order.

In the *Section on Practice of Medicine* the following papers are announced:

Cholera and its Treatment, by J. H. Hollister, M.D., of Chicago. The discussion will be opened by Dr. Austin Flint.

Hemorrhagic Malarial Fever, by Jerome Cochran, M.D., of Montgomery, Ala.

The Differentiation by Means of Pitch of Pulmonary Signs Obtained by Auscultation and Percussion, by Austin Flint, M.D., of New York.

The Germ Theory, by Harold C. Ernst, M.D., of Bost.

Blood and How to make It: Fat and How to Reduce It, by Benjamin Lee, M.D., of Philadelphia.

Resorcin: Its Therapeutic Use, by A. F. Potter, M.D., of Boston.

Similarity of Electrical and Nerve Force, by J. J. Caldwell M.D., of Baltimore.

In the *Section on Obstetrics*, papers will be read on:

Treatment of the Pedicle, by Thaddeus A. Reamy, M.D., of Cincinnati.

Emmet's Operation: When shall It and when shall It not be Performed? by Gustav Zinkle, M.D., of Cincinnati.

Notes on Surgical Gynecology, by Horatio Bigelow, M.D., of Washington, D. C.

The Uterine Stem in Flexions of the Uterus, by Geo. B. F. Fundenberg, M.D., of Pittsburg.

Reasons for, and Results of, some Cases of Tait's Operation, by S. C. Gordon, M.D., of Portland, Me.

A Report of a Cæsarean Operation, by E. W. Jenks, M.D., of Detroit.

In the *Section on Surgery and Anatomy*, Dr. A. Y. P. Garnett, of Washington, D. C., will read a paper on Colo-proctitis Treated with Hot-water Douche and Stretching or Division of Sphincter Ani.

In the *Section on Ophthalmology, Otology, and Laryngology*, Dr. J. F. Fulton, of St. Paul, Minn., will present a paper on The Relationship of Errors of Refraction to Headache.

FRIDAY, MAY 1ST.—In the *General Session*, at 10 A. M., after the reports of the Committee of Arrangements, and of the Committee on Nominations, the *Address in Ophthalmology* will be read by Dr. J. A. White, of Virginia, the *Address in Diseases of Children*, by J. H. Pope, M.D., of Texas, and the *Address in Oral and Dental Surgery*, by W. W. Allport, M.D., of Illinois.

After the transaction of miscellaneous business, the Association will then adjourn.

A committee of ladies will give a reception and ball, which promises to be the most elegant and select affair of its kind given here for a long time. Many private receptions and dinners are also proposed.

Members will be assisted in finding quarters upon their arrival, and the Bureau of Accommodation on Gravier St., opposite the St. Charles Hotel, will be of great service to those who seek rooms.

VIRGINIA.

(*From our Special Correspondent.*)

Medical Examining Board of Virginia.—The State Board of Medical Examiners of Virginia held its first meeting for the examination of applicants on April 8 and 9, 1885.

Under the "Act to regulate the practice of Medicine and Surgery," passed during the session of the Legislature in 1883 and 1884, all persons who propose to practise medicine in Virginia and who have not been licensed *in this State* at any time prior to January 1, 1885, are required to pass a satisfactory examination either before the Board in session or any three individual members of that Board whom the applicant may select. Graduates and non-graduates are subjected to precisely the same examination.

Prior to the meeting of the Board two candidates for practice had stood an examination before three individual members of the Board; one of these applicants passed a satisfactory examination, the other was rejected.

There were twenty-five applicants before the Board at its recent session, all but one of whom were graduates, of this number *nineteen* passed a satisfactory examination and *six* were rejected.

The rejected applicants are required by law to wait three months before they can again apply for examination.

There seems to have been an impression in some quarters that the examination of *graduates* would be a mere matter of form; we trust that the result of the recent examination will prove that this view is altogether erroneous.

Nearly all of the applicants were strangers to the members of the Board, and their place of graduation, if they were graduates, was known only to the President and Secretary.

The Medical Association of the State of Alabama.—The thirty-seventh annual meeting of this association was held at Greenville, on April 14–17. The President, Dr. Benjamin N. Riggs, of Selma, in the Chair. One hundred and four members were present, being an unusually large number. The following were elected officers for the ensuing year.

President.—Dr. F. M. Peterson, of Greensboro.

Vice-Presidents.—Dr. Starr, of Wilcox County, and Dr. Richard M. Fletcher, of Madison County.

State Board of Censors.—Drs. Riggs, Dement, and Ketchum.

Councillors.—Drs. Herbert, Goodwin, Bragg, J. B. Kendrick, Norris, Wheelan, Nicholson, Lowry, and Inge.

Members of the State Board of Health.—Drs. Riggs, Ketchum, and Dement.

Orator.—Dr. Bragg, of Lowndes.

The Association voted to meet at Anniston next year.

The American Journal of Neurology and Psychiatry.—We regret to learn that the publication of this valuable journal ceases with the April number.

The Atlanta Medical College.—The annual commencement exercises of the Atlanta Medical College were held March 2, 1885. The graduating class numbered forty-one.

The Southern Medical College.—The commencement exercises of the Southern Medical College were held March 4, 1885. Thirty-two graduates received the degree of M.D.

The Columbus Medical College held its tenth annual commencement March 3, 1885. The number of graduates was eighteen, a falling off of nearly 50 per cent. from the previous year.

Chicago College of Physicians and Surgeons.—The third annual commencement of the Chicago College of Physicians and Surgeons was held on March 10, 1885. The President conferred the degree of Doctor of Medicine upon sixty graduates.

The Detroit Medical College.—The commencement exercises of the Detroit Medical College took place in Detroit on the 2d of February, 1885. Nineteen graduates received the degree of M.D.

The Michigan College of Medicine held its annual commencement March 4, 1885. Twenty-one graduates received the degree of M.D.

A New Medical School in St. Paul.—It appears assured that a medical school will be established in St. Paul during the present year; the St. Paul members of the Minnesota College Hospital having resigned and having received responsible promises of the necessary funds for a school in their own city.—*Northwestern Lancet*, April 15, 1885.

French Surgical Congress.—The French Surgical Congress was inaugurated on Monday, April 6th, with Professor Trélat, President of the Committee on Organization, in the Chair.

The seven members of this committee, MM. Trélat, Verneuil, Horteloup, Chauvel, Monod, Pozzi, Bouilly, were chosen by acclamation as members of the permanent committee.

M. Trélat was elected President of the Congress for 1885. It is proposed to have an annual session.

A New Medical Clinic has been established at Vienna, under the direction of Professor V. Schrötter. This step of the College of Professors is generally applauded, and the appointment of Professor Von Schrötter is regarded as eminently satisfactory, and will at once inspire confidence in the operations of the clinic.

Professor Huber will assume the position left vacant in Leipzig, by Professor Birch Hirschfeld's removal to Dresden.

Prize Essay on the Prevention of Blindness.—The English Society for the Prevention of Blindness having offered a prize of 2000 francs for the best essay on the causes and prevention of blindness, the international jury appointed to decide upon the relative

merits of the papers presented, has awarded it to Dr. Fusch, of Germany.

Digital Divulsion of the Cardiac Orifice of the Stomach.—On the 23d of February, Prof. Loreta, in the surgical clinic of Bologna, performed the operation of digital divulsion of the stomach for the seventh time with excellent result.

The condition of the patient is in every way favorable, and complete success is expected.

Dr. Bouchardat, Professor of Hygiene in the Paris Faculty, after a service of nearly forty years, has retired, and his name is transferred to the list of Honorary Professors.

Professor Seegen, who for many years has been a practitioner in Karlsbad, has abandoned the practice of medicine, in order to devote himself exclusively to physiological and experimental research.

The Jaksch Jubilee.—Dr. Jaksch, whose name is so intimately connected with the Prague Medical School, celebrated on the 19th of March his fiftieth anniversary.

His excellent service as a successful clinical teacher and fame as a skilful diagnostician are recognized throughout the world, and the many congratulations received on the celebration of this jubilee are a mark of the high esteem in which he is held by his former pupils and associates.

The Hyrtl Jubilee.—The Hyrtl Jubilee, celebrating the fiftieth anniversary of the medical career of Dr. Josef Hyrtl, took place in Vienna on the 23d of March ult. Congratulatory communications were received from all parts of the world.

Deputations comprising representative talent from the various Vienna institutions, proffered their congratulations to the venerable Professor, in addresses fitly expressing appreciation of his eminent services to science, and overflowing with assurances of esteem and goodwill. Professor Hyrtl, who is now eighty years of age, and almost entirely blind, briefly responded to the speech of Professor Zschokke, Rector of the College of Professors of the Vienna University, and also made a short address to a delegation of medical students. At the conclusion of the formalities a rich repast was served, at which Professor Hyrtl presided.

Violation of Professional Secrecy.—The suit against Dr. Watelet, for having divulged a "professional secret," to which we referred in our issue of April 4th, has resulted in the imposition of a fine of 100 francs.

Further evidence of the caution which should characterize the conversation of a physician in relation to his patients on points a knowledge concerning which he has gained in his professional capacity, is shown by the following, which we extract from the letter of *The Lancet's* Paris correspondent (April 4, 1885):

A physician, who was also a pharmacien, but who practised only in the latter capacity, lately died. Dr. Constantine Paul, in announcing the event at a meeting of the Société de Thérapeutique, of which the deceased gentleman was a member, stated that death was caused by tubercular meningitis, of which he had an attack ten years previously. The insurance company in which the deceased had insured his life for 200,000 francs, or £8000, having taken note of this circumstance, has refused to pay the widow, on the grounds that her husband's life was insured subsequent to the attack he had ten years before, he being at the time the subject of a fatal malady which eventually carried him off. The case, which is interesting from more than one point of view, is pending, and it is said that if the insurance company should persist in their refusal, Dr. Constantin Paul will be prosecuted for divulging a professional secret. Examples of this kind are daily to be met with, for we see in the medical and lay papers full descriptions of maladies of persons of note, ante-mortem and post-mortem.

NOTES AND QUERIES.

HAGERDORN'S NEEDLE HOLDER AND NEEDLES.

To the Editor of The Medical News.

Sir: Those desiring the above will find Frick Bros., surgical instrument makers, Ohio Street, Allegheny, Pa., prepared to fill their orders. They have my set to copy from. Some needles made in New York were shown me last week. They are not correct. Yours truly,

R. S. Sutton.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 14 TO APRIL 20, 1885.

McParlin, T. A., *Lieutenant-Colonel and Assistant Medical Purveyor U. S. Army.*—Sick leave extended three months on surgeon's certificate of disability.—*S. O. 88, A. G. O.*, April 17, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING APRIL 18, 1885.

Yemans, H. W., *Assistant Surgeon.*—Detailed as medical officer, revenue steamer "Corwin" during cruise, April 16, 1885.

Battle, K. P., *Assistant Surgeon.*—When relieved to proceed to New Orleans, La., for duty, April 13, 1885.

Brooks, S. D., *Assistant Surgeon.*—Granted leave of absence for ten days, April 16, 1885.

Bailhache, B. H., *Surgeon.*—Chairman of Board for physical examination of candidates for appointment as Assistant Engineer, Revenue-Marine Service, April 6, 1885.

Vansant, John, *Surgeon.*—Chairman of Board for physical examination of officers of the Revenue-Marine Service, April 11, 1885.

Purviance, George, *Surgeon.*—Granted leave of absence for one week, April 6, 1885.

Stoner, G. W., *Surgeon*—Member of Board for physical examination of candidates for appointment as Assistant Engineers, Revenue-Marine Service, April 9, 1885.

Godfrey, John, *Surgeon.*—To represent Service at annual meeting of American Medical Association, April 11, 1885.

Goldsborough, C. B., *Passed Assistant Surgeon.*—To proceed to Pascagoula, Miss., as inspector, April 8, 1885.

Carter, H. R., *Passed Assistant Surgeon.*—Member of Board for physical examination of officers of the Revenue-Marine Service, April 11, 1885.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLVI. SATURDAY, MAY 2, 1885. No. 18

AMERICAN MEDICAL ASSOCIATION.

THIRTY-SIXTH ANNUAL MEETING, NEW ORLEANS, 1885.

THE PRESIDENT'S ADDRESS.

Delivered April 28, 1885.

BY HENRY FRASER CAMPBELL, M.D.,

PROFESSOR OF SURGERY AND GYNECOLOGY IN THE UNIVERSITY OF GEORGIA, AUGUSTA.

GENTLEMEN OF THE AMERICAN MEDICAL ASSOCIATION: At the last meeting you cordially conferred upon me the honor to elect me President of this Association. We all justly esteem it the highest position in the gift of the American medical profession. I am fully sensible of my own unworthiness, and also of the far higher claims of many others, to the office you have accorded me. Let me aver to you my high appreciation of your generous recognition of the South, and of the great Southern State I represent; and for myself, I return you the thanks of a warm fraternal heart, for the kind partiality which has guided you in your decision.

THE PAST AND THE PRESENT.

Exalted as may be the position, by the grand objects of the organization, and by the long years through which it has exercised its improving and perfecting influence over the minds, and hearts, and destinies of the medical profession, the honor is still further emphasized by the long line of noble and illustrious men who have recently and in the past guided the deliberations of this National representative body. Look over the roll of honor—the roster of our rulers—from the venerated Chapman to the revered and beloved Flint, and we find, among both the living and the dead, names and the record of lives which fill our hearts with pride—brilliant lights who, like stars of the first magnitude, must for all time continue to illumine the firmament of our profession with the glow of their godlike benevolence, and the unquenchable fire of their genius—cosmopolitan, as well as national men—followed and quoted and honored—very Gamaliels, at whose feet the Pauls of every nation have sat, contentedly drinking in the inspiration of their wisdom, and taking example and encouragement from their daring and their enterprise.

Far lagging in the rear would have been the old world, had it neglected the record and the literature of the new! In the long line of our noble ancestry, among others who adorn the gallery of our progenitors, Rush and Physick, McDowell and Atlee, Deadrick and Smith, Dudley and Eve, Silliman and Hays, Mott and McClellan, Gross and Sims—some of these among the illustrious dynasty of this Association—have each opened to the minds of all nations new fields of science, of labor, and of literature, in which to energize; and, dying, have all left their impress deeply and ineffaceably graven upon the tablets of scientific progress of the old, as well as of the new world. Now, may we ask, who dares *not* to read?

I might well confine my glorying now to only our glorious dead—embalmed in the frankincense, and myrrh, and the conserving sweet-smelling spices of worthy and undying achievements; enshrouded in the spotless robes of their immaculate lives, they remain with us still, even our entailed inheritance—our inalienable trust—our household gods—the archetypes and guardians of this Association.

When we would turn our minds for a moment from the silent, but eloquent, and never-to-be-forgotten dead, to the active, progressive, and ever-hopeful living, we find, in the contemplation of the present, that our dream of the future may be as bright as has been our golden history in the past.

What means this large convocation of earnest, responsible men, this relinquishment of homes and of professional occupations? What means this sea of congregated heads, some burnished, some gray, and some of silvery white? What means this plane of upturned faces, some seamed and furrowed with lines of toil and anxious thought, others youthful, and bright, and hopeful, but all glowing with the inspiration of a noble enthusiasm, all eloquent of, and stamped with the seal of devotion to a common and holy purpose? Let me answer: What we behold is indeed a culmination of the past, but no less is it the prophecy and assurance of the future; some are here in the very outset of a prosperous career, some, midway in the journey which is to end in brilliant achievement, and others near the goal where the laurel and the crown of the victor await them for their perfected work.

These are the contemporaneous makers of the scientific history of our own times. I would gladly signalize and dwell upon their noble part, but I forbear to depreciate them by a trite and trivial mention of their names and work. Too numerous to accord to each his merited meed of praise, you, gentlemen, constitute the working body and stalwart supporters and defenders of the honor of this Association. To you we look for present labor, and to you we look for future glory.

But can all the living be thus passed by? Must our hearts forever yearn and yearn in silence to tell the honor, the reverence, and the love that burns within us? Must our "Bless you, my brother," and our "Well done, good and faithful," die ever "as a voiceless thought?" Who is it that has fought shoulder to shoulder with another in the veteran grand army of the world's campaigns, and has seen him fall out of the ranks, to rise no more; who is it that has stemmed with another the current of the mighty river of Time, or battled with the waves in the tempestuous ocean of life, and seen him suddenly and forever sink beneath the dark waters, and has not mourned the last word unspoken, and bitterly cried out, "Too late?" The good-will and the assurance he had been longing to utter have failed of their application, and they remain valueless in his tender heart like

"unused spices" in the hands of loving women at the Saviour's tomb.

Gross and Sims, illustrious in their lives, loved and honored in their death, the giants of our pride, and the sacred objects of our reverence, have passed beyond the sound of earthly praise. With shining robes more honorable than any toga of office we can put upon them, with crowns more resplendent than those of earthly monarchs, and with harps and melodies more entrancing than the music of our love, or the anthems of our praise, they hear no more the voice of human adulation. The protestations of love and gratitude, now uttered in the bitterness of our grief and in the magnitude of our irreparable loss, fail to unburden our hearts, and they return to us empty of their reward in the pleasure they *might* have given. We are now forever debarred from pouring into the living ear and into the throbbing heart all which custom withheld, and which now we would gladly tell. We indite memorials, we erect monuments, we build mausoleums, and the dead heed them not.

"Can storied urn or animated bust
Back to the mansions call the fleeting breath?
Can Honor's voice provoke the silent dust,
Or Flattery soothe the dull, cold ear of Death?"

Custom and convention allow praise, panegyric, and loud lamentation to the dead, but command silence and repression to the living, however loved and worthy, and however near their journey's end.

As I glance around this crowded assembly, as I cast my eye over the lengthened list of our membership, here and there among the buoyant, active workers of to-day, my glance becomes a gaze of pleasure, and my eyes brighten as they fall upon the familiar forms and read the names of some—now sadly few indeed—who in a former generation, and through all the toilsome, turbulent years between "then and now," have lovingly worked on, as they are working to-day. To many their faces are unfamiliar; to some the history of their early work and achievements in this Association are unknown. "A new Pharaoh has arisen which knoweth not Joseph;" which knoweth not their patience, their devotion, their inestimable work, and faithful stewardship in the past, as they see and esteem them now. It would be unparliamentary, at least, to call their names, but let me indicate in some degree the valuation and the worth we should set upon them.

I see before me more than one who, present at the first foundation of this Association, assisted—over a generation ago—in organizing out of the chaos of the medical profession of the United States this congenial, facile, and efficient body; multiple in its sections and departments, heterogeneous in its structure, pursuing in each division objects diverse and special, yet each contributing to form an organization powerful in the uprooting of ignorance and error—mighty and invulnerable in the defence and promulgation of truth.

Again, I have before me some still in the ripened prime of vigorous manhood, who were active in our halls and in our discussions over thirty years ago; some, holding honorable and laborious official stations then, are, by their own elections, most active as private laborers now.

Again, among this multitude can the anxious eye of friendship, long familiar with their forms, readily search out some in whose breasts not even the burthen of years, or the calamities and casualties of prolonged and laborious lives, could abate the honor and devotion they gave in the heyday of their early prime to this Association—once the child of their trembling hope, now the object of their pride and triumph.

Make haste to do honor to all these venerable men; our Nestors—the fathers of our history and the sires of our generation—honor them *now*, while still they walk in and out before you, and among the children of men. Let me voice for this Association, in their living ears and in glad gratulation to day, the avowal and the eulogy we may haply sob forth in bitter lamentation to-morrow—let us in manly frankness to-day pour into their throbbing hearts some little of the praise and commendation which to-morrow we may have to engrave in tearful sadness on the cold, insensate marble of their tombs.

Once more—and I will still remain impersonal in the familiar sketch I would portray—our eyes may at this moment rest with honoring gaze upon one who at the present time, and before the present generation of laborers in the field, might stand prominent amongst us only by the encouraging and ever-inspiring magnetism of his presence, and by the stupendous and self-sacrificing labor in which he is ever willing to engage. He labors now as he labored two-score years ago, well entitled to the honored name of "the father." No one of the sons of this Association can excel him in watchfulness for its interests, in tenacity for its honor, in unceasing labor for its advancement. No neophyte or tyro is he in its affairs; he presided at its birth, nursed it through infancy and childhood, was the guide and counsellor of its manhood, and now in its ripe maturity, adds spirit to its energies, watches its progress, faithfully guards its good name, and is the laborious chronicler and promulgator of its intelligence. Too full of the meekness of wisdom to be elated by praise, too worthy of praise to be defiled by flattery, and among all the living, standing foremost in the duration and constancy of his devotion, I could almost ask you to allow me, by virtue of the authority in which I am clothed, to bid him stand, as sovereigns bid their heroes kneel, and dub him with the ensign and the title "*Noblest Roman of us all.*"

Thus have I endeavored to illuminate my brief presentation of the past and of the present with pictures of the *personnel* of the Association—with portraits and groups of dead and living men. Let us honor, cherish, and hold sacred the memory of our illustrious dead; let us not fear to encourage and give solace to our long-suffering, faithful, and noble living.

OUR PLACE OF MEETING.

Already have I referred with cordial comment to your graceful recognition of the South in the appointment of the present place of meeting. Besides the bright sunshine and the balmy air redolent with the perfume of tropical fruits and flowers, enlivened by the glittering plumage and made musical by the sweet spring voices of winged choristers, there ever breathes in the atmosphere and throbs in the pulses of this monster mart a solemn and weird consciousness—a sanctity of association—which in the minds of our profession, neither time nor wide separation, nor diverse political opinions, nor even internecine war, have been able to profane or in the least obscure. The glorious

triumph of our States upon this ground over the foreign foe, their inglorious triumphs upon this ground over each other, when marshalled in mad and mortal but, on each side, manly and patriotic antagonism, fade from our minds when as physicians and philanthropists we remember "The pestilence that walketh in darkness and the destruction that wasteth at noonday." They here, too, often have been the invader and desolater, and here, too, have they often been met by the heroes of our profession, the noble and devoted defenders of the people.

Though with a health-bill and death-rate ordinarily bearing favorable comparison with other great cities of the Union, New Orleans has sometimes, like the happy valley or the peaceful hamlet of romance, become the scene of death and desolation, its bright homes clouded with sorrow, its prosperity changed to adversity.

How often, wherever we may have been, wherever our homes, whether in the green mountain fastness of health, in the torrid interior, or on the dented seacoast, how often, I repeat, have our minds and hearts been turned with fraternal sympathy and profound interest to our devoted brethren of this lovely city of the Gulf, battling with the destroyer, and nobly giving up comfort, and safety, and health, and life itself in a martyrdom to the love they bear mankind. Thus has this region become sacred and heroic ground with the medical chronicler and historian.

How changed is the present aspect. What magic metamorphosis do we find. The whilom shunned and dreaded pest-house of the nation has become the inviting and the crowded Mecca of the wide world's pilgrimage. From the remotest bounds of civilization the call has met response, and now are gathered here, in generous rivalry for excellence in the arts of peace, the representatives of all our States, and of nearly all the foreign nations.

Here are the products of agriculture, of manufacture, and of mines—the triumphs of genius, the achievements of ingenuity. Here, too, are the medals, mementoes, and heirlooms of the past, the proofs of progress in the present, and the unlimited foreshadowings of the future, all collected in one interminable tableaux and unbounded panorama, opening to view the most comprehensive exposition of the world's advance, making the grandest demonstration of man's triumph over the rebellious realm of nature, and of his divine right to subdue, and hold his kingly rule over her wealth, her potencies, and her potentialities.

May I not here congratulate this Association that in our customary annual wanderings, and by the generous hospitality of our brethren of New Orleans, we, too, have been brought to witness a scene so rare and rich in incident, and that we, too, have been made to act a part in a wonderful drama, so abounding in interest, instruction, and enjoyment?

Highly do we value the occasion, and well will we remember our coming to this commercial emporium of the South, and her grand Exposition of the world's progress; warm and grateful will ever be our memory of our brethren and of her people, opening wide their arms as hosts and entertainers of guests from every corner of the world's domain; profound and long will remain our admiration and our wonder for this lovely Crescent City, as she sits like a beautiful queen in stately dignity, commanding her far-reaching iron tributaries, while the great Father of Waters, the mighty monarch of the valley, rests his majestic head upon her lap, pays homage to her power, and pours his libation at her feet.

THE ASSOCIATION A REPRESENTATIVE BODY.

The spirit and intent of our American institutions are, in a certain view, aptly represented and illustrated in the organization and high objects of the American Medical Association. Like the National Congress, each meeting represents, with more or less accuracy and truthfulness, the tone, the energy, the progress, the various shades of opinion, and the sometimes widely differing results of observation and experience, as modified by climate, geographical and social conditions, population, and locality. To generalize and harmonize these diverse elements, and to educe from them laws compatible with the interest and for the general welfare and advance of the whole, is no more the object and the duty of the political National Congress than of this scientific National Association.

They are both representative bodies, each with a broad constituency; the one in the State legislatures and in the direct franchises of the people, the other in the State associations and other medical organizations that have honored and trusted them as delegates to represent and act for them at our annual meetings.

The bills read and discussed, whether originating in the House or Senate, or in a message from the President of the United States, when enacted into laws for the good of the people, are, as we may hold, no more effectual in the attainment of their ultimate and benevolent ends than are the principles evolved, and the perfection of methods accomplished, in the readings and discussions in the several Sections of the American Medical Association. They are each and equally for the enlightenment and guidance of the two great constituencies represented; ours a constituency of unequalled intelligence and benevolence, the noble, humane, and learned medical profession to the remotest bounds of our country. To remedy what may appear to be defects in organization; to supply what may seem to be deficiencies in legislation, is the privilege and the duty of each of these representative bodies, at the time of their convocation or assembling.

A message from the Executive, as I have said, may originate discussion having in view improved or altered legislation in Congress. It is by no means without precedent that the deliberations of this Association may be sometimes influenced by propositions from the Chair. Some of our most important and valuable measures bearing upon our progress and welfare have been thus brought to our consideration—the transformation of our publication of the Transactions of the Association from an annual, tardy, and ponderous volume into a weekly journal, promptly and rapidly presenting our work not only to the members, but to the entire profession, as the proposition of President Lewis A. Sayre, at New York; and the invitation for the Ninth International Medical Congress, to meet in the United States in 1887, as the proposition of President Austin Flint, at Washington, are important and notable instances in which great benefit and improvement to the medical profession of this country will result from action inaugurated

by and emanating from the Chair of this Association;—or, to continue the worthy parallel I have begun, by a message from the Executive to the Legislative Department of this Association.

By a careful consideration and review of the Constitution and organization of this Association, it will be found that the wisdom and forecast of our predecessors have left but little to amend, whereby we can add to the facility of its work or to the scope and comprehensiveness of its design.

THE WORK OF THE ASSOCIATION.

No message from the Chair of the present meeting can equal in their importance some of those fundamental changes heretofore made, as in the organization of Sections and Committees whereby the present perfection has been attained—none yet to be made, so far as can now be seen, can equal in immediate and wide utility and improvement, both to the Association and to the medical profession, that proposition by which the journalizing of the Transactions has been accomplished; and it may also be stated that none has ever been received with more favor and cordial assent than that by which we are to receive the incalculable benefits resulting from the acceptance of the invitation for the Ninth International Medical Congress to meet in America.

The publication of the *Journal* may now be regarded as an assured and satisfactory success. In its first two most trying and perilous years, the foundation has been laid for an influential and commanding future. It has already secured constant communication and comity among the membership of the Association, and it will unquestionably, in time, become the means of organizing for good the entire medical profession of the United States, while the International Medical Congress in America will bring this Association and the medical profession of the world in direct and intimate relation; incorporate us with the scientific organizations and with the advancing and progressive researches of all the foreign nations.

As a member of the Board of Trustees having in charge the publication of the *Journal*, and also as one of the General Committee having in charge the invitation and organization of the Ninth International Medical Congress, and being intimately conversant with the stupendous labors and embarrassing difficulties involved in both these enterprises at their outset, it affords me pleasure to state from this chair that a full amount of praise and commendation are due to the Editor of the *Journal* and to the executive officers of each of these two great trusts. They have faithfully and laboriously brought them both to a state of progress assuring of brilliant and permanent results.

Notwithstanding the apparent completeness of our organization, and the generally satisfactory operation of our working plan, I will ask in this brief portion of the hour usually allotted to the President's Address, to make reference to a matter of recognized importance to the medical profession, and which, it has long appeared to me, should at some early period in the future be made one of the subjects of our diligent and regular investigation; at least engaging our frequent consideration, if not made one of the departments for the annual readings and discussions in one of the Sections.

The subject I refer to has ever been justly regarded as one of much complexity, difficult to present clearly, and still more difficult to expound and elucidate. It is no less one, however, which will be recognized by all as deeply involving, if not compromising, the comfort and welfare, and, still more, the dignity and honor of our conscientious, learned, and lordly profession.

I would comprehensively state the problem—for it well deserves that name—as "The relations of the medical profession to tribunals of laws," or, as I have heretofore more briefly summarized it—

THE DOCTOR IN THE COURTS.

That the position of the medical witness, and, to a certain extent, all professional and expert testimony before the courts of law, is anomalous, and often one of false relation to justice, as well as to the ends of humanity, and sometimes mortifying to the pride and self-respect of the deponent, few will deny; for but few have been so fortunate as to escape the annoying experience of being at one time or another the subject of such arraignments—happy has he been who has had only his intelligence and his integrity assailed, and happy, too, that no malpractice suit has deprived him of his liberty and living as well.

My object is more to bring the position of the medical man summarily before you, as he stands in his several relations to the tribunals of law, rather than to describe minutely that with which we are already familiar, or to present elaborate arguments to establish the existence of evils of which we are already convinced. I will, therefore, briefly refer to only a few of the more prominent *rôles* in the forensic drama (too often a farce), in which he is often forced to play his part, and in which, though he may be repeatedly *encored*, he seldom elicits applause.

At the present time, and in the eyes of most communities, the plane to which the medical deponent and expert has at last gravitated is but little above that of the ordinary, if not the partisan, witness. The light of scientific truth he sheds is even sometimes suspected as coming with bent and refracted rays through the distorting lens of self-interest and a paid opinion. From circumstances which condition his testimony, he seldom now occupies in this country the honorable position of *amicus curiæ* or friend and instructor of the court on scientific questions, upon which may rest an important judicial decision. He is almost invariably presented as the medical witness, or the medical expert in behalf of one side or other of the case upon trial. He is cited to appear as a witness in its behalf more frequently, not because he possesses superior knowledge of the scientific truths about which his testimony is to be conversant; not because his medical opinion *per se* is entitled to more confidence than that of another, and, still less frequently—we could hope, never—because he has been suborned; but he is often selected because, with a certain standing in the community, he is known to hold opinions, or, on the representation of the attorney, can be made to adopt opinions favorable to the side on which he is to depose. Quite often his only claim to the character of a medical expert depends upon a summons thus conditioned. The reliance upon medical testimony and, in time, confidence and respect for the

medical profession, must necessarily be depreciated by such exponents of them both.

Professor Washburn, of Cambridge, quotes the following words of Lord Campbell in addressing the House of Lords in regard to scientific testimony in general: "What are called scientific witnesses come with such a bias on their minds to support the cause in which they are embarked, that hardly any weight should be given to their evidence."

Without further general remark, I will here refer more or less briefly to the three principal positions or attitudes in which, as professional men, we most frequently stand related to the tribunals of law, viz.: first, as the medical witness; secondly, as the medical expert; and, thirdly, as a defendant in suits of malpractice.

In each one of these relations it could readily be shown that the medical man labors under disadvantages which do not, in the same degree, embarrass either the testimony or the defence of any other class of citizens. This is not the occasion to enumerate them, much less to put them under discussion. They have been long and fully recognized by the members of our own profession, while some of the most profound and astute minds of both the bench and the bar have diligently studied and yet have failed to remove them. For the deponent, whether medical witness or expert—and here we can consider them together before the jury—these difficulties often arise from the unlimited number and diversity of facts, and sometimes of principles, necessarily used as predicates for medical induction, and from the unavoidable complexity apparently connected with the reasoning by which conclusions, often perfectly legitimate, are arrived at. Thinking in technicalities, he is yet called upon to express himself in the plainest vernacular, often before an ignorant jury, or at least in terms simplified for the ready comprehension of non-professional minds.

This last requirement is often violated; not always from a pedantic inclination, but from embarrassment under the novelty of the situation and from the little familiarity with and thought given to questions in forensic medicine, and to the object of medical testimony as being instruction to the jury. He may be like Moses, "learned in all the wisdom of the Egyptians," but if he deposes only in the Egyptian dialect, only an Egyptian jury can be enlightened by him.

Not alone in our own country, but at a still earlier date, and apparently with even a more sedulous care, have the forensic wisdom and ingenuity of foreign judicatories been exhausted in various attempts to elevate the position and to render more available to the ends of justice and equity the scientific witness and expert. Prussia, recognizing the evils of ignorant and unworthy experts in the medical profession, as well as in all others, from which scientific testimony has to be elicited in grave questions pending before the courts, has a toxicologist appointed by the Government, and a permanent commission of experts in matters connected with medical science. In Scotland, medical witnesses are said to deliver their examinations in writing, but are subjected to oral cross-examination before the court; in France, the judges decide who shall act as experts in certain cases, also what questions shall be submitted to them, the answer being returned to the jury in writing; "and practically it is said to have the weight of conclusive evidence."—*Washburn.* "In England," continues Professor Washburn, "much speculation and various schemes have been suggested for obviating the objectionable features of expert testimony, but thus far without the adoption of any system."

It will be seen that all these efforts, both in the United States and in the several countries of Europe, comprehend all scientific experts, and among them the medical deponent. They are not made in behalf of the witness, either to elevate his position or, except incidentally, to recognize the high order of his testimony, but only to guard against his oft-time ignorance and unworthiness, and to make his testimony available to the courts. In most of the European courts mentioned, however, there is an incidental protection given to the scientific medical witness from the assaults and indignities offered by the examiner and the advocate.

In the United States, even, this incidental protection is rarely enjoyed by the medical profession. Often each side calls its medical expert, and his testimony, whether scientific or ignorant, impartial or partisan, is dealt with in open court by the advocates and examiners, at whatever cost to the witness, so that it can be made only to subserve the interest of one or the other side. Quite often the cause of justice is lost sight of, the significance of the deposition perverted by the artful methods of the examiners, and the casting of doubt on its credibility by the advocate. He is, as a witness and also as an expert, subject in his deposition to the arbitrary, and sometimes offensive, and often irrelevant interrogation of the interested attorney, whose duty it may become to misinterpret, or to suppress the significance of his testimony, and not infrequently to wrest it to the ends of that which, though the common practice of the law, are not the ends of equity and justice. In this way can the profoundly scientific and strictly conscientious medical witness or expert, on account of the inherent difficulties of his deposition, as before stated, more than any other class of witnesses, be made to appear to the average jury and to all ordinary minds present in the light of a crafty charlatan—the tool of some hidden interest guiding and directing his testimony.

Albeit the situation is one of grave and deplorable falsity and humiliation, I may here, for its aptness, perhaps not improperly indulge in what might otherwise be considered a facetious illustration of this perversion and suppression of medical testimony to the nullifying of justice, and, "for the nonce," to the degradation of the medical witness and expert in the eyes of the jury and "all spectators." The incident is accurate in all essential particulars.

The case was one in which the wife had been accused of causing the death of her husband by poison—all attendant circumstances and testimony in the case confirmed the suspicion; and, lastly, arsenic had been found in abundant quantity, by careful and laborious analysis, in the stomach and tissues of the dead man. The medical expert was one of the most conscientious and distinguished members of our profession, and a founder of this Association; and, withal, "as mild a mannered gentleman as ever"—had his throat cut, or his testimony scuttled, before an American jury. The advocate for the defence was one whose name, if mentioned, would at once be recognized by all present as one of the leaders of the American bar, and a states-

man of the land; and withal, one of the most powerful criminal lawyers that ever swayed the minds of a jury in behalf of the accused.

Scene.—The crowded court-room, many counties distant from the homes of both the medical witness and the advocate.

Lawyer: Are you a physician?

Medical Witness: Yes.

L.: You are a professor in —— College?

M. W.: Yes; Medical College of ——.

L.: What Chair do you hold?

M. W.: Chemistry and Pharmacy.

L.: Are you in the habit of analyzing for arsenic?

M. W.: Yes.

L.: Do you often find it in cases when called upon for your testimony in court?

M. W.: I have repeatedly found arsenic, or other poison in the stomach of such persons.

L. (*with emphasis*): Have you ever failed to find the poison?

M. W.: It has so happened that in the cases I have examined, the existence of poison had been circumstantially made out, and my analysis established the fact.

L.: You have always detected the arsenic, Doctor, in such cases?

M. W.: Yes.

L.: May it please your honor, we are satisfied with the witness.

Medical witness retires.

This was the cross-examination, and this lawyer for the defendant had the closing argument. No further questions were asked the witness. He had shown to the satisfaction of all intelligent persons present that he had, in a most scientific, conscientious, and expert method, supplied the last and convicting link in the unbroken chain of evidence required to establish the guilt of the accused.

This was the attention the lawyer gave to this medical expert testimony:

"Now, may it please the court, as to this medical—what they call 'expert testimony.' Consider the facts: He is a doctor; he is a professor in a college; his chair is chemistry and pharmacy.

"Gentlemen of the jury, he is in the habit of testing for poison—he is the arsenic hunter and arsenic finder for his college, and, you see, he is a good one; he *always* finds the arsenic. He is obliged to find it—it would ruin his college and ruin him if he did not find it; but, gentlemen of the jury, I appeal to you as intelligent and scientific men, you are not going to allow my innocent, unfortunate client to suffer to support the credit of that college!"

The murderess was acquitted by the jury almost without leaving their seats, as any one who knew the giant of an advocate she had might well have expected.

This was *perversio veri*, as well as *suppressio veri*—not by the witness, but by the lawyer. The medical deponent was, in his own way, almost as great a giant as himself, but he was a doctor in the court, and there he was a giant *bound*.

EXTORTED TESTIMONY.

Among many other burdens under which, as a witness, the medical man at present labors, is the *hard lot* imposed by that principle of common law, still existing in most of our States, which declares that the necessary confidential revelations of patients to their medical advisers, however sacredly held by the physician, are not to be regarded, in the courts, as "privileged communications." It reads thus, in exact legal terms, as I find quoted by Prof. Christopher Johnston, of Baltimore (*Trans. Med. and Chirurg. Faculty of Maryland*, Vol. 1874–1878): "Protection is not extended to *medical persons* in regard to information which they have acquired confidentially by attending in their professional characters." *Greenleaf on Evidence:* "The privilege is not accorded to clergymen, although contended for chiefly, if not wholly, in reference to criminal conduct and proceedings;" "Rome punishes the priest who reveals penitential confessions; and Mascardus states that the confession is made, not so much to the priest as to the Deity whom he represents, and that therefore the priest, when appearing as a witness in his private character, may lawfully swear that he knows nothing of the subject."

A very different character is here brought to our minds in the person of one of the witnesses in the trial of Queen Caroline. As we have it stated, "the trial proceeded, and the first witness was Zoödoro Majocchi, postilion to General Pino. If his evidence in chief was believed, he proved abundantly enough to establish the guilt of the Queen; but he entirely broke down when cross-examined by Mr. Brougham, and to questions respecting matters of which he must have had a lively recollection, the only answer to be obtained from him was '*non mi ricordo*,' which passed into and still continue household words in England for denoting mendacity." (*The Lives of the Lord Chancellors*, vol. x. p. 297.)

But neither the conscientious and authorized evasion of the priest, nor the mendacious one of this government witness will answer as a refuge for the doctor in the court; he must either betray the most sacred trust upon the assumed existence of which rest all the unquestioning revelations of all his patients, or he must pay the penalty—ordinarily fine or imprisonment—of "contempt of court," by boldly and honorably refusing to appear.

I believe it to be, however, the natural impulse which soon becomes the habit, more or less, of every honorable physician to forget, as far as may be, all that occurs in his professional relations with his patients, except such points which relate directly to the nature and treatment of the case. These points only recur to his mind when brought again into professional relations with the patient. Of many things left as a strong impression in the minds of the other party to the interview, I doubt not both he and the priest might conscientiously answer, "*non mi ricordo.*"

But we will continue the legal dicta upon our subject: "In regard to *professional* communications, the reason of public policy which excludes them applies *solely* to those between a client and his legal adviser."—*Greenleaf.* "The foundation of this rule," says Lord Chancellor Brougham, "is not on account of any particular importance which the law attributes to the business of the legal professors, or any particular disposition to afford them protection; but it is out of regard to the interests of justice, which cannot be upholden, and to

the administration of justice which cannot go on without the aid of men skilled in jurisprudence, in the practice of the courts, and in those matters affecting rights and obligations which form the subjects of all judicial proceedings.

"This 'privilege' extends to all papers or other communications; all letters written or entries made by the attorney, in his capacity of legal adviser; it extends to all communications made by the client to his attorney, though under a mistaken belief of its being necessary to his case." Every mark or record of a nature relating to, or for the purpose of professional advice or aid upon the subject of his rights and liabilities is placed *under the seal* of the law, which once fixed upon such communications, *remains forever*, unless removed by the party himself in whose favor it was there placed.—*Greenleaf.*

It is plain, then, that *practically* the private communications from the patient to his medical adviser are the only ones that ever become the subjects of extorted testimony, for it is a matter of general knowledge—and the ecclesiastical foundation is heretofore shown——that the devoted members of the Catholic priesthood will welcome fine and imprisonment, and the stake itself, before they would betray one item of penitential revelations made in the confessional. To our honor be it said, in sentiment at least, the medical profession is little or not at all behind them in faithfulness to its sacred trusts. And yet, in some of our States, the hardship is still greater and the penalty more inevitable, perhaps, with the physician than with the priest. "As the law now (1878) stands," says Dr. Johnston, "'the medical person' so confided in has no protection in the law; even if the judge choose to overlook his refusal to appear, the doctor, like any other ordinary witness, may be prosecuted for damages sustained by the party calling him, if it can be shown that by the withholding of testimony the party's interests had suffered."

It is pleasant to find that in the statutes of some of the States a complete *reversal* of this principle of the common law has been made. At an early period the enlightened State of New York began to manifest a liberal and humane state-craft upon this subject of confidential communications. In June, 1813, DeWitt Clinton, mayor, in the court of general sessions, ruled that "no minister of the gospel or priest of any denomination whatsoever *shall be allowed* to disclose any confessions made to him in his professional character in the course of discipline enjoined by the rules or practices of such denomination;" and by the revised statutes, "no person duly authorized to practise medicine or surgery *shall be allowed* to disclose any information which he may have acquired in attending any patient in a professional character, and which information was necessary to enable him to prescribe for such patient as a physician, or to do any act for him as a surgeon;" and by the second revised statutes, "information disclosed to a physician while attending a patient in his professional capacity, which information was necessary to enable him to prescribe for his patient, is declared to be a confidential communication, which the physician is not allowed to divulge without the express consent of the patient, for this is the privilege of the *patient* and not of the medical adviser."

"In Missouri, Michigan, Wisconsin, and Iowa statutes of the same effect have been enacted."—*Greenleaf.* The above was the progress made by the several commonwealths in this country up to the period of the publication of the valuable statistics, from which I have so freely quoted on this branch of my subject. There could be no more seasonable time or any better method or opportunity than this, offered in the present meeting of representatives from all the States, to procure in the near future the exact state of the law as regards extorted testimony in the various States at the present time.

That this principle of the common law, unrelieved by any statute in most of our States, conferring "privilege" on the confidential communications of patients to their medical advisers, deeply concerns the interest of communities, and is a constant and degrading challenge to the honor of our profession, we all must deeply feel.

I have presented *Extorted Testimony* as one of the many anomalous phases of our relations to the tribunals of law, all of which relations, with another yet briefly to be presented, require our early, earnest, and systematic consideration.

THE MEDICAL DEFENDANT.

There are many conditions of professional life in which the medical man may become a defendant, either justly or falsely accused. It is, however, in suits for malpractice that the danger and the evil have, in the course of years, grown so unpleasantly familiar to the medical profession. The scientific, skilful, and faithful surgeon, particularly should he be known to possess means to meet damages, no less than the ignorant and unscrupulous pretender, is constantly liable to have laid to his charge often the unavoidable results of injuries, as the consequences of either incompetence or neglect.

Unavoidable deformities and disabilities remaining after the treatment of fractures and dislocations have been made the most frequent occasions for arraignment of the surgeon; and in complicated cases of fracture the prudent and circumspect surgeon cannot entirely dispel from his mind this *bête noir*—this phantom, which may grow into a reality, to destroy his peace and cast a blight upon his reputation and his fortune.

My own first experience in the courts was in 1842, as a medical witness in defence of a most distinguished member of our profession—my master in surgery, Paul F. Eve, afterward President of this Association, in a groundless suit for damages laid at $20,000. The case was a comminuted fracture of the patella, resulting in gangrene and amputation. Able counsel was engaged, and though the suit was abandoned after the taking of testimony, the loss of time, cost in fees to lawyers, and temporary injury to reputation, summed up an amount of personal damage difficult to estimate adequately.

At various times and in different medical bodies, this question of malpractice suits has elicited attention. In 1856 the Committee on Surgery, Dr. J. W. Hamilton, Chairman, reported to the Ohio State Medical Association that in their opinion, the subject of malpractice was at that time of more importance than any other connected with surgery. "There is a standing and, apparently, a cumulative evil—an evil bearing with the weight of an incubus upon the profession. It is the

frequency of difficulties on account of alleged malpractice in the treatment of fractures . . . During one week in as many counties, four cases were tried."

I think, on examination of the records of the courts in the various States, and also from frequent communications, both private and in published correspondence in our journals, we may safely say that the evil is but little or not at all diminished at the present day.

It had been my design to give extended attention to this evil, than which no other more strongly characterizes the relations of the medical man to the tribunals of law, but the space already occupied with the relations of the medical witness and the expert admits of no further addition here to this address. The evil is, however, unfortunately, too widely recognized and keenly appreciated in our profession to require either elaborate presentation or extended comment.

A SECTION OF FORENSIC MEDICINE.

There are certain departments of medical science which apparently have no *special body of facts*, so to speak, which may be regarded as intrinsically their own. They are based, and often very broadly too, upon the facts and developments which specially pertain to some other department, and sometimes to many other departments of knowledge and practice growing out of them. The science of sanitary medicine is a department preëminently of this kind, hence it could have had no separate existence until after advanced progress had been made in such branches of investigation as those upon which we now find it expansively based.

"Modern sanitarians," says a recent writer, "do not pretend to lay claim to the origination of the knowledge that preventive medicine has utilized in the establishment of its principles, or in the efficient application of the measures to secure the public health. The rapid advances which curative medicine has made in the study of the causes of disease, whether atmospheric or telluric; also the rapid strides in pathology and in the discovery of disinfectants—all have contributed largely toward the present satisfactory status at which sanitation has arrived."

Forensic medicine in this respect is just such a department as sanitary medicine. It has no body of facts especially its own, and while it has wide and intimate relations with all the branches of science, it is individually the province of none of them. It depends upon bringing them all, when necessary, into combined relation with law, as sanitation has brought them into combined relation with the public health, and with the hygiene of communities.

I am aware that in the not distant past medical jurisprudence was, in some sort, comprehended in the scope of the regular Sections of this Association, affiliated with chemistry on account of its frequent relation to toxicology; or with psychology, on account of its perhaps more frequent exercise in questions of insanity; or with surgery, on account of the appeals made to it in suits for damages after the treatment of fractures; or again, with obstetrics, because criminal abortion or bastardy may give rise to questions of law. In any one of these individual associations it would be curtailed of its domain, dwarfed in its dignity, and perverted from what should be the comprehensive and beneficent intent of the department of legal medicine as an object worthy the study and cultivation of this Association.

As recognized by this Association, the Department of Forensic Medicine should comprehend all the subjects as referred to in these several departments; but besides them, every question or occasion through which the medical man can be brought into relation with the tribunals of law; whether, as a medical witness, as a medical expert, or as a medical defendant; or in time, when he shall have attained to his true dignity as *Amicus Curiæ*, or Adviser of the Court, his dictum equivalent to conclusive evidence, his scientific wisdom worthily rewarded as enlightment, indispensable in the upholding of justice; and his profound and conscientious opinion accepted with the same unquestioning confidence as to its integrity, as that which is yielded to the judicial ermine, and the charges from the bench.

In the organization and subsequent changes of the sections, medical jurisprudence seems at last to have disappeared as a fully recognized platform for our readings and discussions. There can be no one who values more highly than I, or recognizes more fully the dignity of every subject, even be it on the very outskirts of the domain of medicine, but none can be of higher importance in the present and the future, than attention to our concern in the department of Forensic Medicine. I would not wish to appear either invidious or irreverent, when I charge you. Let us still in our deliberations continue to "pay tithes of anise, and mint, and cumin, but among them all, let us not neglect the *weightier matters of the law*."

In conclusion, gentlemen, I would with great deference recommend that a committee—of which I would ask to form no part—be appointed to consider the expediency of organizing, or of rehabilitating a section of forensic medicine, for the reception and discussion of papers and reports on all subjects conversant about the important, but, at present, anomalous and little understood, relations of the medical man to the tribunals of law.

In time, may we not be able to prophesy of legal medicine in the words of the now almost mythic Seneca: the day will come, when those things which are now hidden shall be brought to light by true and persevering diligence—when our posterity will wonder that we should have been so ignorant of that which is so obvious.

THE ADDRESS IN MEDICINE.

Delivered April 29, 1885.

By HENRY D. DIDAMA, M.D.,
OF SYRACUSE, N. Y.

The prescribed duty of the Chairman of the Medical Section is to acquaint you with the progress made during the past year in Materia Medica, and the Practice of Medicine. A literal compliance with the mandate would subject you to a wearisome recital of facts and fancies which have been gathered already by enterprising medical journals and scattered broadcast throughout the world. The spirit of the injunction may be honored by the omission of minor and as yet unestablished additions to our armamentarium, while a few comments are made on the two recent discoveries, which have not entirely escaped popular and profes-

sional attention—Comma Bacillus and Hydrochlorate of Cocaine.

THE HYDROCHLORATE OF COCAINE.

The prompt and unprejudiced experiments made with the new local anæsthetic; the cordial, enthusiastic, and universal acknowledgment of its merits are a refutation of the charge that the medical profession is hampered by a blind and dogged conservatism. The drug is still in its infancy. Its anæsthetic properties are so remarkable that its use has been limited mainly to surgery, and especially to operations on the eye. But that it has a valuable future in medicine also there can be no doubt. Its ability to produce contraction of congested bloodvessels and pallor of the mucosa early suggested its probable utility in various pathological conditions.

Used as a collyrium in conjunctivitis, and in the form of spray in acute and chronic nasal and laryngeal catarrh, it has been of service not only as an adjuvant, but as the principal remedy. Speakers and singers afflicted with sudden and even persistent hoarseness and aphonia, have found speedy relief, and a restoration of vocal functions. It is not improbable that, used with the atomizer, it may mitigate the severity of the paroxysms of pertussis, and alleviate the dreadful distress of tubercular laryngitis. Internally—if its price shall not continue to forbid its general employment—it may be found serviceable in gastric irritation and catarrh, and like the leaves from which it is extracted, it may prove to be a quick and powerful muscular invigorator.

THE COMMA BACILLUS.

The brilliancy of the discovery of the comma bacillus by the already immortalized Koch, is universally admitted, but the claim that this microbe is the pathogenetic factor in cholera, is stoutly denied by some eminent observers. This denial is echoed by many worthy people who are constitutional doubters, and who habitually substitute prejudice for patient investigation.

It is asserted on the one hand that the comma is not pathognomonic of Asiatic cholera, being found in the dejections of cholera morbus, and even in healthy oral secretions, and on the other hand that in many cases of Asiatic cholera it is entirely absent, and that if it happens to be found its presence is a harmless coincidence. So confident has been this scepticism that its devotees have actually indulged in cholera dejections swarming with bacilli as a beverage. Surviving the somewhat repulsive experiment, the inference has been drawn that these microbes have no infectious properties.

Klein and others have demonstrated that the tank water in various parts of India is fairly alive with these punctuating bacilli, and that the natives drink it and them with avidity and impunity. The poor maligned comma microbe seems now in a fair way to have a reputatation for innocence fully established. His brother, the bacillus of tubercle, had a similar checkered experience. Miliary tubercle, it was asserted, identical with that caused by the bacillus, could be produced by inhalations of glass-dust, or by inoculations with any inert substances. One zealous doubter hastened to proclaim that the microbe was a base impostor; that what seemed to be a living organism was simply a masquerading fat crystal. But more extended observations and experiments, which excluded former sources of error, have so established the morbific character of this microbe that the affirmation may be made with some assurance—*every tubercle comes from a bacillus.*

In regard to the comma, Klein, in a recent discussion, admits that while this bacillus in and of itself is harmless, it yet does excrete or produce a virus or poison which causes cholera, so that after all the comma is actually essential to the existence of cholera, and the formula is justified—*no comma bacillus, no cholera.* Let it be admitted that the harm is done not by the living microbe, but by some dead excretion. Still, as there can be no excretion without an excretor, the comma cannot be allowed thus to shirk responsibility. The common law maxim, *qui facit per alium, facit per se*, will hold the principal liable for all the legitimate actions of its representatives.

It is admitted by Klein and his supporters that the poison produced by the bacilli is self-multiplying. Then it must be alive; for a dead excretion has no power of propagation. And if it be alive, it must itself be a microbe, the vicious offspring of the amiable comma. So that at last the contending parties occupy the same platform; one party laying the blame upon the mother microbe, the other party insisting that guilt rests on the wicked daughter.

Too much admiration cannot be felt for the army of patient and zealous investigators who brave danger, who sacrifice ease, who spurn lucrative pursuits in their devoted hunt among uncanny objects for some new minute enemy of the human race. They deserve all the plaudits which they receive.

But does not truth compel the sad confession that bacteriology with all its brilliant discoveries, has furnished little help to what is of the greatest practical importance to physicians and patients: the Art of Healing. The fatal march of consumption has not been arrested, and its treatment has not been even modified by the discovery of the bacillus. The dreadful disease still continues to kill one-sixth of the human race; and its ravages would not cease even if the bacillus could be exterminated. For consumption exists and runs its deadly course where no tubercles are present.

No new remedy has been suggested by the discovery of the cholera microbe. It is known that this bacillus thrives in alkaline soils, and has its growth and propagation hindered or arrested by acid conditions. But the acid treatment of cholera was employed with some success more than a decade of years before it was known whether the cause of the disease was shaped like a comma or an interrogation point. Ague yielded to Jesuits' bark ages before the bacillus malariæ was dreamed of; and the knowledge that vegetable germs are the fountain and origin of the complaint has not added one jot to our ability to manage it.

These facts are admitted, but they do not detract from the merit of the germ-seekers. No practical—certainly no commensurate—good has come from Arctic explorations. But Franklin and Kane and Greeley, and all their noble associates, deserve honor and reward not for what they achieved, but for what they attempted. Let the spirit of inquiry suffer no discouragement.

The ugly duckling becomes at length the beautiful and graceful swan. The helpless and useless babe

grows into vigorous manhood in time. Through untold ages the sun has been sending to us line upon line ardently acknowledging our good mother earth as his beloved daughter. The messages were unseen by dull mortal eyes till the Bavarian optician, Fraunhofer, came. He discovered the affectionate hieroglyphics in the solar spectrum, but he could not decipher them. He did what he could. He patiently observed and measured and honestly recorded five hundred and seventy-six apparently meaningless lines. And then he waited for the advent of some Champollion capable of furnishing an interpretation. For forty-five years the epistle remained untranslated. Then Kirchhoff, another German, after much patient search revealed to us the kinship of things terrestrial and celestial. Some good, let us hope, will yet come from the cruel and murderous Arctic explorations.

In some way Mycology may aid in preventing and curing disease. Let us labor and wait. But may we not, with all due humility and deference, suggest to our friends whose eyes are worn out looking through their fiftieth-inch objectives that the shape of the microbes, or even their behavior in cultivation fluids is no longer of supreme importance. Is it not time that a little more attention be directed towards discoveries in prophylaxis and therapeutics. Already the antiseptic precautions introduced by Lister have been of incalculable benefit to surgery. Those who decry Listerism, and claim that cleanliness is sufficient, actually pay tribute to the genius of the great antiseptic apostle. Dirt is harmful only because it contains noxious germs; cleanliness to the extent that excludes these germs is asepticism; and asepticism is Listerism.

We await the advent of some medical Joseph who shall discover a germicide which is not a homicide at the same time.

These remarks are introductory to my brief and fragmentary address.

THE ETIOLOGY OF DISEASE.

The mycologist is inclined to claim that a legion of diseases arise from microörganisms. Included among them are the exanthems, typhus, typhoid, and yellow fevers, diphtheria and mumps, tuberculosis, venereal indiscretions, and cholera asphyxia. Included also are complaints like pneumonia, whose contagiousness is not generally admitted, and rheumatic and malarial fevers which are non-contagious. It is not pretended that the specific *contagium vivum* of every one of these complaints has been demonstrated by propagation experiments. But as the spirillum of anthrax, the micrococcus of diphtheria, the bacillus of phthisis and cholera have been captured and exhibited and caused to multiply, the inference—conjecture, if you choose—does not seem forced that all diseases which resemble these specified in having contagious properties, or a period of incubation, or a definite cycle, or capabilities of preventing subsequent attacks, have as their causes certain minute, even if undiscovered, organisms. Further observations will be made. Alleged discoveries will be subjected to rigorous investigation. The false will be brushed away. The truth will be established. Carping criticism will yield to peaceful acquiescence.

The neurologist is confident that a multitude of complaints have their origin in the nervous system. And he has good grounds for his opinion. Fever as a Neurosis is the subject of an able paper by an eminent writer at this very session of our Association. That a high temperature—the highest recorded—has resulted from injuries of the spinal cord—and where the influence of microzymes is excluded—is not a matter of question. In one instance the temperature reached 122° F. and remained for seven weeks between 108° and 118°. The patient was a lady, the result was recovery. An incidental inference, which I will not press, is that if recovery can take place after a continuous average temperature of 115° for nearly two months, it is not the fever which kills or produces rapid softening of the heart and other organs in fatal cases of typhoid. Whether there be special calorific nerves which may be stimulated in moderately severe spinal injuries to increased production of heat, or whether, from continuous compression of the nerves, heat is produced by increased resistance—as in the galvano-cautery—are questions which may merit investigation. Fever, so far as it consists in elevation of temperature, can be a simple neurosis.

That rheumatism involves the nervous system, even if it does not originate in it, may be inferred from the erratic behavior of the joint affections in rheumatic fever, and from the causes of arthritis deformans, which are often grief, prolonged anxiety, and injury or disease of nervous centres, as shown by Charcot, and ably presented by Ord at the last meeting of the British Medical Association. Many cutaneous affections, notably zoster, urticaria, eczema, are of nervous origin. Pneumonia sometimes arises from injury of the brain. Diabetes, both the glucose and the insipid varieties, can be produced, as is well known, by irritating certain nerve centres. Some kidney diseases and liver complaints are the result of persistent nervous disturbance.

The humoral pathologists still adhere to the belief that our physical ailments arise from disorders of the blood. Plethora has its numerous attending evils, congestions, hemorrhages, cardiac disturbances. Anæmia is the prolific parent of a thousand aches and pains; of indigestions, palpitations, mental and physical debility. Blood containing an excess of a certain element causes diabetes. Contaminated with another, it occasions Bright's kidney and diseases of the urinary tract. Rheumatic fever, with endo- and peri-carditis and permanent valvular disease, is produced by the ingestion or injection of a certain acid, and its absorption into the blood, as shown by the experiments of Richardson and Foster. This acid is produced normally from certain elements of the food. It is transformed before reaching the systemic circulation. Produced in excessive quantity, or failing to be transformed, it poisons the blood—as it does when introduced experimentally—and causes rheumatic joint affections and cardiac lesions. As is well known, these endocardial disturbances and valvular injuries are limited almost exclusively to the left heart. The right heart escapes because the acid is normally present there, and so an accustomed stimulant. The transformation is effected in the lungs. In failure of this transformation, the acid passes into the general circulation, and, being an unaccustomed stimulant, poisons the left heart and works its well-known mischief.

Many dermatologists believe that certain cutaneous

affections are caused by impure blood. Eczema is one. The solidists pin their faith to cellular pathology. We need not be confused by this conflict of opinions. Neither of the views is exclusively true; neither is wholly false. Living foreign organisms; the nervous system; effete impurities of the blood; disorder of the minute cells of which every part of the human frame is constructed; each of these may be a factor in the origination of disease; each may be first, or midway, or last, in the vicious circle of causes—the etiological Round Robin.

Germs may develop a countless brood and contaminate the blood, either by their own abnormal presence or by a poison which they exude. This poisoned blood stimulates or obstructs the nervous system, and the heat of fever is developed by the correlation of forces. The presence of certain microbes is made known to the nervous centres. A mandate is sent to the vaso-dilators of the lung; congestion and pneumonitis result. Some irritation at the origin of the vagus produces hyperæmia of the liver, over-production of sugar, impairment of the transforming power, disturbance of the kidney, and diabetes. From disordered digestion, an abnormal condition of the blood may result; the nervous system may become involved. Gout may be a product, sometimes appearing in its true character as a torturing joint affliction, and sometimes masquerading as eczema or asthma.

The blood, the nerves, the cells, the microbes, are thus seen to have a pathogenic partnership harmony, and to be interdependent. Without the aid of the nervous system there could be no fever. But the nervous system alone can never originate any specific fever, typhoid, or rheumatic, or pneumonic. Rheumatism is intimately associated with a poison in the blood, but the excessive production of the poison and its circulation in unwonted vessels are the result of abnormal nervous influence.

From the ovum to the cadaver, man is constantly exposed to this conspiracy of morbific influences and agents to destroy him. There are foes without and foes within; foes which march up in front and boldly smite him in the face; foes which approach insidiously and undermine him; foes which are so attractive that he counts them as friends, till he finds himself dangerously smitten under the fifth rib. The destructive influences and agents are in the air he breathes, the food he eats, the water he drinks, and a hundred-fold more in the substitutes for water which he imbibes. These foes are the accidents and sudden dangers which he encounters; the misplaced switch of the railroad; the lurking miasm, the infected air, the defective drainage, the insufficient light which sap the foundations of life. They are the seductive habits and vices which sparkle and smile, and then bite like the serpent and sting like the adder. These morbific foes find access to the citadel of life through sometimes one avenue and sometimes another. This one comes in through the blood which it poisons, that one along the path of the nerves which it throws into abnormal vibrations, and the other creeps from cell to cell corrupting and enfeebling every fibre and tissue. Whatever the manner of entrance, the result is the same: nerves and blood and cells all become at length involved in the mischief.

To counteract these ruinous influences and agents—to fight with greater or less success against the open and concealed enemies, many means of defence and attack are provided. There is wisdom gained by observation and experience. There is the obtainable skill of the sanitarian and physician. There are certain inherent powers of resistance and recovery which, ever on the alert, are more potent protectors than that human wisdom which often sleeps; than that human skill which sometimes gropes and sometimes blunders.

We are familiar with what is called the *vis medicatrix naturæ*. It is a power which is sufficient in many—perhaps most—cases of disease to effect a cure. Sometimes it brings relief while the physician simply watches or gives inert drugs—and claims all the credit. Sometimes it corrects disorders with the well-timed aid of the doctor. Sometimes it triumphs over the combined attack of the disease and the blundering medicine-man. This reparative power is the best friend and ally of the wise physician. It may be too weak to accomplish its purpose, and so may need timely and sufficient aid. It may overdo the matter, and so need wholesome restraint. It may be irregular in its action, and so need careful guidance.

THE VIS MEDICATRIX.

Now while we are familiar with this reparative power, we may not be so attentive to another conservative force which is especially important: The Resisting Power. From the *vis medicatrix* this power differs essentially. One is a restorative force—a tendency to come back to the normal condition after departure from it. The other is the conservative force, which *prevents* departure. A steel spring yields readily to external force, but its elasticity—after the disturbing cause is removed—enables it to resume its original condition. This is the *vis medicatrix*. Granite rock is not easily affected by external violence. Its power of resistance is great. When the force brought to bear upon it is strong enough to cause it to yield, it goes to pieces, having no recuperative power. There may be great toughness combined with great resisting power. The iron-clad vessel when struck by ponderous ball or steel bolt, may be perforated, but it is not hopelessly shattered.

This resisting power is akin to what is called inertia in physics—the tendency of a body in motion to keep going; of a body at rest to remain quiet forever. Light bodies with little substance are easily set in motion, and easily deflected from their course, or arrested in it. A feather can be wafted or stopped by the slightest breath. A cannon ball, an avalanche, are turned aside by no obstacle; they move onward to their destination.

Every human being has more or less of this resisting power. It may be feeble and yet so united to a recuperative force, that the individual possessor manages to get along fairly well. Any trifling mishap or exposure may prostrate him, as a reed may be shaken in a moderate wind; but his elasticity, like that of the reed, brings him up promptly when the storm ceases. He has his frequent ups and downs; we all know many such cases; he is delicate of constitution; he may be like an estimable old lady of my acquaintance, at the point of death at odd spells for thirty years; and yet he lives on by virtue of the *vis medicatrix*, of which he

seems to be composed, till all his acquaintances have passed off the stage of action.

On the other hand, this resisting power may be like that of the granite. Its owner may violate all sanitary laws, may laugh to scorn all counsel about what he should eat or drink, or wherewithal he should be clothed. He may expose himself unprotected to cold and wet. He may go without sleep and food. He may tax stomach and brain and muscle to the utmost. And yet he may remain undisturbed. We know such men—men who guzzle poor whiskey every day, and live to be a hundred years old. We know men of granite constitutions, who prowl around late at night, when they should be snugly in bed; who gormandize, who exercise vigorously all the vices; and yet who remain a standing refutation—as superficial observers think—of all rules for preserving good health. But when some overwhelming calamity comes they are stricken down forever; their first illness is their final one; they crumble to atoms.

In every community are those whose resisting power is so feeble from inheritance or so thoroughly impaired by excesses that they are but walking dead men—apples of Sodom perhaps—fair to look upon, but ashes or putrefaction at the core. They yield to influences which are trivial in their nature, and go into the hands of the undertaker before their neighbors had even heard of their illness. These are children of old, or debauched, or scrofulous parents, whose resisting power is so nearly *nil* that their aspirations to stand with the angels receive early gratification, in spite of all that love and skill can do to keep them away from their heavenly home. We name the messenger who summons them cholera infantum, or tuberculous brain disease, or white swelling; and as parents, while we wonder at the mystery, we bow submissively to Him who gives and then takes again so soon. But as physicians, we are not surprised that diseased and mushroom cells should hasten to early destruction.

No man liveth for himself alone. The good constitution, the strong resisting power of the temperate and upright man is not only a sure personal defence against disease and a guarantee of longevity; it is transmitted to his offspring down to many generations. The dissolute man, broken down with diseases acquired while sowing his wild oats, suffers not alone. If he did, we might view the transaction with mitigated sorrow. He had his coarse enjoyment, and he can afford to reap corruption. But the evil that he does lives after him in the blighted and wretched lives of his innocent children and his children's children.

A priceless inheritance is a strong resisting, combined with a vigorous recuperative power. He who has it and preserves it, and fortifies it, living a clean and active life, eschewing bodily and mental excesses, and clinging to the Divine promises, may bid defiance to disease in its multifarious forms. He need not be afraid for the pestilence that walketh in darkness, nor for the destruction that wasteth at noonday. Free from fear—the greatest depressant—he shall walk unscathed through all perils. A thousand may fall at his side and ten thousand at his right hand, but disaster shall not come nigh him. And even when the onslaught of disease cannot be wholly warded off, the wounds inflicted shall have speedy healing.

MEDICAL PROGRESS.

Uncontrollable Hysterical Vomiting; Cure by Cocaine.—Professor Kohler has successfully employed cocaine in concentrated solution in several instances with noteworthy results. In one case he, without injury to his patient, sounded and dilated the larynx and trachea after application of the drug. In a second remarkable case, a hysterical woman was attacked with uncontrollable vomiting, from which she became so much reduced that to sustain her it became necessary to resort to peptonized enemata. The first application of the solution of cocaine enabled the woman to partake of liquids, and the second rendered the ingestion of solid food possible. On abandoning the use of the cocaine, the vomiting was at once renewed.—*L'Abeille Médicale*, April 6, 1885.

Early Resection of the Long Bones during Growth in acute Osteomyelitis, with Suppuration of the Neighboring Joint.—Dr. A. Cerné, at the last meeting of the French Surgical Congress, read a paper upon the early resection of the long bones during growth in acute osteomyelitis, complicated with suppuration of the neighboring articulation, of which the following are the conclusions:

1. Early resection in acute osteomyelitis during growth may be substituted in nearly every case for which, up to the present time, amputation has been considered necessary.

2. Resection can and should be limited to those parts affected by necrosis, if the disease is limited to the bone.

3. Invasion of the neighboring joint does not constitute a contraindication to the operation, but renders it the more imperative.

Resection of the Hip in Coxalgia; its Indications and Ulterior Results.—Prof. Eugene Bœckel, at the meeting of the Congrés Francais de Chirurgie, recently held at Paris, expresses his views as to the operation of resection of the hip in coxalgia, as follows:

1. Suppurative coxalgia in a young subject is never cured except when the head of the bone is luxated or destroyed.

2. The operation of resection is in itself not dangerous, but is influenced or complicated by the general condition.

3. Tuberculosis or meningitis causes the death for the most part in those undergoing the operation for resection, as does it also in those affected by coxalgia.

4. The more opportune and less extended the resection the more perfect and rapid the cure.

5. The arrest of development in favorable cases is slight.

6. After delayed resection such arrest is considerable; also in those cases of suppurative coxalgia whose cure has been extended over some years.

7. Resection is the surest method of curing, quickly and well, a case of suppurative coxalgia.

8. Contraindications to resection are furnished by pronounced tuberculosis of any internal organ. Albuminuria, which is susceptible of cure after resection, is not an absolute contraindication.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 2, 1885.

DRY PLEURISIES.

SIR ANDREW CLARK, in London, and DR. J. R. LEAMING, in New York, have on many occasions during the past twenty years insisted on the importance of primitive pleurisies in the natural history of phthisis. The former has recently in his Lumleian Lectures, at the Royal College of Physicians, London, given a full and detailed statement of his views, to which we shall briefly call attention.

A dry pleurisy is defined to be such an "inflammation of the pleura as issues in an exudation of lymph into the substance and upon the surface of the membrane, unaccompanied by an amount of serous effusion sufficient to yield physical signs conclusive of its presence." In the first lecture the clinical aspects are considered and twelve cases are selected for narration, from material which is referred to as embarrassing in its richness. An analysis of these cases makes us question whether all come under the category of *primitive* dry pleurisies. Case II. we should regard as a somewhat anomalous pleuropneumonia. In Cases IV., VII., IX., and XI., there seems every probability that the pleurisy was originally *wet*, and that the dulness with retraction of one side resulted from the gradual absorption of the fluid and organization of the thick exudation. Case IX., certainly, with the remnant of an old empyema in the diaphragmatic pleura, communicating with an abscess in the liver, cannot be regarded as one of ordinary plastic pleuritis. Many of the cases were followed for years, which adds greatly to the interest, and they are related in a very pleasant way, so that one does not weary in the perusal.

The second lecture opens with a criticism on the current anatomical description of a lung lobule, and an original account by Sir Andrew, which, so far as we can gather, does not differ essentially from the descriptions criticised, except in discarding the terms *alveolar passage* and *infundibulum*, and the statement that the air cells are cubical, not hemispherical.

Sir Andrew's remarks on the structural character and changes in blood-clot and exuded lymph illustrate what a pathological Rip van Winkle a man may become, engrossed in the cares of practice, for we have here the antiquated assertion of the formation of the fibrous elements directly out of the exudation or from a fibroid basis substance. The exudations are classed under three heads: fibrinous, characterized by the scarcity of cell forms; the croupous, by their abundance and rapid degeneration; and the proliferative, with numerous cells which display active structural development. The two former are accompanied by the phenomena of inflammation, while the proliferative is a textural growth. By a gradual extension of the indurative changes into the lungs, at first along the interlobular septa, then about the vessels and bronchi, and, finally, the alveolar walls, a fibroid condition of the organ is produced. Later changes are the development of bronchectasis, and the destruction of tissue with the formation of cavities and the production of a fibroid phthisical lung. The anatomical picture is, on the whole, faithfully and accurately drawn, but it is too restricted, and we should have liked more information on the differences between *primary* cirrhosis, and that which is an outcome of chronic pleurisy. In the third lecture the clinical features and symptoms are considered, and the local physical signs very fully and ably discussed. Some most interesting points on the history of bronchectasy are dwelt upon at length.

The tubercle bacillus has evidently been a source of not a little worry to Sir Andrew Clark, whose well-known divisions of phthisis into tubercular, pneumonic, and fibroid, have been somewhat disturbed by its advent. He holds, very justly, that its "exclusively causal agency, although extremely plausible, is not conclusively proved;" and, even if the views regarding the unity of phthisis should prevail, the fact remains that there are subsidiary groups which require separate and permanent recognition. "Why," he suggests, "under the generic name bacillary phthisis should we not recognize the subordinate independence of tubercular bacillary phthisis, caseous bacillary phthisis, and fibroid bacillary phthisis?" The contention for non-bacillary ulcerative processes in the lungs appears perfectly well taken.

In these admirable lectures two omissions strike us as being very odd, viz., the absence of any reference to primitive dry tubercular pleurisy which may induce enormous thickening of the membrane, and

last for years before the lung is involved; and secondly, no mention is made of the all important part played by neglected pleurisies and empyemas in the etiology of fibroid phthisis.

For one case in which *primitive* dry pleurisy causes induration of the lung, we should say there are at least a dozen the result of a pleurisy, serous or purulent, left to nature and undergoing resorption only after months of ill-health. Sir Andrew Clark, at the beginning of the first lecture, asked the question, Do primitive dry pleurisies exist? and admitted that their influence in producing secondary disease of the lung had been hotly contested. That they occur with great frequency every one knows, that they may induce fibrosis of the lung we readily allow, but after a tolerably extensive experience we never met among numerous specimens of cirrhosis one which in its etiological and anatomical features, bore out the views of the distinguished Lumleian lecturer.

THE BACILLI OF SYPHILIS.

At the recent Kongress für Innere Medecin, held at Wiesbaden, Lustgarten, the clinical assistant of Kaposi, described a new microphyte, which, by the aid of a novel process of coloring, he had constantly found in the primary, secondary, and tertiary lesions of syphilis, and which he regards as the cause of that disease.

The bacilli are short, straight, or curved rods, with irregular, undulating, and slightly notched contours, of a deep blue color, and contain from two to four spores. They are never free, but are invariably included in wandering cells, in groups of from two to nine. The cells themselves are rarely found at the centre of the infiltration, but exist in pretty large numbers at its edges, and in the adjacent apparently healthy tissues. Lustgarten has also demonstrated the presence of these bacilli in the spinous cells of the rete Malpighi in papular eruptions, through which he explains the clinical fact that moist papules become contagious when they are deprived of their epithelial investment.

For the information of those of our readers who may desire to enter this special field of investigation, we reproduce the method of staining adopted by Lustgarten: Sections, which have been hardened in alcohol during twelve to twenty-four hours, are placed for two hours in a fluid composed of eleven parts of a concentrated alcoholic solution of gentian violet and one hundred parts of aniline water, at a temperature of 104° F. The sections are then decolorized by washing with absolute alcohol, and next placed for ten seconds in a one and a half per cent. solution of permanganate of potassium, when they are transferred to pure sulphurous acid, and allowed to remain until they are nearly deprived of color. They are then washed with distilled water, reintroduced into the permanganate solution for three or four seconds, and again placed in sulphurous acid. This manœuvre is repeated several times, or until the preparations are entirely colorless, when the water is extracted by alcohol, and the sections mounted in oil of cloves.

From the peculiar tinting reaction of the bacilli, which has not hitherto been observed in other microscopic organisms, Lustgarten assumes that he has discovered a bacillus which stands in the same relation to syphilis that the bacillus tuberculosis does to tubercle. In two of the other infective tumors at least, namely, lepra and tubercle, the virus has been demonstrated to be a rod-shaped bacillus contained in the granulation tissue of the neoplasm, and we have every reason to presume that the syphilitic virus is connected with a particular form of bacillus, although the fact has as yet not been demonstrated. Pure cultures in sterilized gelatine, and possibly other media, as well as direct inoculation, must be practised, before Lustgarten's bacilli are accepted as the cause of syphilis; and, when we bear in mind the failures of Klebs, Ziegler, Von Rinecker, and others in this direction, we must accept his statements with great reserve.

ARSENICAL WALL PAPERS.

The use of arsenical pigments in coloring wall papers, and many kinds of wearing apparel and other articles, is sufficiently common to warrant the enactment of a law prohibiting the manufacture and sale of articles of domestic use containing poisonous coloring matters, or at least making it compulsory that they should be advertised as containing deleterious matter, so that the purchaser may have full knowledge of the danger which is incurred by their use.

Many continental countries have very rigid regulations on this subject, those of Sweden being by far the most stringent. In England strenuous efforts have been made, but without success, to have a law enacted prohibiting the manufacture, sale, or importation of articles of domestic use, containing arsenical pigments, or containing arsenic in any form. In this country less attention has been given to the subject, but certainly not because there is less need of such a law, for there is every reason to believe that the trade in poisonous articles is extensive. It is only necessary to read the article in the fifth annual report of the State Board of Health, Lunacy, and Charity of Massachusetts, by Professor Edward S. Wood, on "Arsenic as a Domestic Poison," to be convinced of this unwelcome fact. Professor Wood's paper is a valuable supplement to the exhaustive article of Dr. Draper, "On the Evil Effects of the Use of Arsenic in Certain Green Colors," which was published in 1872. It shows how very extensive is the

employment of arsenic in the manufacture of articles intended for domestic use; and that this substance, when used in the manufacture of domestic articles, such as wall papers and clothing, may, and frequently does, cause very distressing symptoms, and sometimes dangerous, and even fatal, poisoning.

According to Professor Wood, the most common source of domestic arsenical poisoning is wall paper, which frequently contains an excessive amount of arsenic in the coloring matter. Green papers were at one time supposed to be the most dangerous papers on account of the use of certain preparations of arsenic in the coloring matter; but at the present time, although many of these papers contain dangerous pigments, arsenic is more frequently found in wall paper of other colors. This is accounted for on the supposition that the public have been specially cautioned in regard to the poisonous character of green papers and pigments, and have avoided them unless assured that they are not arsenical. Manufacturers have, therefore, been obliged to produce these colors without using the objectionable arsenical coloring matter. It is stated that red and blue papers are more frequently arsenical than the green. Even the delicate French grays contain a very considerable amount of arsenic. In fact, papers of any color or any shade may contain arsenic; and, therefore, color is not a reliable guide in distinguishing a poisonous from a non-poisonous paper.

The examination of a large number of specimens by Professor Wood developed some startling results. A number of the specimens contained as many as six grains of arsenic per square yard; a large number of them over one grain per square yard. One specimen of the so-called "glazed and plated" papers, so much used by children in kindergarten schools, contained as much as 55.88 grains of arsenic per square yard. It was found that no reliance could be placed on the color as indicating whether a paper was poisonous or not, and that the price of a paper is no security against its poisonous nature, as some of the most expensive papers contain a large amount of arsenic, while some cheap papers have none at all.

Poisoning is caused not only by the inhalation or contact with the body of arsenical dust, but also by the absorption by the skin and lungs of a very poisonous gas, arseniuretted hydrogen, which is evolved by the decomposition which takes place when arsenic is in contact with moist organic matter, such as the size or other vehicle for the color.

The symptoms of arsenical poison are difficult to recognize, as they simulate those of other diseases, and doubtless many cases of illness due to this cause are ascribed to other agencies, and their true character overlooked, because it does not occur to the medical adviser to think of the arsenic in domestic articles as the source of the trouble.

Since the evil is widespread, what defence have the public against it? Manifestly the employment of arsenical pigments in every shape in domestic articles should be prohibited. This is a matter which should claim the prompt and careful attention of the legislature. Pending some definite legislation on the subject, it would be well to require from the vendors of wall papers a reliable test showing that the papers contain no arsenic or other poisonous matter, since mere inquiry would be met with the assurance, given in good faith, that the article was harmless,—an assurance which is entirely untrustworthy. It is not practicable for the purchaser to institute a test on his own account, though this is done in some cases, and the security thus obtained amply repays the trouble and expense. Some firms, with commendable regard for the public safety, require the products to be submitted to exacting chemical tests, and thus are enabled to assure their patrons of the harmless nature of their stock. This practice, however, cannot be expected to be universally adopted, and therefore the self-imposed labor of some manufacturers should be supplemented by a general investigation by the analyst of the health board, who can render a valuable service to the public by a searching examination of the stock of paper-hangings offered for sale.

The physician should not forget the possibility of wall paper poisoning, and, in ill-defined and suspicious cases of sickness, he would do well to cause the wall paper to be submitted to a chemical test.

THE CHAIR OF CHEMISTRY IN THE JEFFERSON MEDICAL COLLEGE.

WE have the pleasure to inform our readers that Dr. J. W. Holland, of the University of Louisville, was elected on Monday last, Professor of Medical Chemistry and Toxicology in the Jefferson Medical College. Prof. Mallet, who was elected in September, 1884, in succession to the late Professor Robert E. Rogers, returns to the University of Virginia, from which he has not been able to separate himself permanently, although he has made two efforts to do so.

Dr. Holland has had thirteen years' experience as a teacher of medical chemistry, having been appointed to that chair in the University of Louisville, on the retirement of Prof. J. Lawrence Smith, whose assistant he had been. Dr. Holland is an admirable speaker and lecturer, and a gentleman of superior culture and of refined manners. His address before the Jefferson Alumni Association, at the last annual meeting was a finished and scholarly production, and did justice to his high reputation as a speaker.

The college to which he comes, and the medical profession amongst whom his lot will be cast hereafter, are to be congratulated on this agreeable addition to their resources

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Thirty-sixth Annual Meeting, held at New Orleans, April 28, 29, 30, and May 1, 1885.

(*By Telegraph.*)

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, APRIL 28TH.—FIRST DAY.

THE Thirty-sixth Annual Session of the American Medical Association was called to order at 11 o'clock in Tulane Hall, in the City of New Orleans, by Samuel Logan, M.D., Chairman of the Committee of Arrangements. After prayer, DR. HENRY F. CAMPBELL, of Georgia, the PRESIDENT-ELECT, was introduced and took the Chair.

DR. LOGAN, on behalf of the medical profession and the citizens of New Orleans, then delivered a cordial and eloquent *Address of Welcome*.

The former Presidents and Vice-Presidents of the Association were invited to seats upon the platform.

DR. HENRY F. CAMPBELL then delivered the

PRESIDENT'S ADDRESS.

(See page 477.)

DR. I. N. QUIMBY, of New Jersey, moved that a committee of five be appointed to consider the suggestions contained in the President's Address. Adopted.

The report of the Special Committee appointed at the last meeting to take such action as it might deem proper regarding the

DEATH OF DR. SAMUEL D. GROSS,

was presented, in behalf of DR. AUSTIN FLINT, Chairman, by Dr. T. G. Richardson, of New Orleans. The report submitted some reflections on his life—a life memorable for services in behalf of medicine and the medical profession; a life precious as an example; and a character which inspires esteem and affection.

The life of Prof. Gross, from the beginning to the end of his long professional career, was a life of work—work as a student, a writer, a teacher, and a practitioner. From first to last he was a diligent student. His pen was never idle, and the six editions of his great work, *A System of Surgery*, represent an immensity of labor. At the outset of his professional life he resolved to become a medical teacher, and in many respects he was a model teacher. As a speaker, he was fluent, deliberate, clear, and emphatic. His tall, commanding figure, his clear voice, his zealous manner, all contributed to render his teaching effective, but his pre-eminent success was an outcome of his love of the labor, and a deep sense of the responsibility which the duties of a teacher involve. As a practitioner, his characteristics, irrespective of his ability and skill, were attentiveness and a deep interest in his cases, conjoined with geniality and kindness.

Turning from the life-picture of Prof. Gross in its professional aspects, the contemplation of his character as a man awakens higher sentiments than admiration. As a student, author, teacher, and practitioner, he was grand, but it is more pleasing to associate his memory with his domestic and social relations. We cannot but admire the achievements of his intellect, but the excellency of his heart inspired affection and love. We shall see him no more in this world, but his life-work and his character death cannot destroy. These remain a priceless legacy to the profession which he loved, and which will ever hold his memory in grateful remembrance.

DR. J. S. BILLINGS, U. S. A., in behalf of DR. AUSTIN FLINT, of New York, who was unavoidably absent, presented a report from the Committee to secure a Congressional appropriation for a fire-proof building for the

ARMY MEDICAL MUSEUM AND LIBRARY.

He stated that through the efforts of the Committee and the individual aid of the members of the Association, Congress, after having had the subject under consideration for four years, at its last session granted the requisite appropriation for the erection of the building, and the work will be commenced at once. The building will be located on the Smithsonian grounds, near the National Museum, and will be a plain but substantial structure. On behalf of the Surgeon-General, he extended thanks to the Committee and to the Association for their confidence in the present management of the Library and Museum, as shown by their continued and earnest endeavor to secure this appropriation.

DR. BILLINGS also, in behalf of Dr. Flint, Chairman of the Committee appointed at the last meeting to present at Copenhagen an invitation, "on behalf of the Medical Profession of the United States," to

THE INTERNATIONAL MEDICAL CONGRESS

to meet in Washington, in 1887, with power, if accepted, to make all necessary arrangements therefor, reported that the invitation had been tendered and accepted; that meetings of the Committee had been held in Copenhagen in August, in New York in October, and in Washington in November, and the result of their preliminary work was stated. He further stated, that the Committee expected to be prepared to present a full programme for the Congress at the next meeting of the Association.

DR. J. M. KELLER, of Arkansas, moved that the consideration of the report be made the special order for Wednesday, at 12 o'clock.

DR. A. L. GIHON, U.S. N., presented, through the Secretary, a report of the Committee appointed to consider the advisability of the erection, in the City of Washington, by the Association of a

STATUE OF DR. BENJAMIN RUSH.

Consideration of the report was made a special order of business for Friday.

MEMBERS BY INVITATION.

On motion, Drs. Edward Jones, A. B. Miles, C. J. Rickham, of New Orleans, A. E. Foote, of Philadelphia, J. G. Ganthreaux, of Louisiana, and James R. Scarborough, of Kentucky, were invited to seats on the floor.

THE DISCOVERY OF ANÆSTHESIA.

THE SOUTH CAROLINA MEDICAL ASSOCIATION presented a communication stating that at its meeting in 1884, the following resolution was adopted:

Resolved, That the delegates from this Association be requested to present to the American Medical Associa-

tion at its next session, the Report of the Committee on the Discovery of Sulphuric Ether, made to the Association at its last session, and request that body to take such action on the subject of the report, as they in their judgment may determine in view of the claims therein set forth.

Dr. R. Beverly Cole, of California, remarked that the importance of the resolution rendered it deserving of careful attention, and he moved its reference to the Section on Practice of Medicine with a request for a report. Adopted.

Wednesday, April 29th.—Morning Session.

After prayer, and the reading of a telegram from ex-President William O. Baldwin, of Alabama, regretting his inability to be present, the Committee of Arrangements presented a further report, and the Secretary announced the names of the members of the Nominating Committee.

Dr. H. D. Didama, of Syracuse, N. Y., then delivered

THE ADDRESS IN MEDICINE.

(See page 484.)

Dr. R. Stansbury Sutton, of Pittsburg, delivered

THE ADDRESS IN OBSTETRICS,

which will appear in full in The Medical News of next week.

Dr. W. C. Van Bibber, of Maryland, then made some suggestions in regard to the

CONSTRUCTION OF A HEALTH CITY IN FLORIDA.

Before he had completed his remarks the order of the day was called for, and his paper was referred to the Section on State Medicine.

The consideration of the report of the Committee on Organization of

THE INTERNATIONAL MEDICAL CONGRESS

was then announced to be in order.

Dr. J. V. Shoemaker, of Pennsylvania, protested against the acceptance of the report, and stated that the American members who were present at Copenhagen had been entirely ignored by the Committee. He declared that the advocates of the New Code had given the Committee to understand that they must be recognized. The Committee had joined hands with these men, and had elected themselves to the most prominent offices of the Congress. He asked whether the Association had authorized this Committee to elect officers for the Congress. The members of this Committee had ignored the Association, and they have made fun of it for the last ten or twelve years. He asked what was meant by the statement that a complete programme would be presented at the next meeting? It meant the Councils of the Sections would be filled by a clique, and then those who had been left out would be told that there was no more room.

Dr. F. E. Daniel, of Fort Worth, Texas, offered the following preamble and resolution:

Whereas, At the last meeting of the American Medical Association a committee was appointed to confer with the International Medical Congress, at Copenhagen, with a view to securing the next meeting of that body in 1887 at Washington, and to arrange for the said meeting; and

Whereas, This Committee, after accomplishing this object, have proceeded, without authority from this body, to appoint the officers of the Congress, which have been published in detail in the Journal of the Association and other publications, thus giving the aspect of authoritative action on behalf of this Association; and

Whereas, This Association recognizes the Committee as a Committee of Arrangements only, and in so far as the duties of the Committee have been performed, it declines to endorse the said appointments; therefore,

Resolved, That the Committee on Nominations be instructed to prepare and present to the Association nominations for the officers of the Congress and its various Sections.

Dr. J. S. Billings, U.S.A., expressed surprise at this movement. The statement which had just been made, that the Committee was threatened by New Code men, or that any bargaining was had with them, or anyone else, was totally and absolutely false. No New Code men were consulted by the Committee, or had any knowledge of the preliminary work at Copenhagen. He called attention to the resolution of last year which appointed the Committee, and gave it the power—if the invitation was accepted—to add to its membership, to perfect its organization, to elect its officers, and to proceed to act as an Executive Committee, with full power to fix the time and to make all necessary and suitable arrangements for the meeting, and to solicit funds for this purpose.

This Committee, consisting of Drs. Austin Flint, of New York; Henry F. Campbell, of Georgia; L. A. Sayre, of New York; I. Minis Hays, of Philadelphia; Christopher Johnston, of Baltimore; George J. Engelmann, of St. Louis; J. M. Browne, U. S. N.; and J. S. Billings, U. S. A., presented the invitation at Copenhagen, and, upon its acceptance, were constituted the Organizing Committee of the Congress. This Committee, under the power given it, enlarged its number to twenty-five, so that it should thus be thoroughly representative of every section of the country. It then proceeded with the necessary preliminary work for the organization of the Congress, which was done, thus early, after conference, and in accordance with the advice and experience of the Committee of Arrangements of both the London and Copenhagen Congresses.

One fact he desired to impress upon the Association, that whether the Committee had acted erroneously or not, it had acted to the best of its ability and with pure and honest motives, and the character of its members was the best guarantee of his assertion. As a member of the Association, he advised that no hasty action should be taken to overthrow the reported work of the Committee, because such action would cause an unfortunate delay in the organization of the Congress, and was calculated to create an unfavorable impression abroad.

Dr. J. F. Gabriel, of Piqua, Ohio, complained that he had not been consulted at Copenhagen by the Committee.

Dr. J. M. Keller, of Hot Springs, Arkansas, considered that the Committee was responsible to the Association for its action, and it had overlooked its responsibility. He offered the following amendment to Dr. Daniel's motion:

Resolved, That the Committee appointed to arrange for the meeting of the International Medical Congress in Washington in 1887, be enlarged by the addition of thirty-eight members, one from each State and territory, the District of Columbia, and the Army and Navy, to be appointed by the Chair. That the Committee thus enlarged proceed at once to review, alter, and amend the action of the present Committee as it may deem best.

He stated that the enlarged Committee should take into consideration what had been said in the discussion, and it should place no man in any position who is in direct opposition to the Code of Ethics of the American Medical Association.

Dr. R. Beverly Cole, of California, in seconding the amendment, said that in his opinion the Committee had erred in its action after inviting the Congress, but he was too cosmopolitan to accuse men of such high standing of participation in any but honorable procedures, but he was strongly opposed to giving positions of honor to any New Code men. He had always been taught to reverence Eastern men, and he still reverenced them, but too much exaltation had made them arrogant. He hoped that, if the resolution were adopted, the selections and appointments already made would be revised, but that the whole preliminary work of organization would not be undone.

Dr. Willis P. King, of Sedalia, Mo., said that he could not accuse of dishonesty such men as compose this Committee, but they had considered only the great North and East, neglecting the West and South. He was fully in accord with the spirit of the resolution offered, especially as regards the decapitation of New Code men.

Dr. J. V. Shoemaker, of Pennsylvania, said that New Code men had made threats at Copenhagen in his presence, hence the statement that he had made was true, as men who made these threats are now on the Committee.

Dr. D. D. Saunders, of Memphis, Tenn., objected to any action which would overturn the regular, systematic arrangements which had already been made, which would be the effect of rejecting the report. He moved as an amendment, That the report of the Committee be accepted and the Committee continued.

Dr. J. B. Roberts, of Philadelphia, said that he could speak on the subject—perhaps from a standpoint that the majority could not,—for, although a Philadelphian, he was acquainted personally with but a single member of the Committee; the remainder he knew, as everyone does, by reputation. He could advocate the endorsement of the action of the Committee without the bias of interest or personal friendships.

The officers selected by the Committee would, by their reputations, give character to the Congress in foreign countries. He thought, that as successful an International Congress could be held there to-day, as would be held at Washington, in 1887, if the work of the Committee was overruled. If it was the success of the Congress which was desired, he thought it would be better to endorse the action of the Committee,—even if it had exceeded its authority,—than to make public the fact that dissension and dissatisfaction exist at home.

Dr. W. N. Smart, of Grand Haven, Mich., believed that the Committee had exceeded its power, and that the Association, without question, should proceed to endorse what is proper in its action and to correct its errors.

A vote was then taken on Dr. Saunders's resolution to accept the report—yeas 88; nays 129.

Dr. Keller's amendment was then adopted: yeas 131; nays 92.

Dr. W. A. Byrd, of Quincy, Illinois, moved, as an amendment, that members of the Committee from the States represented at the meeting shall be appointed by the delegations, and those not represented shall be appointed by the President. The original resolution, as thus amended, was then adopted.

Thursday, April 30th.—Third Day.

The session was opened with prayer. The Committee of Arrangements submitted an additional report, and the reading of the roll of members was, on motion, dispensed with.

the amendment to the by-laws

offered by Dr. Foster Pratt, of Mich., last year, that each Section shall, in the future, elect its own officers, was called up.

Dr. A. S. Purdy, of New York, thought that the effect of the amendment would be to split the Association into so many smaller Associations.

Dr. N. S. Davis, of Illinois, thought that the amendment was defective, inasmuch as it did not specify the time of election.

On motion, its further consideration was postponed until next year.

Dr. N. S. Davis, on behalf of the

committee on meteorological conditions,

and their relations to the prevalence of diseases, reported that the Committee had endeavored to secure full reports from the twelve principal cities of the Union through the official bureaus. It had made a special study of ozone production and its value, and also of its tests. Of these, Schönbein's paper is the best, but it reacts to other agents. Thallium was found to be very sensitive. Observations were interrupted in some cities by changes of residence of observers. Physicians were requested faithfully to record the beginning of all epidemics. He said it was difficult to secure such service, as many promise and do not perform; yet he thought that accumulating material will permit the Committee in after years to report conclusions of value. The report was accepted.

Dr. Davis also presented a report from the Committee on the

collective investigation of disease,

which was appointed to act in coöperation with the Committee of the British Medical Association. He stated that at the International Medical Congress held at Copenhagen, an International Committee had been appointed with members from Denmark, Sweden, Russia, Germany, France, and England, and North and South America. A sub-committee had been appointed to consider subjects for consideration and to tabulate a programme to be distributed throughout the world. The Committee had decided that few questions should be asked, that they should be simple in character, and that they should relate, 1st, to geographical distribution; 2d, to prevalence of diseases in certain localities; 3d, to other etiological factors not so connected.

The report asked that the Committee should be continued, with instructions to urge upon other societies to take up the work. Several States, among which are Illinois and Pennsylvania, have already done so.

DR. DAVIS, from the Special Committee to report Explanatory Resolutions of Certain Sections of

THE CODE OF ETHICS,

stated that the Committee had given the subject due consideration, and respectfully submitted the following brief report in the form of preamble and resolutions:

Whereas, Persistent misrepresentations have been, and still are being made concerning the provisions of the Code of Ethics of the American Medical Association, which many, even in the ranks of the profession, are led to believe—as, for instance, that the Code excludes persons from professional recognition simply because of difference of opinion on doctrines—therefore

Resolved, First, that Clause I., Article IV., of the National Code of Medical Ethics, is not to be interpreted as excluding from professional fellowship on the ground of difference in doctrine or belief, those who in other respects are entitled to be members of the regular medical profession. Neither is there any other article or clause in the said Code of Ethics that interferes with the most perfect liberty of individual opinion and practice.

Second, That it constitutes voluntary disconnection or withdrawal from the medical profession proper, to assume a title indicating to the public an exclusive or a sectarian system of practice, or to belong to an association or party antagonistic to the general medical profession.

Third, That there is no provision in the National Code of Medical Ethics in any wise inconsistent with the broadest dictates of humanity, and that the article of the Code which relates to consultations cannot be correctly interpreted as interdicting under any circumstances the rendering of professional services whenever there is pressing or immediate need of them; on the contrary, to meet promptly the emergencies of disease, of accident, and to give a helping hand without unnecessary delay is a duty fully enjoined on every member of the profession, both by the letter and the spirit of the entire Code. But no such emergencies or circumstances can make it necessary or proper to enter into formal professional consultations with those who voluntarily have disconnected themselves from the regular medical profession in the manner indicated by the preceding resolution. Adopted.

DR. DUNCAN EVE, of Tennessee, then delivered the

ADDRESS IN SURGERY.

He reviewed many points in the history of surgery from the most ancient to the present time. He dwelt upon the improvement in the treatment of fractures of the skull, cleft palate, and vesical calculi, and in the application of orthopædic apparatus. The address closed with an eloquent eulogy upon the late Dr. Gross.

THE TREASURER'S REPORT

showed a balance of $932.11, and exhibited an increase in the receipts over last year of $320. The provisions made last year for the increase of membership have added one hundred and twenty-five names to the roll.

THE COMMITTEE ON PUBLICATION

presented their report, in which they stated that they had done all in their power with the small means at their disposal. They wished to place on record their high appreciation of the services of Dr. Davis as editor. The journal is free from debt. The number of members entitled to receive it is 3050, the number of subscribers is 850, and the exchanges and advertisers require 120 more. The total number of copies published is 4200, and the probable income is not much less than $6000. The total income from dues is $21,000. The expenses are $12,000, not including the expenses of the editorial office. The Committee concluded to retain the publication at Chicago, and had unanimously requested Dr. Davis to continue as editor, which he has consented to do under certain conditions.

DR. DAVIS spoke at length of the difficulties in the way of conducting the journal, and advised the exercise of prudence and patience, with a careful husbanding of resources. He opposed increasing the annual dues, as it would have the effect of decreasing the number of members—especially of new members. He said that with application and patience in ten years the *Journal* would stand in the lead.

DR. HARVEY REED, of Ohio, moved that the Association offer

PRIZES

for the first and second best papers containing original research, presented in each Section yearly. Adopted.

DR. J. B. ROBERTS, of Philadelphia, from the Section on State Medicine, offered a resolution recommending the appointment in each State of an examining board whose certificate shall be a license to practise. Laid on the table temporarily.

The Committee appointed to consider the advisability of erecting

A MONUMENT TO BENJAMIN RUSH

in the city of Washington, recommended that such monument be erected by dollar subscriptions, and provided for the appointment of a Committee to carry out the object of the resolution.

The Nominating Committee then presented the following list of

OFFICERS FOR THE ENSUING YEAR:

President.—William Brodie, M.D., of Michigan.

Vice-Presidents.—Samuel Logan, M.D., of Louisiana; A. Y. P. Garnett, M.D., of the District of Columbia; Charles Alexander, M.D., of Wisconsin; and W. F. Peck, M.D., of Iowa.

Section of Medicine.—J. T. Whittaker, M.D., of Ohio, Chairman; B. L. Coleman, M.D., of Kentucky, Secretary.

Section of Obstetrics.—Seth C. Gordon, M.D., of Maine, Chairman; J. F. Y. Paine, M.D., of Texas, Secretary.

Section of Surgery.—N. Senn, M.D., of Wisconsin, Chairman; H. H. Mudd, M.D., of St. Louis, Secretary.

Section of Ophthalmology.—Eugene Smith, M.D., of Michigan, Chairman; J. F. Fulton, M.D., of Minnesota, Secretary.

Section of Diseases of Children.—W. D. Haggard, M.D., of Tennessee, Chairman; W. B. Lawrence, M.D., of Arkansas, Secretary.

Section of State Medicine.—J. H. Rauch, M.D., of Illinois, Chairman; F. E. Daniel, M.D., of Texas, Secretary.

Section of Oral and Dental Surgery.—J. S. Marshall, M.D., of Illinois, Chairman; A. E. Baldwin, M.D., of Illinois, Secretary.

Committee on Necrology.—J. M. Toner, M.D., of the District of Columbia, Chairman.

Judicial Council.—R. A. Kinloch, M.D., of South Carolina; D. D. Saunders, M.D., of Tennessee; T. G. Richardson, M.D., of Louisiana; C. A. Ketchum, M.D., of Alabama; George Baird, M.D., of West Virginia; J. M. Toner, M.D., of the District of Columbia; A. M. Pollock, M.D., of Pennsylvania.

Time and place of next meeting.—St. Louis, on the first Tuesday in May, 1886.

AMERICAN SURGICAL ASSOCIATION.

Sixth Annual Session held in Washington, D. C., April 21, 22, 23, 24, 1885.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, APRIL 22D.—MORNING SESSION.

IN continuation of the discussion on Dr. Roberts's paper on

THE FIELD AND LIMITATION OF THE OPERATIVE SURGERY OF THE HUMAN BRAIN,

DR. DAVID PRINCE, of Jacksonville, Ill., said that he agreed in the main with the principles of the paper. From being one of the most dangerous, trephining has become, since the introduction of antiseptic methods of treatment, one of the safest operations of surgery. He could call upon his experience with regard to the difference between the results under the old and the new methods of treatment. He had never seen serious complications as the result of the operation. With reference to the statement that the patient could go home immediately after having his head trephined, he thought the paper misleading, for there is nothing so important to an individual after a serious operation like this as rest. Even where the patient was in perfect health prior to the operation, rest for a considerable period should be enjoined.

DR. JOHN H. BRINTON, of Philadelphia, spoke with reference to the first paragraph of the paper, "The complexus of symptoms called 'compression of the brain,' is not due so much to displacing pressure exerted on the brain substance as it is to some form or degree of intracranial inflammation." Is that, he said, altogether true? Is it not calculated to carry with it some misunderstanding? I do not think that we can say that these symptoms are due, to any great extent, to intracranial inflammation. The displacing pressure is more probably the point to which we look, and to which we should address our treatment. In a case seen by him, an individual, seventeen or nineteen years of age, had received a depressed fracture of the frontal bone extending almost from one external angular process to the other. One fragment overlapped the other. With a Hey's saw, he removed a considerable portion of the protruding bone, and coaptated the edges, the bones slipping into place with a snap. All the symptoms were immediately relieved, and the patient conversed rationally with him almost before the completion of the operation. He believed in the early use of the trephine, but not because he considered it a trivial operation.

One of the previous speakers had pronounced the lateral ligature of a sinus an impossibility. This was a mistake. In a case that came under his observation, in which a child's skull had been fractured by the kick of a horse, he had succeeded in tying the lateral sinus laterally. The difficulty of the operation disappears when a large enough piece of the bone is removed to enable the operator to get rightly at the vessel. He did not think that there was much difficulty in arriving at the proper line of treatment in cases of compound fracture, whether the symptoms be mild or grave. The only cases in which there is doubt are those in which an individual is suffering from a simple depressed fracture with few or no symptoms. Such a case may to-day have no symptoms, but to-morrow, or next day, he may have acute traumatic encephalitis and die, or he may pass out from observation for a long time, and eventually suffer from epilepsy. What is the treatment? This has been well summed up by a distinguished author who was well known to the Association, when he says, in his *System of Surgery*, "Surgeons have been much divided in opinion, some favoring, others condemning operative interference. The judicious practitioner will be governed in the choice of his remedies by the circumstances of each individual case. When the fracture is of small extent, free from comminution, and without much depression, the only rational plan is not to attempt elevation, but to treat the patient upon general principles, using depletion by the lancet, leeches, and other means, with a view of preventing inflammation and other evil consequences. If, on the other hand, the bone is forced down considerably, so as to impinge very decidedly upon the brain, or if it be comminuted or jagged at the edges, the sooner it is raised or removed the better, since if it be allowed to remain it cannot fail to become a source of trouble, either by exciting inflammation, or by causing serious secondary effects. I am fully, indeed painfully, sensible of the responsibility which I incur in giving this view; but I feel satisfied, after mature consideration, aided by the light of experience, that it is the best, if not the only proper course to be pursued under the circumstances. A man laboring under such an affliction is never free from danger; he may get well, or be well to all appearance, and yet be only partially cured, subject at any moment to have his mind and life imperilled by the broken bone. It is like the sword of the tyrant suspended over the head of his subject." It seemed to Dr. Brinton that there is in that lesson but little to be added and but little to be taken away.

DR. T. A. MCGRAW, of Detroit, remarked that it had been stated that the brain will accommodate itself to a reasonable amount of pressure. That is true of children, but it is hardly so true of adults. He then reported the case of a negro painter, who fell from a scaffold, sustaining a simple fracture of the skull with smooth edges. A year elapsed before any symptoms arose; then the individual began to become giddy whenever he ascended to a scaffold, and was obliged to abandon his employment. Finally, he came to the hospital, and into the care of the speaker. The trephine

was applied, the depressed bone removed, and all the symptoms immediately disappeared. This he considered most certainly a case of simple and uncomplicated compression. He referred further to what had been said by a speaker of the day previous, that after the symptoms of inflammation have developed, operative procedure is of no value, and remarked that he must take exception to that opinion. If you have a felon, you lance it to relieve the tension, before suppuration has really occurred; the same may be done in these cases for the same purpose.

Dr. P. S. Conner, of Cincinnati, remarked that the Fellows appeared to be of one accord upon the general statements of the paper, namely, that for an open fracture of the skull, the trephine should be employed. Where we trephine in the absence of an open wound, we take away the chances for the case to become a severe one. He did not consider the operation a trivial one, however, for the apparently most trivial cases have a mortality of 10 or more per cent. But we know that the worst cases are those in which the injury produced little damage of the outer table, at the same time producing serious fracture of the inner table. Under such circumstances some individuals recover much more favorably when the damaged portion of bone is removed than if it is allowed to remain. While the laceration of the soft parts adds some danger to the case, and while it is better to have the wound remain a closed one, the danger is so little increased by converting it into an open wound that we should not hesitate in doing so, if we can do good by it.

With reference to the exploration of gunshot wounds of the cranium, he expressed surprise at the confidence of some of the speakers of yesterday. It is not a simple matter for the surgeon, and especially an inexperienced one to push probes into the skull. It is sometimes impossible to follow the course of a bullet, for we have no means of knowing what direction it will take. Besides we are told of late that the bullet, or the spicula of bone that are sent in all directions through the brain, do no harm, but that it is the entrance of germs that cause irritation. This, he considered erroneous, and that there is always danger from laceration of the brain-substance. As a rule, however, a very large amount of the vault of the cranium has to be depressed before there will be produced any symptoms of compression. It is estimated that from a twelfth to an eighth of the vault must be depressed before these symptoms will arise. In most cases we will find that other causes, as a blood-clot for instance, are making the compression. Between the ages of eight and twenty, a considerable compression can be made without danger. While all believe in prompt operations, we are all ready to wait and watch, for if too hasty operations are performed, it is clear that some cases will die that would otherwise recover.

Dr. N. P. Dandridge, of Cincinnati, reported a case that came under his observation during the late riots in Cincinnati. A German was struck on the right side of the head by a bullet, on a level with the median line and about two inches from it. He was taken at first to the hospital in an unconscious state, but was removed next day to his home, and he did not again see him until six weeks after. He then found a linear fracture without evident depression. The symptoms which were present were a paralysis of the forearm of the opposite (left) side, and a frequent twitching of the face, occurring at short intervals without unconsciousness. The man had not fully recovered his intellectual powers, but was able to take nourishment, and was improving in general condition. Following the accident there was complete unconsciousness, lasting for some hours, and at the time when he saw him again, the patient was not able to recall what had happened during the first few days after the injury.

This was a case of compound fracture of the skull over the motor area, followed by a paralysis of the muscles of the opposite side, corresponding to the centres which we have learned lie under the point of injury. Of course, the question of operative procedure at once arose. But as the case was progressing so favorably without aid, it was decided not to attempt interference. In the course of a few days, the spasm ceased entirely, and the man made a good recovery, the paralysis of the forearm entirely disappearing in the course of three or four weeks, leaving only slight numbness of the little finger which is still present after the lapse of a year. Had he seen the case at the start, he thought that he would have been inclined to apply the trephine at once and elevate the depressed bone.

With regard to the brain symptoms as a guide to the resort to operative procedure, he did not think sufficient stress had been placed upon the difference in the severity of the symptoms corresponding to the differences in severity of the injury. If we were to wait until the appearance of symptoms after fracture of the frontal bone, we would often wait until permanent damage had occurred. The question of operative procedure is to be decided, in many cases, very largely by the seat of the fracture.

Dr. B. A. Watson, of Jersey City, reported a case illustrative of the power of the brain to accommodate itself to pressure. A case was brought to him with a depressed fracture of the inferior angle of the right parietal bone, twelve hours after the receipt of the injury, still unconscious and incapable of being aroused. He was able distinctly to locate a fracture of the external table. He hesitated somewhat with regard to the procedure to be adopted, but finally determined not to interfere. The individual suffered for three weeks from acute delirium, then gradually regained his senses. Within six weeks he had so far recovered that there was left only a paresis of the side of the face and a partial aphasia. A year and a half after the receipt of the injury there was still a marked depression at the seat of the fracture, but the man was able to perform his duties as a police officer. Since this time he entirely recovered. While it is true that the brain of the child will accommodate itself to pressure, it is also true that in a great many cases the brain of the adult will, in like manner, submit to such circumstances.

Dr. W. T. Briggs, of Nashville, said that this is one of the most vexed questions in surgery, and one of the least settled, as is proved by the length of the discussion which the paper has elicited. He would only speak of one or two points that were not touched upon in the paper, and they were with reference to the character of the injury. There are two distinct classes of fractures of the cranium. The first is a diffused fracture, as where an individual falls from a height, or has a large body

strike his head. In these cases the injury does not stop at the cranium, but involves the brain, and in these cases the trephine is not to be employed. It cannot benefit the injury to the brain. In another class of cases the fracture is not so extensive, and in those cases the trephine is called for where there is a circumscribed injury of the bone, and where it is confined to that structure. For the simple symptom of compression due to depressed bone, except in rare instances the trephine is unnecessary. Most symptoms are dependent upon disturbances of circulation or molecular changes. The symptoms of compression and of inflammation he considered very similar. Where the depressed bone is broad the symptoms will pass off, and there is no need for the trephine; but where the fragment is acuminated, we do not meet with symptoms of compression from the depression of bone. Where compression manifests itself in such cases, it is generally due to some other condition. In many of the cases it is due to an accumulation of blood, and where blood is thus poured out, there is danger that, by the continual accumulation of blood, the compression will be kept up until death occurs.

Where the compression is due to the formation of pus, we should follow the rule for such conditions in other parts of the body, namely, to evacuate the pus. But the chief, and in fact the only use of the trephine, is for the removal of points of irritation produced by depressed fragments or spicula of bone which are pressing upon the membranes and depressing the brain. We may and we may not have signs of compression in these cases. These symptoms may pass off in a short time, to be followed by other symptoms—symptoms of irritation of the brain, indicative of the commencement of inflammation. The patient then lies upon one side, with his arms and legs drawn up, and there is a twitching of the face. He is semi-comatose, but can be aroused by calling his name. Where there are symptoms of compression of the brain, it is the imperative duty of the surgeon to resort to operative procedure and to apply the trephine at the earliest possible moment. It is then only useful for preventing those changes which cannot be cured. He had for the most part made a mistake in comparing open fractures of the skull with open fractures of other bones, and the question that had been asked—Who would think of converting a simple fracture of one of the long bones into a compound fracture?—had no bearing upon the question under discussion. There is an anatomical difference between the cranial bones and the other bones, both in their structure and in their surroundings. It had been his practice to cut down upon a fracture of the skull and make a free opening, in all cases of doubt. This gave to the surgeon a feeling of relief in the consciousness that he knew the actual condition of the case.

As for the operation of trephining, there was no danger in the mere removal of a button of bone, so long as care was taken not to injure the tissues beneath. But he thought that exploratory perforations of the cranium should be done very guardedly, and he would not resort to it unless symptoms were present indicating at least the possibility of more serious damage to the internal table than to the external. With regard to the operation of ligating the vessels of the skull, he had never experienced any difficulty in arresting the hemorrhage by pressure.

Dr. Roberts, in closing the discussion, remarked that the views that had been expressed, although critical, had tended rather to strengthen than to overthrow his faith in the propositions he had stated, the truth of which he thought would be more generally accepted five years from now than at the present time.

A distinction must be made between the term compression and pressure. The brain is a jelly-like mass, filling up an oval cavity and a long tube. It is so surrounded by fluid that compression is almost an impossibility. Pressure upon it, unless of extraordinary severity, will not compress it. It has been urged in opposition to the statement in the first proposition, that symptoms come on too rapidly to be due to compression. This is not an evidence that the brain has been compressed; neither is it an evidence that there has not been developed an inflammation. If a man runs his finger into his eye, he does not develop compression, but within a very few seconds there are symptoms of irritation and inflammation. The symptoms that are usually attributed to compression are, as a rule, due either to shock, laceration, contusion, or that obscure symptom called concussion, which he did not believe in as a functional disease. It should be called multiple or comminuted laceration. The nerves of the brain, branches for the most part of the trigeminal nerve, are usually lacerated in these cases, and may have something to do with the symptoms which so quickly develop, and which are due to rapid inflammation; and it is not at all impossible for inflammation to arise before the surgeon has arrived. If the brain were a hard ball enclosed in the skull, there would be no such thing as intravenous hemorrhage of any consequence.

He did not intend to convey the idea that open wounds were to be preferred to closed ones. On the contrary, he thought it wise to permit the wound to remain closed, if possible; but he would prefer in all cases an open wound to a closed one, with obscurity as to the damage with which he was dealing.

The statistics of Amidon had been criticised by a former speaker. Admitting that that author had been incorrect in fifty per cent. of his cases, and dividing his statistics by two, the statement of his paper was still correct, namely, that the operation of trephining is but little more dangerous than that of amputation through the metacarpal bone.

With regard to probing and drainage, he said that we owe to Dr. Fleurer more than to any man who has written lately for his remarkable success in these respects. The method of that surgeon was then described. The probe that is used for exploration of the brain should be very light and should be armed with a large olive-shaped tip, so that it cannot do injury to the brain. It should then be allowed to drop into the track of the ball by its own weight without any force from the hand of the operator. Dr. Fleurer has had a probe made of aluminium, in order to secure lightness.

Referring to the case reported by Dr. Prewitt, he said that the reason for there not being disturbances of sensation in the case in which so large an amount of brain matter was removed from the parietal region, was that the point of injury was in the posterior portion of the

parietal bone, and not in the anterior, where the centre of sensation is situated.

He then reported the case of a child in which there was a fracture of the parietal bone of so great extent that pressure over the seat of fracture caused blood and air to escape from the ear. It was a case that would have been considered one of fracture of the petrous portion. He trephined, removed the fragments, and the child recovered.

In conclusion, he called attention to the fact that he had not said that the trephine should be applied in all classes of cases but two. In two classes of conditions, he had said that the trephine should not be employed under any circumstances; in two, that it should possibly be used; in two, that it should probably be used, and in another, that it should always be used.

Dr. S. W. Gross, of Philadelphia, then read a paper on

NEPHRECTOMY: ITS INDICATIONS AND CONTRAINDICATIONS.

The information for his paper he had collected from a large number of sources; from the authorities who had written on the subject and from correspondence with a large number of eminent men at home and abroad. He was inclined to think that the operation was made more frequently than is proper, and he had endeavored to define as accurately as can now be done the cases in which it should and those in which it should not be performed. He also considered it in connection with the operations of nephrolithotomy, nephrotomy, and nephrorrhaphy.

The paper will appear in full in *The American Journal of the Medical Sciences* for July.

Dr. L. McLane Tiffany, of Baltimore, then read a paper on

NEPHROLITHOTOMY.

It was based upon the report of a case in which the author had successfully removed a calculus weighing 556 grains from the pelvis of the right kidney after the subject had suffered from symptoms for a period of six years. After reviewing the several steps of the operation and the methods employed, he entered into a discussion of the etiology of the affection, the symptoms and the various modes of treatment, together with a review of the statistics of operations. In discussing the symptomatology, considerable stress was laid upon the character of the pain, and the statistics of a large number of cases were reviewed with reference to this and other symptoms. This paper will appear in full in an early issue of The Medical News.

Dr. S. W. Gross congratulated Dr. Tiffany upon the successful termination of his case, the more particularly because he had removed from an otherwise healthy kidney the largest calculus that has as yet been recorded, the only one approaching it being the concretion, weighing nearly one ounce, excised by Mr. Bennett May.

As Dr. Tiffany has stated, the operation is a comparatively safe one. Thus, of 21 cases that Dr. Gross had collated, 2, or 9.52 per cent., died—the patient of Cullingworth from the blocking of the opposite ureter by a stone, and that of Mr. Pepper, as he writes me, from the effects of morphia. In Mr. Thornton's 3 cases, the operation was by the combined lumbar and ventral incision, while the remainder were by the lumbar incision. In the cases of Butlin, Anderson, and Cullingworth, the stone was removed through an incision in the pelvis of the kidney.

He also agreed with the author of the paper in regarding the diagnosis of renal calculus as being far from easy. Intermittent attacks of renal colic, with tenderness on pressure, the presence of blood, and, it may be, of a little pus, in the urine, with frequency of micturition, are, in the absence of vesical and prostatic lesions, the best diagnostic signs; but they may be present in cases of highly acid urine, and in the early stage of tubercular kidney. The group of symptoms which he had just mentioned being present, the surgeon is certainly warranted, after the failure of ordinary remedies to relieve them, in cutting down upon the kidney through the loin, with the view to its exploration with the fingers, a needle, and, if needed, by an incision of the kidney substance itself, through which the finger can be carried into the calices and pelvis of the organ.

And this brought him to the third conclusion, that incision down to and exploration of the kidney are eminently proper, in which he entirely agreed with Dr. Tiffany. Thus, of 22 exploratory operations which he had collated, all recovered, and the organ was incised in 3. Should incision in every case of failure of the ordinary methods of exploration to detect a stone be the practice of the future, the risks will doubtless be added to; but he believed that Mr. Morris is right in recommending its adoption. It certainly should be resorted to before the kidney is sacrificed by extirpation.

Dr. J. W. S. Gouley, of New York, called attention to the report of a somewhat similar case that was read at the first meeting of the New York State Medical Association. In his opinion, a great deal of good was done by crushing the stone before an attempt was made at its removal, as had been done in both these cases. In the case just reported the stone was made up chiefly of the phosphate of lime. This he considered an important point, as throwing light upon the remarks that were made at the last meeting of the Association, when it was stated, in contradiction of his views, that a stone found in the prostatic portion of the urethra, and consisting chiefly of the phosphate of lime must of necessity have had its origin in the prostate. This he thought proved his former statement, that any inflamed mucous membrane would lead to the formation of such a calculus. He also considered the incision through the outer edge of the kidney preferable to the incision through the pelvis, as being less liable to result in permanent fistula. A free incision should also be made.

Dr. T. A. McGraw, of Detroit, remarked that calculi are rare in the State of Michigan, but for that reason he could give one or two suggestions as to their pathology when they do occur. The stones are almost invariably the result of obstruction, coming chiefly from a stricture of the urethra or an injury of the prostate. While stones are rare, there are a good many cases of renal abscess in the State, and he had observed that in these cases, where the ureters remained impervious, there were found no small calculi, but where the ureter has become thickened so as to cause an obstruction to the flow of urine, calculi are apt to be met with.

Dr. P. S. Conner remarked that we are much en-

couraged in resorting to operative procedure in serious cases by the happy result that has been reported for these cases. We are encouraged to cut down upon these kidneys, knowing that if we find a stone we will relieve the kidney of its trouble, and that if we do not find a stone we will do no injury to the patient.

Dr. T. F. Prewitt, of St. Louis, asked for more definite statements in regard to the comparative advisability of cutting through the kidney substance and the pelvis.

Dr. Tiffany stated that all the cases with which he was acquainted, including that reported in the volume of the New York Medical Association's Transactions, which, however, he did not think properly came under this head, where the incision was made through the substance of the kidney, had recovered. As far as his own views were concerned, he would prefer that method of operation. He thought further, that the part of the kidney that was exposed by the incision was the proper place to incise the gland, without attempting to get at the posterior part. In his operations, he had opened the abdomen by means of Langenbeck's incision and cut through the kidney at the point where it brought him upon it.

Dr. Gouley still maintained that the case to which he had called attention should be classed in the same category as the case reported by Dr. Tiffany, for if we eliminate all cases in which there is something in the pelvis of the kidney besides the calculus, there will remain no such cases as pure nephrolithiasis, and carrying the point a little further, there is no such thing as a case of pure vesical calculus.

Dr. Gross stated that there is no cause to fear hemorrhage from an incision of the kidney-structure, for the flow of blood can readily be arrested by the application of pressure with a sponge for half a minute. With regard to the point of the kidney that should be incised, he thought that we should enter at the spot which is the most accessible, whether that be the pelvis or the cortex. He further called attention to the difference between the operation for calculus and that for calculous pyonephrosis, or calculous hydronephrosis.

The Association then adjourned.

The afternoon was devoted to a visit to the Johns Hopkins University and Hospital, in Baltimore.

Thursday, April 23d.

Morning Session.

Dr. J. Collins Warren, of Boston, presented a communication on

the healing of arteries after ligature.

He apologized for the presentation of a paper upon a subject that had been discussed by the Association so recently as last year, by the statement that it was a subject to which he had for several years given especial attention.

After reviewing briefly the history of the subject, and referring to the investigations that have been made by numerous authorities, ancient and modern, he remarked that the investigators who have interested themselves in the process of repair in arteries, have considered the question usually from some special standpoint, such as "the organization of the thrombus," "the part played by the white corpuscles," "the endothelium," etc. The object of this paper was, however, to study the various pathological changes which occur in and around the vessel during the entire process of cicatrization. These changes may be compared not inaptly to those which occur in the repair of fractures of long bones. In both we find an external and an internal callus, the former having only a provisional existence in the case of arteries, the latter undergoing certain changes through which the lumen of the vessel is, though imperfectly, reëstablished by the so-called "canalization" of the thrombus. In the meantime, the walls of the vessel are undergoing changes which enable them to participate in the final process of repair.

Where a large artery is tied in its continuity, the intima and a portion of the media are usually ruptured, and the adventitia is gathered into a dense pseudo-tendinous sheath around the constricted ends. The first noticeable change is the formation of the thrombi, and the development of a granulation-like mass of cells about the ligature, which, if it has been cut short, is completely enveloped by it. This is a true connective-tissue growth, and covers the end of the vessel just as the granulations cover the surface of a wound. We find further, that this tissue extends some distance up and down the sides of the divided vessel in the peri-adventitial tissue, the round cells of which it is composed invading only the superficial layers of the adventitia. At first, the cells do not penetrate at the point of ligature where the fibres are densely packed, but they follow the ligature as it cuts through, and appears to exert a solvent action on the resisting fibres of the adventitia. In case a double ligature has been placed upon a vessel, the granulation cells enter the isolated central portion at the retracted ends, and not directly through the walls, as some investigators have supposed, and gradually disintegrate the various coats, invading them eventually from every point. The process is, however, a slow one.

Advanced changes are seen in the proximal thrombus as early as the fourth day. By the fifteenth day, the new tissue has become very abundant, and has the appearance of granulations growing into and replacing the thrombus. By the end of a month only fragments of the thrombus remain, and the granulations presented themselves to the lumen of the vessel. The walls of the vessel are, during this time, undergoing certain changes. The cells of the intima unquestionably proliferate. This proliferation can be studied in specimens in which the distal thrombus is small, and in the space between two ligatures; the amount of this tissue developed is, however, sufficient to supply but a small part of the internal callus. The part taken by the endothelium appears to be one which furnishes a new endothelial covering to the cicatricial tissue, and a lining to the new vessels that have been formed. At an early stage of the process, cells are seen springing from the muscular layers and projecting into the thrombus. Later, elongated spindle-cells with stellate nuclei become apparent. These are sometimes single, sometimes in bundles, and were, he believed, a new growth of muscular tissue. At the point of ligature, the elastic lamina appears frayed out, and is seen extending in various directions through the new tissue; the media begins by the end of the second week to retract, as does

also the adventitia, leaving a space through which vessels eventually find their way, and communicate with those coming down from the lumen. At the end of three months, the cicatricial process is complete and only a cicatrix remains.

He called attention to the remarkable infrequence of aneurismal dilatations after ligation, and gave in explanation thereof this development of a tissue so closely resembling the three layers of the vessel wall, and having all the powers of resistance which they possess. In the larger vessels of the human subject, where there is less muscular and more elastic tissue, the new muscular tissue is not so apparent, but the connective tissue is greatly increased in quantity and extends for a long distance into the lumen of the vessel. In the specimen of the ligatured carotid artery of a horse, this amounted to about four inches.

Dr. N. Senn, of Milwaukee, expressed gratification at the beautiful specimens presented by Dr. Warren, as well as for the demonstration which he had given, but especially for the view he had expressed regarding the part taken by the muscular fibres in the formation of the cicatrix. He took exception, however, to the manner in which the experiments had been made, because traumatisms of the vessel walls had occurred in almost every instance, and because antiseptic precautions had not been carefully employed. All that is necessary for the definitive closure of a vessel is simply to approximate the surfaces of the intima without causing rupture of any of the tunics. In the first illustration exhibited by the author, both intima and media had been ruptured. It was, in his opinion, on account of this rupture that embryonic corpuscles were found in the vessel. Such rupture, he further thought, was not only unnecessary, but positively harmful. The behavior of the tunics depends upon the character and material of the ligature used, and upon the intensity of the inflammation which results after the application of the ligature. The amount of callus that is produced corresponds closely to the amount of inflammation that is developed. In his own experiments he had observed that in cases where his antiseptic precautions failed, an enormous amount of callus was developed; and although he had not, in any of his experiments, met with secondary hemorrhage, the fact is patent that such an accident may take place at any time, regardless of the amount of callus, provided suppuration has occurred.

When the ligation is performed with the "temporary ligature" (catgut), it is unnecessary to cause division or absorption of any of the tunics of the vessel. After contact of the vessel walls for a period of from seven to twenty days, union occurs and the callus is removed without the division of the tunics. Such, however, is not the case when a permanent ligature is applied. The ideal ligature is one which, being applied, keeps the parts in contact until the definitive closure of the vessel has occurred, and which is then capable of being absorbed. He expressed pleasure at the comparison made between the conduct of a vessel after ligature and that of a bone after fracture. He would, however, carry it a little further and remark that the proper treatment of a fracture of bone is to hold the fragments in contact in such a manner as to insure as small an amount of callus as possible. Callus is only necessary for the purpose of establishing the continuity of bone. In a fracture in which the fragments are not in apposition, or for some reason are not kept in apposition, there is always an abundance of callus. We should endeavor also after ligature to obtain a minimum amount of callus, for if we succeed in obtaining primary union, there is no need of the callus.

The idea of the development of a muscular cicatrix is a new one, which, he hoped, future observation would prove correct; although it was evidently contrary to analogy. We all know that repair of muscle after rupture or division takes place not by the growth of new muscular fibres, but by a cicatricial formation developing from the connective tissue substance lying between the muscular fibres. He had further observed that after muscles were wounded, the fibres invariably underwent fatty degeneration. Finally, he considered the rarity of the occurrence of aneurism after ligature, due to the development of so large an amount of connective tissue, rather than to any growth of new muscular tissue.

Dr. Moses Gunn, of Chicago, in referring to what had been said about ligating vessels without rupturing their coats, said that he had for several years carried in his mind a plan by which he thought that, if called upon, he could so apply a ligature to the innominate artery as to secure its closure. The contribution of Dr. Senn, a year ago, had, however, caused him to alter his method. If it is not necessary to wound the tunics of the vessel, he thought that if he were called upon to ligate that vessel he would do so by the method of double ligature referred to by Dr. Senn. Passing one ligature around the innominate and securing it, he would place a second ligature upon the subclavian and a third upon the carotid, and after having forced all the blood out of the intervening portion of the vessel, draw them down with sufficient firmness to approximate the walls of the vessel. With regard to Dr. Warren's theory of the action of the muscular fibres he could express no opinion, but he felt sure that, whatever the method adopted, it is of the utmost importance to secure union as rapidly as possible in order to have the whole strength of the vessel to aid in resisting the pressure of the blood.

Dr. Warren agreed with Dr. Senn with regard to his statement that the amount of inflammatory action corresponded in these cases to the extent of the traumatism. He had sometimes found it difficult to discover external callus, but even in cases where the strictest antiseptic precautions had been employed, as in the experiments of Mr. Lister himself, there was observed "a ring of new tissue" which was in reality the external callus. He further stated that when he at first began his experiments, he had been inclined to adopt the theory of Dr. Senn, namely, that there was no necessity for a trauma, but that he had later concluded that the view was incorrect. He had observed what he had believed a primary union between the internal coats of the vessel, but upon closer observation of the process about the beginning of the second week, he discovered that a slow process of absorption was taking place within the substance of the vessel-wall, and that this absorption was followed later by a growth of granulation tissue. He expressed full aquiescence in the theory of Rindfleisch, that so long as the intima of a bloodvessel remains intact the blood will not coagulate no matter how slow the current be, or even if the blood come to a

stand; but when once this coat is injured in the slightest degree, coagulation rapidly ensues, and a thrombus is produced.

With reference to his theory of the new growth of muscular fibres, he asked attention to the fact that there is a decided difference between the behavior of striped and unstriped muscular fibres, and that while a new development of striped muscular fibres would be an anomaly, such was not the case with the unstriped variety. Whenever we have repair of any kind going on in the body, we have new bloodvessels with muscular walls developed; new muscular fibres develop in the gravid uterus, as well as in every variety of myomatous tumor.

Dr. T. F. Prewitt remarked that Dr. Senn, in his paper of last year, ascribed no importance to the clot which forms within the ligated vessel, and that Dr. Warren had expressed himself as favoring as slight a formation of clot as was possible. He, therefore, asked what value, if any, was to be placed upon it.

Dr. Warren replied that so far as the histological process is concerned, the clot was of no importance at all, but that he considered it of great value in the prevention of secondary hemorrhage. In small vessels, its value is small in ratio, but in large vessels, where the pressure is great, its value is great. It is the first stage of a protective callus.

Dr. E M. Moore, of Rochester, inquired whether Mr. Lister had not been quoted in the Association as saying that a catgut ligature might become organized. An affirmative reply being received, he stated that when Mr. Lister's attention was called to the report of his having made the statement (as published in the Society reports), he pronounced it an error, and ridiculed the idea of a catgut ligature being converted into humanity.

Dr. J. W. S. Gouley, of New York, next read a paper entitled

SOME POINTS IN THE SURGERY OF THE HYPERTROPHIED PROSTATE.

Since the time of Sir Everard Home, our knowledge of the pathology and surgery of the prostate gland has come from the single source of M. Mercier, of Paris. His writings require careful study. Little has been added to the principles which he has inculcated, and many of his procedures are new. He has stated that fifty per cent. of all men above the age of fifty years are afflicted with more or less hypertrophy of the prostate, although only seven per cent. of these suffer any marked signs of the disease. The points to which he desired to direct particular attention with reference to this condition were the physical exploration, and the medicinal and surgical treatment of it.

Physical exploration. Digital examination per rectum will give some idea of the size and consistency of the prostate; whether one lobe is larger than the other; if it is nodulated or smooth; and whether it is of normal length or there is longitudinal increase. Very frequently a considerable enlargement of this gland will escape observation if the examination is confined to this method. Other methods of examination are, therefore, required before a diagnosis is arrived at. The next step in the examination of a case is to ask the patient to urinate in the standing posture. If he is able to urinate spontaneously, some idea of the condition of the prostate may be arrived at from the character of the stream. But it is always to be remembered that a man with a constricted urethra voids his urine in precisely the same manner as a man with an enlarged prostate. The stream flows steadily for a time, then stops, a few drops escape, the stream again flows, then a few drops, then a dribble, and so on. After the individual has discharged all the urine he is able to void spontaneously, a soft catheter is introduced, and the residual urine drawn off, measured, and examined chemically and microscopically. It may be clear, but is generally cloudy. The physical examination is further carried out by the use of certain rectangular sounds of a peculiar size and shape. Most of these instruments are of no value. To Dr. Mercier belongs the credit of having invented a small rectangular sound, which is of the greatest value. Its chief advantages are in the extreme shortness of its beak, being only seven-eighths of an inch in length. He then described minutely the method of using these sounds. Not only the size, but the exact form of the enlargement of this gland could in many instances be outlined, but for this purpose he had devised an instrument having two bars and possessing many superior qualities, all of which were detailed. Some further remarks were made as to the various conditions that were likely to be found in hypertrophy of the prostate.

He then passed to the consideration of the medicinal treatment. Although the idea of reducing the hypertrophied gland by purely medicinal means had been exploded long ago, it was constantly being revived in the hope that an infallible remedy had been discovered. Among the fashionable remedies at the present time, are mineral waters, and while he did not wish to condemn their use, he regretted that they too often led to the neglect of other more valuable methods. Remedies can also often be employed for the relief of concomitant symptoms and to the improvement of the general health of the individual.

The consideration of the surgical treatment was subdivided into two distinct parts: first, mechanical means of relief; and, second, the removal of the organ by surgical means. All hard catheters should be discarded except in cases of false routes. The method of using several curved, hard, and soft catheters, including the elbowed and the double-elbowed instruments of Mercier, were described. Among other requirements for a soft catheter was that it should have as small and as smooth an eye as possible, and never two eyes. Small catheters are usually preferred, but too small an instrument should never be used. Where false routes exist, a large catheter should be employed, and where this fails, the invaginated catheter of Mercier is usually successful, but it requires to be used with the greatest care and caution, for unless the surgeon keeps the male portion of the instrument under perfect control, it may do injury.

Evacuatory catheterization should be commenced early in the history of each case, but in old cases, where the bladder has become distended, it is of the greatest importance that all the urine be not removed at one time. The catheter should be used as often as from twice to five or six times daily. If the catheter be too freely used, many of the alarming symptoms are

relieved and the individual appears to be in a much better condition than before, but at the expiration of a few days the individual begins to show symptoms of disease of the kidneys, which rapidly increasing in severity, lead to his death at the expiration of a month or six weeks.

In some of these cases there is great difficulty to determine the proper course of treatment. Without the use of the catheter the individual must succumb; it use is unsafe. Under such circumstances, he advised the withdrawal of but a small part of the residual urine at intervals of once in several days, until tolerance was established. In one case that had come under his observation, the enlarged bladder, extending above the umbilicus, was mistaken for a hydatid cyst and tapped. After its true nature was discovered, the method of small and infrequent catheterization was adopted, with the effect of producing a toleration. Polyuria is, however, very apt to develop and carry off the patient, as the author had seen in several instances.

Another method upon which he laid great stress was the injection of medicated fluids into the bladder in a quantity to correspond to the amount of urine removed. For this means a solution of borax was most employed, but various other agents might be used, as when the urine was strongly alkaline, an acid might be added; when large accumulations of mucus and pus were present alkalies were indicated; and when phosphates were deposited in the cavity of the bladder, he recommended the use of weak solutions of acetate of potash. The use of carbolic acid he did not endorse, but considered the nitrate of silver, in properly diluted solutions, one of the most valuable agents we possess. Morphia, hyoscyamus, or cocaine, may be added in cases of great vesical irritability. Finally, hot and cold water have had their advocates.

Removal of the gland. This operation was first performed by means of incisions by John Hunter. Caustics have been employed; Dr. Physick, of Philadelphia, dilated the neck of the bladder; others have made compression with a metallic sound. Attempts have been made to ligate the tumor and some have tried to grasp it and tear it away with Jackson's lithotrite. Mercier devised an instrument for the removal of the prostate as early as 1838, and since then he has made three modifications, one for incising, and two for excising the tumor. As the inventor had not given any special name to either of these instruments, the author had taken the liberty of calling them respectively, prostatitome and prostatectatome; naming the operations prostatotomy and prostatectomy.

Dr. S. W. Gross, of Philadelphia, considered the remarks which had been made especially proper in their application to the treatment of patients after they have entered upon their "catheter life." He also endorsed the remarks upon the propriety of prostatotomy.

There can be no doubt, he continued, that the operative treatment of enlargement of the median portion of the prostate, giving rise to obstruction of the vesical orifice of the urethra, is capable of great advances. Up to the present date he regarded prostatotomy, as practised by Mr. Reginald Harrison, as fulfilling the indication more surely and with less risk to the patient, than any operation that has been devised. In the case of an old man, that surgeon opened the membranous urethra through the perineum. The obstruction was then divided, partly with a probe-pointed knife and partly by divulsion with the finger, and the edges kept apart for eight weeks by means of a large tube, through which a smaller tube was passed to conduct off the urine. The patient was able to go about in ten days. On the withdrawal of the tube, a large bougie was passed regularly until the perineal wound closed. The results of this operation were that all obstacle to normal micturition was overcome, the urine was passed every few hours, and the bladder was completely emptied. At the end of six months the patient had a paralytic seizure, but there was no necessity for a resort to the catheter.

The case was a most unfavorable one for operation, but the result was most brilliant. Through the small perineal wound the nature of the obstruction was accurately determined, and the incision was made with a degree of accuracy and safety which cannot be attained with Mercier's cutting instrument passed through the urethra.

In the *Gazzetta degli Ospitali*, for February 11, 1885, he found that Professor Bottini, of Pavia, has successfully operated on a similar case with the thermo-cautery applied to the median portion for forty-five seconds. A catheter was retained in the bladder for four days, when it was removed, and the bladder emptied every six hours. The first natural emission of urine took place on the twenty-fourth day. At the expiration of three months, micturition was normal, and the urine was clear and acid. At the end of three months and a half more, the patient was fully restored to robust health. As in the operation of Mercier, there is no certainty in operation through the urethra with the thermo-cautery; and when we consider the great tendency of cicatricial tissue after burns to undergo undue contraction, it is a matter of grave doubt whether the improvement will be permanent. Hence, he believed that the operation of Harrison is the better one, and one that is entitled to extended trial.

Dr. E. M. Moore agreed with Dr. Gouley that the greatest element of danger in the cases is the complete evacuation of the bladder. He thought the introduction of injections of borax, boric acid, etc., a measure that would prove of much service. He further stated that a case incorporated in the paper just read, in which, as an effect of a rapidly developed polyuria, twenty-seven pints of urine were withdrawn from a bladder in twenty-seven consecutive hours, was a case treated by himself. He stated further that he had obtained beneficial results from moral treatment, teaching the patient to overcome the desire to micturate until he could retain his urine for four hours at a time. Where the catheter could be tolerated, he preferred to use it only after the individual had evacuated as much urine as possible spontaneously; then introduce the instrument and withdraw the residual urine.

Dr. Gunn remarked that he had employed the method of moral treatment with benefit for at least five years.

Dr. Gouley, in closing the discussion, claimed priority for the operation of excision of the prostate, and stated that, in some instances, due credit had not been given him, although Dr. Mercier had put it on record as his operation.

Afternoon Session.

Dr. Harold C. Ernst, of Boston, made some remarks on

CULTURE EXPERIMENTS ON THE GROWTH OF THE MICROÖRGANISMS OF DISEASE.

Most of the work in this field, he stated, has been done by Rosenbach, who has demonstrated that there are several forms of microörganisms which are invisible with the use of the older methods of staining. The discovery by Koch of the method of culture by dry culture-media has enabled Rosenbach and others to cultivate and render visible many of these otherwise invisible forms. As a specimen of work which he himself had done, he exhibited cultivations from a perinephritic abscess in which two forms of micrococci were observed, one white, the other yellow (arias and albus); one of erysipelas ten days old; and one from a tumor of the leg. In the latter specimen he had found a micrococcus which differed from any that he had seen described, in that the cultivation was of a different color. To it he had given the name sepiacoccus, but did not hold to the correctness of the term, inasmuch as the color was not a pure sepia. In his cultivations, the pus from whatever source was transferred to a sterilized fluid with all the precautions possible. The culture-media which he had found best suited to all purposes was the fleisch-peptone agar-agar of the Germans. The methods of culture upon this and other media were then briefly described. He closed his remarks with a description of the difference between the comma-bacillus of cholera, as described by Koch, and that of cholera-morbus, chiefly in its behavior upon the gelatine culture-fluid, the former liquefying the gelatine to a greater depth in the same length of time than the latter.

In conclusion, he invited the members to examine some microscopic preparations of various germs in an adjoining room.

Dr. Warren remarked that the methods of Rosenbach promised us an easy and sure method of diagnosis in many obscure surgical cases. He further narrated several cases in which culture tests in the hands of Dr. Ernst had been of considerable value to him. In one instance to which Dr. Ernst had made casual reference, a tumor of the knee was incised, a small portion of the fluid or juice removed, and a cultivation of it made. The colony resulting was of a peculiar citron color, not described in the book of Rosenbach. The tumor was removed, and microscopic examination of it revealed the fact that it was an epithelioma. He did not, however, go so far as to claim that he had found the germ of that disease. He stated that he has been in the habit of late of using sterilized cotton as a dressing of all wounds, and considered it better than ordinary applications. A temperature of 150° C. had been found sufficient to sterilize several pounds of cotton in an hour.

Dr. Ernst stated that he had not intended to claim any originality for his studies, but merely to show that when carried out according to the directions given by Rosenbach, the result of such investigations proved as described in the work of that author.

Dr. N. Senn, of Milwaukee, then read a paper entitled

AN EXPERIMENTAL AND CLINICAL STUDY OF AIR EMBOLISM.

As indicated by the title, it was based both upon a thorough review of the literature of the subject and a large number of original experiments. In some instances as many as forty experiments were reported in proof or disproof of a single statement. The treatise was divided into eleven chapters, from each of which were drawn a number of practical suggestions. The titles of these respective chapters were:

I. Introduction, in which the subject is considered in a general manner as regards its application to surgery, and to some extent the causes and manner of its production. The term air embolism was defined, "The pressure of free atmosphere within the vascular system during life and in sufficient quantity to give rise to symptoms of obstruction."

II. The history of air embolism.

III. The intravenous production of air. With regard to this phenomenon, he expressed the belief that it is of very rare occurrence, and that inasmuch as nearly all cases in which air has been found in the vessels post-mortem, were cases in which death had occurred as a result of hemorrhage, the air had been aspired into the open mouths of the bleeding vessels. In cases in which no wound on vessels can be found, however, he thought it possible that the bubbles were a gaseous substance produced from decomposition of the blood, although it had not been found in sufficient quantity for the determination of its chemical constituents.

IV. Effect of the heart and respiration on the venous circulation.

V. Aspiration of air into the superior longitudinal sinus. This was considered chiefly with regard to its importance as a complication of operative procedures about the head. The author also considered the views of various writers in regard to its production. A number of experiments were reported, and from them a list of practical suggestions was adduced.

VI. The immediate cause of death after intravenous insufflation of air.

VII. Intra-arterial insufflation of air.

VIII. The clinical study of air embolism. In this section was considered the various symptoms that result from the entrance of air into the principal vessels of the body, together with the comparative fatality of each.

IX. Experiments on venous air embolism. These experiments were made for the most part upon dogs, and demonstrated, in the opinion of the author, not only the innocence of the operation of aspirating the heart, but that it is absolutely indicated as a therapeutic method in cases of the introduction of air.

X. Prophylactic treatment of air embolism. The chief of these methods are position, compression, ligature, and the aseptic tampon.

XI. The operative treatment of air embolism.

In conclusion, he submitted the following résumé:

1. The presence of adventitious air in the vascular system during life gives rise to air embolism.

2. Each air embolus constitutes a mechanical source of partial or complete obstruction to the flow of blood in the vessel in which it is located.

3. Aspiration during the inspiratory movements of the chest is the direct or exciting cause of ingress of air into a wounded vein or sinus.

4. Elevation of the head is the sole predisposing cause of the entrance of air in wounds of the superior longitudinal sinus.

5. In veins, the predisposing causes consist in

(*a*) Elevation of the part wounded; (*b*) Pathological or anatomical conditions which prevent collapse of the vein when it is wounded.

6. Insufflation of a fatal quantity of air into a vein produces death by:

(*a*) Mechanical over-distention of the right ventricle of the heart, and paralysis in the diastole; (*b*) Asphyxia from obstruction to the pulmonary circulation consequent upon embolism of the pulmonary artery.

7. Insufflation of the same quantity of air into arteries is less dangerous than when introduced into veins. When death is produced in this manner it results from:

(*a*) Acute cerebral ischæmia; (*b*) Secondary venous air embolism; (*c*) Intense collateral engorgement of the vessels of the brain and spinal cord, the manner of death being determined by the amount of air injected, and the direction in which the injection is thrown, as well as the time which has elapsed between the operation and the fatal termination.

8. Air injected into arteries is readily forced through the systemic capillaries into the venous circulation and right side of the heart by the powerful contraction of the left ventricle.

9. Air embolism of the pulmonary artery is relieved in a comparatively short time, provided the contractions of the right ventricle continue unimpaired for a sufficient length of time to force the air through the pulmonary capillaries into the general circulation.

10. The prophylactic treatment consists in proximal or double compression, or ligation, of the vein which is endangered by the operation.

11. The indirect treatment has for its objects:

(*a*) The prevention of the admission of air; (*b*) The administration by inhalation or hypodermatic injection of cardiac stimulants; (*c*) Venesection.

12. The direct or operative treatment by:

(*a*) Puncture and aspiration of the right ventricle; (*b*) Catheterization and aspiration of the right auricle, which is proposed with a view to obviate the direct cause of death by the removal of air and spumous blood, thus relieving directly the over-distention of the right ventricle, and, at the same time, to guard against a fatal embolism of the pulmonary artery.

13. The results obtained by experiments upon animals warrant the adoption of the operative treatment of air embolism in practice, as a last resort, in all cases where the indirect treatment has proved inadequate to meet the urgent indications.

In Executive Session the following surgeons were

ELECTED TO FELLOWSHIP:

J. Edwin Michael, A.M., M.D, Professor of Anatomy and Clininal Surgery in the University of Maryland; Roswell Park, M.D., Professor of Surgery in the University of Buffalo; W. H. Carmalt. M.D., Professor of Surgery, Medical Department Yale College, and Surgeon to New Haven Hospital; J. Ford Thompson, M.D., Professor of Surgery, Columbia Medical College, Washington; Theodore R. Varick, M.D., of Jersey City.

HONORARY FELLOWS:

Sir James Paget, Bart., Mr. John Eric Erichsen, Sir Joseph Lister, of London; Thomas Annandale, Regius Professor of Clinical Surgery in the University of Edinburgh; Prof. Esmarch, of Kiel; Prof. Von Langenbeck, of Berlin; Prof. Volkmann, of Halle; Prof. Czerny, of Heidelberg; Prof. Billroth, of Vienna; Prof. Nussbaum, of Munich; Prof. Verneuil, of Paris; Prof. Ollier, of Lyons.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Moses Gunn, of Chicago.

Vice-Presidents.—Drs. Christopher Johnston, of Baltimore; Thomas P. Russel, of Oshkosh, Wisconsin.

Secretary.—Dr. J. R. Weist, of Richmond, Indiana.

Recorder.—Dr. J. Ewing Mears, of Philadelphia.

Treasurer.—Dr. John H. Brinton, of Philadelphia.

Member of Council.—Dr. L. McLane Tiffany, of Baltimore.

Chairman Committee of Arrangements.—Dr. J. S. Billings, of Washington.

Time and place of next meeting, Washington, D.C., on the Wednesday preceding the meeting of the American Medical Association.

MISCELLANEOUS BUSINESS.

The following resolution offered by the Council was adopted:

That names of candidates for admission must be accompanied by a statement of official positions held, writings, and the claims upon which the application is based.

Resolved, That at future meetings of the Association one hour be the limit of time allotted for the reading of a paper.

(*To be concluded.*)

MEDICAL ASSOCIATION OF GEORGIA.

Thirty-sixth Annual Meeting, held at Savannah, April 15, 16, and 17, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE Thirty-sixth Annual Session of the Medical Association of Georgia was held in Savannah, April 15th, 16th, and 17th.

The Association was called to order on the morning of the 15th, at 11 o'clock, by the retiring President, Dr. A. W. Calhoun, of Atlanta.

Addresses of welcome were made by Dr. W. H. Elliott, of Savannah, and Hon. R. E. Leston, Mayor of Savannah. These were reponded to by Dr. T. W. Holmes, of Rome, on behalf of the Association.

The retiring President then introduced the President-elect, DR. EUGENE FOSTER, of Augusta, who delivered

THE ANNUAL ADDRESS,

the subject of which was

THE EXTENT, CAUSES, AND PREVENTION OF PREMATURE DEATH.

The speaker claimed that the inherent potential longevity of man was from eighty to one hundred

years, and that every human being had an inborn right to this period of life.

In seeking causes of premature death, he cited the fact of the 1146 diseases—general, local, etc.—which affect mankind, 27 caused fully 75 per cent. of the total mortality in 1870, and he contended that every one of these diseases is wholly preventable by application of definite and well-known hygienic measures.

He contended that there are mainly four essentials to procurement of health and longevity: 1. purity of atmosphere and water. 2. Wholesome food in quantity and quality. 3. The inheritance of a healthful constitution. 4. Freedom from contagious and infectious diseases. Man, in his individual efforts, has but little power over either of these essentials of life, with the exception of food. The only power which can secure the other three to the individual is the State. Minute and elaborate presentations of the filthiness of all cities, and the need of thorough sewerage and drainage, were made, and contained food for reflection.

The importance of, and the right to inheritance of a healthful constitution, were fully presented, and the growing evil of marriage among persons diseased with consumption, scrofula, syphilis, epilepsy, chorea, insanity, and alcoholism, was severly condemned.

Upon questions of freedom from contagious and infectious diseases, the speaker pointed out the enormous mortality from these diseases, and criticised man's stupidity in permitting cases of contagious and infectious diseases to scatter abroad the seeds of their infection when he is all-powerful to prevent the evil. He cited the fact that five preventable diseases—*i. e.*, smallpox, measles, scarlet fever, whooping-cough, diphtheria—kill 50,000 Americans every year, and yet the authorities, National and State, are indifferent to these causes of death, and are only fearful of cholera and yellow fever. He showed that the mortality from these latter two diseases was insignificant in comparison to that from other preventable diseases over which man has absolute control, and yet does nothing to prevent. He urged education of the public in sanitation as the remedy which it was the duty of the profession to promote.

THE COMMITTEES ON EXPERT TESTIMONY, AND ANATOMICAL MATERIAL

reported that bills had been presented to the Legislature, and that the legislative committees to whom they were referred reported favorably upon them, and they had every reason to believe that the bills as prepared would become laws at the approaching session of the Legislature.

These bills, as proposed, provide for proper compensation for expert witnesses, and material for dissecting purposes. Both bills have been very carefully drawn, and cover the grounds well.

DR. HOWARD J. WILLIAMS, of Macon, delivered an excellent address on

THE IMPORTANCE OF GOOD NURSING, AND THE TRAINING OF NURSES.

He advocated the establishment of schools for nurses in every city, supported by local medical boards, giving instructions in hygienic and the simpler forms of practice. He regarded women, by their nature, especially adapted to this work.

The Association abolished the present form of

PUBLICATION OF THEIR TRANSACTIONS,

and will hereafter publish them in journal form, selecting the *Atlanta Medical and Surgical Journal* as the journal of the Association.

A large number of voluntary papers were read. Among the number we present the titles of a few of the most interesting: *The best Nutriment for the Bony System*, by Dr. R. J. Nunn, of Savannah; *A New System of Treating Diphtheria*, by Dr. R. J. Nunn; *Glaucoma following the Excessive Use of Atropin*, by Dr. J. M. Hull, of Augusta; *A Case of Double Uterus, with Fœtus in Each*, by Dr. E. W. Lane.

DR. A. W. CALHOUN, of Atlanta, read a paper on

TRACHOMATOUS GROWTHS IN THE LARXNX IN CHILDREN,

removed under the influence of a twelve per cent. solution of hydrochlorate of cocaine. He stated that these growths are extremely rare, and that until the use of cocaine was suggested it was very difficult to remove them, but under the influence of a twelve per cent. solution he had little trouble in removing them.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—R. J. Nunn, M.D., of Savannah.

Vice-Presidents.—L. B. Alexander, M.D., of Forsyth, and T. F. Walker, M.D., of Cochran.

Secretary.—James D. Cray, M.D., of Atlanta.

Treasurer.—E. C. Goodrich, M.D., of Augusta.

Orator.—C. W. Hickman, M.D., of Augusta.

Augusta was selected as the next *place of meeting*.

LOUISIANA STATE MEDICAL SOCIETY.

Annual Meeting, held at New Orleans, April 21, 22, 23, 1885.

(Specially reported for THE MEDICAL NEWS.)

APRIL 21ST.—FIRST DAY.

MORNING SESSION.

THE Society was called to order at 12.20 P.M., by the PRESIDENT, DR. R. H. DAY, M.D., of Baton Rouge, and about seventy-five members answered to their names.

DR. G. A. LAWRASON, as President of the Orleans Parish Medical Society and in behalf of that Society, tendered the Society a cordial welcome to the city and wished the members a profitable and successful session.

DR. S. E. CHAILLÉ as Chairman of

THE COMMITTEE ON STATE MEDICINE,

presented his report. Nothing of great moment had been done by his Committee since the last meeting. The coming Legislature was composed of the same members as the last, and the Society's advocate and friend therein had expressed it as his opinion that any further endeavors before that particular body of men would be entirely useless.

At the meeting in Baton Rouge last May, some ten propositions had been presented to the Society. Of these five had been laid before the Legislature for action, viz.: 1st. A proposition for the establishment of a veritable State Board of Health. 2d. One protecting confidential communications to physicians. 3d. One

providing for compensation for expert testimony. 4th. One requiring hygiene and physiology to be taught in the public schools. 5th. An act amending the act regulating the practice of medicine. Of these five only one was passed. No. 1 was withdrawn as premature. No. 2 was passed, but the Governor failed to sign it. No. 4 was defeated by the negroes and members for Orleans. No. 5 was defeated.

Notwithstanding this bad showing Dr. Chaillé moved: That the Society re-endorse the report of 1884 of the Committee on State Medicine, and recommend the adoption of its proposition by the Legislature. Adopted.

THE RECORDING SECRETARY'S REPORT.

Dr. P. B. McCutcheon reported that 400 copies of the Transactions for 1884 had been distributed to various organizations and individuals, and that 125 were still on hand. He had received quite a number of valuable reports and monographs as additions to the Library of the Society.

Evening Session.

Dr. R. H. Day delivered the

PRESIDENT'S ADDRESS.

Its title was *The Mission and Methods of Medicine.* He referred to medicine as an art whose date of origin was lost in mystery, though perhaps coeval with the needs of mankind for its offices. However crude the practice of medicine by primeval man, it is undoubtedly a fact that they were strict observers of the main laws of hygiene—a practice which contributed to antediluvian longevity. A man to be a physician must be prepared to spend his life in earnest endeavor and striving after the hidden secrets of nature. It is the uneducated, unscientific, as well as irregular physician who brings discredit on medicine and lessens the influence of the profession upon legislation which would be calculated to be of benefit to humanity.

At the conclusion of this address, Mr. W. H. Goodale delivered the annual oration upon *The Blameless Physician.*

April 22d.—Second Day.

Morning Session.

THE TREASURER'S REPORT

showed the Society to be on a very good financial basis. Receipts, $773.75; disbursements, $240.70; balance on hand, $533.05, which will be materially increased by receipts at this meeting.

Dr. J. J. Newton read a paper on

HEMORRHAGIC MALARIAL FEVER,

which contained a fairly complete résumé of what had been written on the subject.

Dr. Jos. Jones spoke of a parasite having been found in cases of hemorrhagic malarial fever and the likelihood that it bore some relation as that of cause and effect. It is well known that rice is a great habitat of fungi and it may be that the special cause of this form of malaria may yet be determined. In this connection he stated it as his opinion that the cultivation of this cereal will yet work a great injury to Louisiana by its effects upon the health of its inhabitants.

Dr. Newton asked if the cases presumably caused by this parasite were new in type.

Dr. Jones thought they were.

Dr. Pugh asked if it was proper to give quinine in hæmaturia.

Dr. Lyons believed that the idea that quinine is a sheet-anchor in this disorder is a mistake. The complications resulting from large doses of quinine, such as profound prostration and nausea, were elements of great danger. Some physicians have abandoned its use entirely. Though he had never treated a case without some quinine, yet if called upon to choose between heroic doses and the total non-use of the drug he would choose the latter.

Dr. Langworthy thought small doses did good, but he placed much faith in acetate of potassium.

Dr. Newton thought quinine useful until structural changes had occurred. It should then be discontinued.

Dr. Day stated that several cases in his Parish treated with large doses had died. He related a case of malarial hæmaturia in which there was no fever, but rather a subnormal temperature. He had used diuretics such as nitre and copaiba, and after the attack small doses of quinine.

THE REPORT OF THE CORRESPONDING SECRETARY

showed a total of 1043 physicians in Louisiana. Of these, 764 were regular, 219 irregular, and 60 were unknown.

On motion, a committee of five, consisting of Drs. Allen, Lyon, Dupre, Chaillé, and Langworthy, was appointed to consider the recommendations contained in the President's Annual Address.

Evening Session.

Dr. L. L. Holcomb presented a paper on *The Neutral or Alkaline Saturation Plan of Treatment in Malarial Irritation and Idiopathic Fevers;* and Dr. Ashton, of Shreveport, one on *A Rational Common-sense View of Therapeutics.*

A. G. Friedrichs, M.D., D.D.S., of New Orleans, read an instructive paper on

THE RELATIONSHIP OF THE TEETH TO THE GENERAL SYSTEM.

The importance of the teeth in their influence upon the general system, he urged, is too often overlooked. Physicians are apt to overlook the fact that they have nerves and accompanying ganglia; that they are in close relation to the antra, and through them to the nerve fossæ, the tonsils and Eustachian tubes, and the external and internal ear, the orbit, and spheno-maxillary fossæ. Through the trigeminal nerve how easily may neuralgia be caused by reflex action from a diseased tooth. A gentleman came to his office with an acute neuralgic pain extending from one orbit to the other. No form of treatment of a month's duration had done any good. A semi-decayed dead posterior superior bicuspid, with no connection between the cavity of decay and the pulp cavity, was found. Communication was made, and instant relief followed. Another patient having neuralgic eye trouble, with conjunctivitis, intolerance of light, and lachrymation, had a tooth for its cause. Dr. Tendian relates a case of insanity from a diseased tooth. Epilepsy, paralysis, general or partial, have frequently followed from bad teeth. Dental abscesses have simulated scrofula, and

caused caries and pyæmia. He pointed out that it is important to remove thoroughly the concretions which are deposited upon the teeth in febrile affections, else decay rapidly ensues.

(To be concluded.)

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 14, 1885.

THE VICE-PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

DR. GERSTER presented a patient upon whom he performed

MIKULICZ'S OPERATION

on the 17th of January, 1885, and who was able to walk with only a very slight limp. The man was a professional nurse, forty-eight years of age, who in May, 1881, had an attack of erysipelas in the region of the heel and foot for which he was treated in Bellevue Hospital. A large abscess formed, the calcaneum became involved, and superficial necrosis followed for which the bone was scraped out and he was finally dismissed from the hospital, but not improved.

In 1883, he came under Dr. Gerster's care in the German Hospital with epithelioma in the situation of the ulcer upon the heel about the size of a trade dollar which had never healed, and the character of the new growth had been determined by a number of microscopical examinations. It was sessile and firmly attached to the calcaneum. Dr. Gerster removed it, and at the same time exsected the entire tuberosity of the calcaneum, thus hoping to gain sufficient space for the use of a skin flap formed from the planta pedis to cover the defect with, but succeeded in covering only about one-half of it. Necrosis of this flap followed, due to the compressory dressings used, and to the atheromatous condition of the arteries. The remaining defect was cicatrized over completely within the next three or four months, and ultimately a scar remained, extending from the planta pedis up to the insertion of the tendo Achillis with the foot in the position of pes equinus. The cicatrix frequently ulcerated, especially in cold weather, and finally the ulceration became almost permanent, so that the patient pleaded for an amputation. Dr. Gerster proposed, however, instead of amputating the leg, to perform Mikulicz's operation after having taken into consideration the advisability of a plastic operation according to the usual method of cutting out a flap from the other limb and transposing it to the ulcerated surface, holding the limbs by means of plaster splints in such apposition as to permit the flap to come in contact with the denuded surface, and afterward separating the pedicle of the flap when the circulation in its new attachment had become sufficient to maintain nutrition. In view of the man's atheromatous arteries necrosis of a flap raised for such a plastic operation was almost certain, wherefore, partial exsection of the tarsus was decided upon. The principle of the operation is as follows: in cases in which the heel is denuded of its integument Mikulicz thought that the length of the limb could be preserved and made available for motion without the assistance of complicating apparatus if the calcaneum and astragalus were removed and the anterior portion of the foot saved and brought into contact with the tibia and fibula. The first incision is made almost in the same manner as for Pirogoff's and Symes's operation, cutting down to the bone, beginning a little anterior and below the malleolus of one side, carrying it across the planta pedis to the corresponding point upon the other side; the incision is then extended up to the centre of the malleolus and carried round the leg behind, corresponding to the insertion of the tendo Achillis. Through this latter incision the posterior aspect of the ankle-joint is exposed and the same is entered and dissected up until the head of the astragalus is denuded, and then the astragalus and calcaneum are severed out of their last connections in Chopart's joint.

When this has been done the remnant of the foot, containing the scaphoid, the cuboid, the cuneiform bones, and the metacarpals, and the toes, is hanging by a flap, situated on the anterior portion of the limb, the nutrition of which is sustained through the dorsalis pedis artery.

The tibia and fibula are then sawn through the malleoli, and also the cuboid and scaphoid bones are separated from the soft parts sufficiently to permit the saw to be carried through them on a vertical plane. In this way are left two rather extensive bony surfaces, which are brought together and rendered immobile by driving a nail slantingly through the scaphoid into the spongy portion of the tibial epiphysis. Finally the cutaneous edges are united by a continuous catgut suture, and the limb swathed in an antiseptic dressing.

The patient presented was the second one upon whom he had performed the operation, and the result was the better of the two. As far as his knowledge extended, these two operations were the eighth and ninth which had been performed. In the other case the final result would be satisfactory. In that case the limb was lengthened half an inch, so that the patient would be obliged to have an elevated shoe upon the opposite side. In the case of the patient presented, Dr. Gerster removed a trifle too much of the bone, and produced a shortening of one-fourth of an inch, which was so slight a matter that the patient was able to walk with scarcely a perceptible limp. On account of the free removal of the scaphoid and cuboid bones, he came very near the joint between the scaphoid and the cuneiform bones; in fact, so near that the ligaments fastening that joint were detached, and the mobility present was due to mobility at that articulation, but this was rather an advantage than otherwise.

When the Esmarch bandage was removed, the blood-vessels did not bleed at all, and he was somewhat startled at the thought of the possibility of the atheromatous condition of the vessels, and the constriction to which they had been subjected might seriously interfere with the circulation, but when the foot was brought into its normal position free hemorrhage set in, so free that it became necessary to apply nearly twenty-five ligatures to arrest the hemorrhage. After this was done the bones were brought into apposition, and, as previously mentioned, a long nail was driven through the remnant of the scaphoid bone into the tibia, which gave firm apposition of the sawn surfaces. An antiseptic dressing was applied, and a correct healing of the

wound took place, with primary union of the sawn surfaces.

By February 2d, the nail could be withdrawn; its vicinity never showed any evidence of reaction. The track of the nail secreted a little sero-purulent matter for a few days after its removal, and then closed up. Very soon afterward the patient was ordered to walk about. Mikulicz said that he was obliged to perform tenotomy of the short flexor to allow hyperextension of the toes, but in this case Dr. Gerster had not found it necessary, and by the aid of a shoe, in which the heel was somewhat elevated, the patient was able to walk very comfortably, and with a good deal of elasticity.

In reply to a question, Dr. Gerster said the line of section extended vertically through about the middle of the scaphoid, and through the posterior portion of the cuboid.

CORRESPONDENCE.

THE NINETEENTH CONGRESS OF GERMAN SURGEONS.

BERLIN, April 11, 1885.

MORE than four hundred prominent German surgeons gathered in Berlin to attend the sessions of the German Surgical Congress, which were held from April 8th to 11th, under the presidency of the Nestor of German surgeons, Baron Von Langenbeck. There were also present all the leading physicians of Berlin, among whom may be mentioned Bardeleben, Rose, Gurlt, Hirschberg, and Fränkel. Many professors and practitioners from the provinces also attended, among whom were Volkmann, of Halle, Esmarch, of Kiel, and König, of Göttingen. Numerous representatives from foreign countries were also present—Mikulicz, of Krakow; Winiwarter, of Liege; Ranke, of Groningen, Holland; Albrecht, of Brussels; and Haberen, of Buda-Pesth. The absence of Parisian surgeons was noticeable, not one being present.

Previous to its formal opening, Sir Joseph Lister and Sir James Paget were elected honorary members of the Congress, and a complementary telegram informing them of the fact was forwarded.

PROF. VOLKMANN, of Halle, opened the Congress with an address on the *Surgical Consideration of Tuberculosis*. To Robert Koch he assigned the credit of first discovering the real cause of tuberculosis—the tubercle bacillus—and called attention to the fact that the so-called "consumption" of the lungs may attack almost any organ whatever, and that the surgeon may discover the existence of tuberculosis in the organism, apart and distinct from its presence in the lungs, and as such it is to be considered more as a surgical than as a general physical disorder, and surgeons, therefore, must consider remedial agencies, and duly observe their effect. Volkmann arranged his observations under forty-eight heads, of which the most important may here be stated.

The tuberculous character of a disease is not to be doubted when examination gives positive proof of the presence of the tubercle bacillus, and when anatomical examination confirms the characteristic structural appearance of tubercular tissue.

The diffusion of tuberculosis follows in a marked degree (*a*) by means of the increase of the original infection deposit, (*b*) through the entrance of tubercular virus (bacilli) from the original infection mass into the lymph canals. This common occurrence does not ordinarily conduce to the generalization of the disease, inasmuch as the lymphatics not only impede its progress but plainly, in many cases, render the disease harmless. The importance of the lymphatic glands as a protective apparatus and filter, in local infectious processes, has not been sufficiently appreciated. General tuberculosis only is evident when the gland infection becomes so far extended as to invade the ultimate lymphatics which lie between the blood current and the diseased tissue, or when the thoracic duct itself becomes the seat of infection.

(*c*) Through the introduction of the tubercular poison into the inner wall of a serous sac through the extension of a neighboring tubercular mass, or through the introduction of bacilli-containing pus, etc.

(*d*) In the same manner, through the entrance of the tubercular poison into the various cavities and canals covered with mucous membrane, in which it may become stagnant, or from which it may be removed only with great difficulty.

(*e*) Through the entrance of the poison from an adjoining collection of tubercular material into a non-thrombotic venous trunk, or into a lymph channel communicating directly with the blood current, and as a result of which acute general miliary tuberculosis results.

The discussion concerning the identity of tuberculosis and scrofulosis is not yet determined. By *tuberculosis* is generally meant a local manifestation of the disease, while by scrofulosis a general and constitutional vice of nutrition, a special diathesis or heredity is indicated.

Discussion of Professor Volkmann's paper was deferred until the following day.

PROFESSOR BRAUN, of Jena, then followed with a paper upon *Intestinal Invagination*, and its operative treatment. The Congress expressed the opinion that, in future, cases of intestinal invagination should be committed to the surgical clinic, to which, up to the present time, resort has only been had in hopeless cases.

At the second session, held on April 9th, DR. FEHLEISEN, First Assistant in the Berlin Surgical Clinic, read a paper upon the *High Operation for Diseases of the Bladder*. PROFESSOR MAAS, of Würtzburg, recommended as a substitute the median lithotomy incision on account of its greater freedom from danger. Discussion concerning both these operations for lithotomy will be held at the meeting of the Congress to be held next year.

PROFESSOR KÖNIG, of Göttingen, next described a new method of *Resection of the Joints* of the foot in articular tuberculosis, which already in 32 cases has yielded favorable results. VOLKMANN, of Halle, stated that he still preferred the method of Langenbeck, but cautioned against the too frequent performance of the operation, which, though giving brilliant results so far as the usefulness of the foot is concerned, still, in children, is not necessary and in persons of advanced age may be dangerous. PROFESSOR LANGENBECK reported that his experience with operations for resection in tubercular disease of the joints of the feet and hands has been unfavorable, and expressed astonishment at the favorable results obtained by Professor König.

DR. GAERTNER, Marine Physician, next read a paper upon *The Disinfectant Properties of Carbolic Acid Solutions*. To Professor Koch he gave credit for first accurately demonstrating the proportion of carbolic acid required in solution to insure its germicide effect. Koch's experiments he has repeated and like him finds a three per cent. solution destructive to all known forms of bacilli.

In the Afternoon Session Professor Volkmann's paper upon tuberculosis was brought up for discussion.

On the third day of the Congress, April 10th, PROFESSOR LANGENBECK exhibited a young man upon whom he had operated two years previously for *Spina Bifida*, by injection of iodine into the sac, with the result of entire cure. DR. BERGMAN also brought before the Congress a small girl similarly operated upon with like good result.

Discussion was next held upon the *Treatment of Cleft Palate*. As pertaining to the subject of oral surgery, two cases of recovery from fracture of the lower jaw were exhibited. A case of ankylosis of the lower jaw (cured by resection of the joint) was exhibited by Professor Ranke, of Holland.

The most important discussion of the day, however, was that upon *Resection of the Stomach*. DR. RYDIGIER produced two cases lately operated upon by himself. In one case not only was a carcinoma of the stomach removed, but also a large section of apparently sound tissue, which, upon close examination, was found to contain foci of disease. Dr. Rydigier holds that where, after an operation, the disease returns too little tissue has been resected. No danger of removing too much tissue need be apprehended. He also holds that women endure the operation for resection of the stomach much better than do men. Of five cases operated on by him, three were women and two men. The women are all alive, while both men are dead.

DR. VON HACKER, of Berlin, then referred to Prof. Billroth's operations for resection of the stomach, of which there is a total of 18 operations, 14 of which were for carcinoma. Of these 14, 8 died from the effects of the operation. Of the 6 remaining cases the disease has returned in 5 cases, leaving 1 in which favorable results have been obtained. In view of these statistics, Dr. Von Hacker holds that this operation for cancer of the stomach offers no prospect of favorable results, and advises that in severe cases the operation be avoided, and the patient be left to the natural course of the disease.

DR. BESSEL, of Berlin, in the afternoon session, spoke concerning *Joint Extirpation in Clubfoot*, and expressed the opinion that extirpation of the joint is to be avoided, and, without doubt, limited to cases in which it is specially indicated, and is not to be generalized.

DR. KUMMEL, of Hamburg, then reported the experiments made at Hamburg upon the best methods of *Disinfection during Operations*. As the best means of disinfecting instruments, first of all it is recommended to wash them with ether and wipe thoroughly with wadding, or to cleanse them with soap and warm water, and then to lay them in a three per cent. solution of carbolic acid. Sponges also may be cleansed in this manner, if they are allowed to soak in the carbolic solution. For a thorough cleansing of the hands, a solution of corrosive sublimate, in proportion of 1 to 1000, is insufficient. For this purpose a two to five per cent. solution of carbolic acid seems best adapted, together with washing in chlorine water.

Efforts to purify the air of the operating room have been ineffectual. Simple washing of the floor and walls with soap and water is useless, and, indeed, the use of water may be the origin of fungi, and even steam has no destructive effect upon these fungi. The interesting statement was made, in conclusion, that examination of the expired air of diseased patients revealed the presence of no bacteria.

At the close of the session it was resolved to renew the discussion of Prof. Volkmann's paper upon the surgical aspects of tuberculosis.

At the final session, on April 11th, PROF. ESMARCH, of Kiel, exhibited several *New Apparatus Adapted to Military Surgery*, among which were a new elastic bandage, made of nickel-plated, highly tempered, wrought steel, and a modification of Volkmann's apparatus for shot or otherwise severely wounded limbs.

PROF. ESMARCH then spoke upon *The Transplantation of Large Skin Flaps upon Fresh Wounds*. In order for these to heal quickly, whether they be obtained from freshly amputated limbs or other source, all fat must be thoroughly removed. This method of treatment is especially serviceable in war, on account of the abundance of material.

PROF. ESMARCH also spoke of the *Results of Operations in Complicated Cases of Harelip*, in which, as statistics show, a great proportion of cases operated on at a tender age give, after a longer or shorter time, fatal results. Experience shows the operation to have no settled value. Statistics must be published before the question can be intelligently decided.

PROF. ALBRECHT, of Brussels, next exhibited a series of interesting curiosities, among which were specimens illustrative of the significance of the diverticula of the pharynx, which though met in other suckling animals, in man are rare.

DR. LAUENSTEIN, of Hamburg, returned to the subject of *Resection of the Stomach*, and referred to cases operated upon by himself, and discussed the *technique* of the operation.

At the close of the Congress, Prof. Volkmann earnestly requested Prof. Von Langenbeck, who, on account of ill-health, no longer wished to preside over the meetings of the Congress, to withdraw his resignation. The whole Congress united in this request, and the distinguished surgeon finally consented to yield to the wishes of his associates.

TAIT'S OPERATION.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of February 21st there is an editorial article on the use and abuse of Battey's and Tait's operations, upon which I will ask your courtesy to enable me to make one or two remarks. Two points I must first of all speak briefly of, because they are points upon which I have now entered my protest time without end, and apparently with very little effect, for I find that every succeeding writer falls into exactly the same error, but I propose to go on drawing attention to my views until, I trust, I may some day see them accepted.

In the first place, I protest against names of persons

being attached to operations, it is such a slip-shod and easy method of description that it is certain to lead to mistakes. In the second place, you say that in the operation which you allude to under my own name, "the conditions which are alleged to require it are not so plain, and the diagnosis is more difficult," I presume, than in the operation which you describe as Battey's. Here, again, the use of these two names is the cause of great confusion. I take it for granted, that you mean, by Battey's operation, "the removal of the ovaries for the purpose of bringing about the menopause under conditions where the disease appears to be due to, or largely dependent upon, the recurrence of menstruation." If this is what you really mean, it must be perfectly evident to any one that such an operation must be always largely speculative, and that really no kind of diagnosis can be made.

If by Tait's operation you mean the removal of diseased tubes, then the diagnosis is perfectly simple and easy; nothing could be more so. It is perfectly true that it is not always easy to diagnose and differentiate hydrosalpinx, pyosalpinx, hæmatosalpinx, and tubal pregnancy. This I have admitted over and over again; but the diagnosis of diseased tubes requiring removal is a perfectly simple and easy matter, in which I am perfectly certain now my mistakes cannot amount to more than five or six per cent.

Perfectly exact diagnosis is not possible in any realm of surgery—even in tumors of the breast, for in many cases it is absolutely impossible to say what the exact nature of the tumor is until it is in the operator's hands, and a section has been made of it. Just so with diseased Fallopian tubes.

The third point to which I want to draw your attention is that in which you say that the operation which you are kind enough to describe as my operation finds no favor with some of the best London authorities—Sir Spencer Wells and Dr. Matthews Duncan. In this you are absolutely mistaken. Dr. Duncan has not in a single instance that you can point to expressed disapproval of the operation for removal of diseased Fallopian tubes. At least, from a large acquaintance with his writings and with his opinions from personal conversations, I have not gathered any such impression; in fact, my belief is absolutely to the contrary. With Sir Spencer Wells's views I am now not much concerned, but so far as I know them on this point, he does not object to the operation. He says the cases do not exist, or, if they do, they all go to Birmingham. I have published details of four cases, and I am in possession of the facts of many others, which have passed through Sir Spencer's own hands, and which he has failed to recognize. He will not do as some of his London brethren do, and as many of your countrymen do, come to Birmingham and be taught, so he must go on in his wilful ignorance. In this instance, happily, Sir Spencer Wells's ignorance will not stop surgical progress as it has done in the past.

But the last piece of evidence concerning Sir Spencer Wells which has come before me, on the authority of the Editor of the *British Journal of Gynecology*, is certainly not at all in favor of your statement of Sir Spencer Wells's opinions. In fact, it seems to me that Sir Spencer Wells, from being an obstructive, has suddenly turned round to be one of the most advanced promoters of our new form of abdominal surgery—in fact, he has advanced to a degree which I for one certainly shall hesitate for a long time to follow. He has actually, on the authority given, removed perfectly healthy ovaries in a woman who was the subject of recurring puerperal mania, in order to prevent her having more children. This may be, or it may not be, a justifiable proceeding; this is not the point under discussion; but it is a proceeding which I venture to say has not yet been advocated by any British surgeon, and it is one upon which the strongest possible opinions may be expressed in an adverse direction. Certainly, after having performed such an operation as this, Sir Spencer Wells's mouth must be forever closed against anybody else.

I am, sir,

Yours very truly,

LAWSON TAIT.

7 The Crescent, Birmingham.

NEWS ITEMS.

MONTREAL.

(*From our Special Correspondent.*)

The Smallpox Epidemic.—For the last five years this city has been quite free from smallpox, and the authorities began to think that we would never again experience an epidemic, so the Civic Smallpox Hospital was closed and vaccination was, except among the well-to-do classes, almost altogether neglected. The public vaccinators had but little to do; in fact, up to a week or two ago the offices of Public Vaccinators were vacant. Some few weeks ago (four) two railway employés came from Chicago suffering from smallpox. The city having no means of isolation ready, one case went to a private house, and the other to the Hôtel Dieu Hospital. From these two cases the disease has spread in every direction; already several deaths (five) have occurred, and the reopened Civic Smallpox Hospital contains twenty cases, the majority of them traceable to the case admitted into the Hôtel Dieu. The Hôtel Dieu, in consequence of the number occurring there, has been closed, and is now undergoing thorough disinfection.

The Board of Health, under the active management of the new Chairman, is doing everything in its power to stamp out the disease, and where patients will not go to hospital (there being no law to compel them), guardians are placed before the house containing the smallpox patients, to warn all people against entering, and the whole neighborhood is vaccinated. Physicians are required to report all cases occurring in their practice, and every case is then investigated by the Board of Health, and proper disinfection and isolation enforced. It is hoped that the disease will by these means be soon under control.

New Act Respecting Lunatic Asylums.—As a result of the discussion provoked by Dr. Hack Tuke's report on the lunatic asylums of the Province of Quebec, the provincial government has introduced a bill which is an attempt to remedy some of the evils complained of. The only important change is the provision for the appointment of two medical officers in addition to the medical superintendent, all to be paid by the government. These officers are not *required* to

reside in the asylum. The medical superintendent's residence is not specified. The house physician must reside *near*, but not in the asylum, and the assistant house physician is to reside "in the asylum itself or its immediate neighborhood. The house physician and his assistant are required to devote their whole time to the service of the patients. The proprietors of the asylums and their subordinates are bound to carry out the orders of the house physician or his assistant (not as heretofore, to act under the orders of their masters, the proprietors), they may also require the proprietors to dismiss keepers, nurses, and guardians, for incompetence and insubordination.

These changes will, no doubt, prove of great benefit, provided the proper medical officers are obtained, men having some more knowledge of the treatment of the insane than is obtained by a short college course, and large political influence. So many internal reforms are needed that it will require determined men to carry them out, seeing that it will be to the advantage of the proprietors to place as many obstacles in the way as possible. What is needed is the abolishing entirely of the iniquitous *farming* system, but this reform the government apparently has not the courage to propose.

THE UNITED STATES TO BE REPRESENTED AT THE INTERNATIONAL CHOLERA CONFERENCE.—The President has detailed Dr. George M. Sternberg, U. S. A., to attend, as the delegate from the United States, the International Cholera Conference which convenes in Rome on May 15th. Dr. Sternberg sailed for Europe on Wednesday last.

CHOLERA IN CALCUTTA.—The Surgeon-General of the Marine-Hospital Service is informed that cholera is prevailing in Calcutta to an alarming extent.

VOLUNTEER SURGEONS FOR RUSSIANS.—Drs. J. A. Post, and George E. Ranney, of Lansing, Michigan, according to the Lansing *Republican*, have forwarded through the medium of the Secretary of State a communication to the Russian Minister at Washington, tendering the services of themselves and a corps of twenty-three experienced Michigan surgeons for the field, in case of war between England and Russia.

INTERNATIONAL CONGRESS OF HYDROLOGY AND CLIMATOLOGY OF BIARRITZ.—The first International Congress of Hydrology and Climatology of Biarritz will open at Biarritz, October 1, 1886. The French Minister of Commerce is the honorary, and Dr. Durand Fardel the acting, president.

The sessions of the Congress will last eight days, after which excursions will be made to the different thermal and principal sanitary stations of the Pyrenees.

MULTIPLE PREGNANCY.—An account is given in *L'Echo d'Oran*, of February 14, 1885, of an Arab woman who gave birth at one confinement to five children, three of whom are still alive. The report seems to be well authenticated.—*Le Progrès Medical*, March 14, 1885.

THE COLLEGE OF PHYSICIANS AND SURGEONS OF QUEBEC will require, previous to admission to the study of medicine for the session of 1885–1886, a preliminary examination in Latin, French, English, Belles-Lettres, History, Geography, Arithmetic, Algebra, and Geometry, all of which are obligatory. The three following subjects are elective: Greek, Physics, and Philosophy.

NOTES AND QUERIES.

CORRIGENDUM.

DISINFECTANTS.

IN the paper on Moist Heat, published in the issue of THE MEDICAL NEWS of March 14, there has been a transposition of the figures, in brackets, on page 285, representing the degrees of the Fahrenheit corresponding with the degrees of the Centigrade scale.

In the paper No. IX, *The Disinfecting and Antiseptic Powder* recommended on page 425 is withdrawn. This powder was introduced by the Chairman of the Committee, after the paper had been submitted to the scrutiny of the entire Committee, on his own responsibility, and in the belief that a disinfectant in this form would prove useful. There are practical objections to the formula as given, but when circumstances permit some additional experiments, another will be substituted for it.

On page 425, second column, near bottom, after the directions, "one fluidounce of this standard solution to the gallon of water will make a suitable solution for the disinfection of clothing," refer to the following foot-note: Decolorize the solution before using by adding to it a little chloride of lime or Labarraque's solution.

On page 426, second column, twenty-sixth line, after word "water," refer to foot-note as follows: Decolorize by adding a little chloride of lime or Labarraque's solution.

After this reference the text should read: The walls and ceiling, if plastered, should be brushed over with this solution, after which they *should* be whitewashed with a lime-wash.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 21 TO APRIL 27, 1885.

Lieutenant-Colonel JOS. R. SMITH. *Surgeon*, Major JNO. S. BILLINGS, *Surgeon*, Major HENRY MCELDENY, *Surgeon*.—Detailed to represent the Medical Department of the Army at the annual meeting of the American Medical Association, to be held at New Orleans, La, April 28, 1885.—*S. O. 91, A. G. O.*, April 21, 1885.

CRAMPTON, L. W., *Captain and Assistant Surgeon*.—Assigned to duty as Post Surgeon, Fort Bridger, Wyoming Territory.—*S. O. 33, Department of the Platte*, April 22, 1885.

BORDEN, WILLIAM C., *First Lieutenant and Assistant Surgeon*.—Ordered for duty at Fort Douglas, Utah Territory.—*S. O. 33, Department of the Platte*, April 22, 1885.

ROBERTSON, R. L., *First Lieutenant and Assistant Surgeon*.—Granted leave of absence for one month.—*S. O. 43, Department of Texas*, April 16, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING APRIL 25, 1885.

SAWTELLE, H. W., *Surgeon*.—When relieved, to proceed to Detroit, Mich., and assume charge of the Service, April 23, 1885.

URQUHART, F. M., *Passed Assistant Surgeon*.—To assume charge of Cape Charles Quarantine Station, April 23, 1885.

WILLIAMS, L. L., *Assistant Surgeon*.—When relieved, to proceed to Norfolk, Va., for temporary duty, April 23, 1885.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

AMERICAN MEDICAL ASSOCIATION.

THIRTY-SIXTH ANNUAL MEETING, NEW ORLEANS, 1885.

THE ADDRESS IN OBSTETRICS.

A BRIEF REVIEW OF THE GROWTH OF MCDOWELL'S OPERATION DONE AT DANVILLE, KENTUCKY, IN 1809; ITS PRESENT STATUS.

Delivered Wednesday, April 29, 1885.

BY R. S. SUTTON, M.D., LL.D.,

OF PITTSBURG.

IN the bleak cold of a December day, in 1809, a woman riding on horseback, arrived in Danville, Kentucky. She had taken farewell, perhaps forever, of relatives and friends, and had just completed a journey of sixty miles that she might be near a surgeon, who had promised to open her abdomen, and attempt to remove the large ovarian cyst it contained. She was to be the subject of an experiment—an experiment at the hands of a surgeon living on the borders of civilization—an experiment which would involve her life, and to which she must submit without the blessing of chloroform or ether. This woman possessed of marvellous courage, was Mrs. Crawford, McDowell's first patient in ovariotomy, and the first patient upon whom the operation was ever deliberately undertaken. She recovered and lived to the advanced age of seventy-nine years, a period of thirty years beyond the operation.

The conditions surrounding, and forming part of this operation, are worthy of more than a passing notice. At the present time, they are declared by the ablest operators to be of more than accidental importance.

In the light of all recent advances concerning the environs of an ovariotomy patient, I ask you to listen thoughtfully, and inquire of yourselves: Have modern operators had better environment than McDowell? Is their quarantine better than his was? Whether accident, or necessity, or the simplicity of border life, provided these conditions so favorable to recovery, your orator will not inquire, but hopes to show that McDowell did operate under conditions as favorable as does Dr. Keith or Mr. Lawson Tait.

1st. The patient was refused operation in her own home.

2d. She was operated upon in Dr. McDowell's own house.

3d. History mentions but one assistant present at the operation.

4th. The patient had never been tapped.

5th. We may safely infer that the room in which the operation was performed, contained, at this early date in Kentucky, no superabundance of furniture or upholstery.

6th. That the room was ventilated by an open fireplace is more than probable.

7th. The atmosphere was that of a healthy border town.

8th. No sponges were introduced into the abdomen.

9th. He ligated the pedicle and dropped it in.

This operation will stand the criticism of the most exacting specialist of the year 1885, save in two particulars: viz., the ligature was not carbolized or scalded, the ends of it were left hanging out of the lower angle of the wound, and merely turning the woman on her side to permit all fluids to escape from the cavity of the abdomen was scarcely enough in that direction.

The incision was made to the left of the rectus muscle, but in his next case McDowell made it in the linea alba, between the umbilicus and pubis.

Pause a moment! Think; at the end of almost three-quarters of a century, the operation stands almost where McDowell left it, with one solitary exception, viz., the ends of the ligature surrounding the pedicle are cut short.

Restless human nature, not satisfied, sought other means of treating the pedicle, a review of which is fraught with good instruction. For eleven years the operation remained in the hands of McDowell, and he adhered to ligation of the pedicle, leaving the ends of his ligature hanging out at the lower angle of the wound. In 1820, Chrysmar, of Würtemburg, tied the pedicle in two portions, leaving the ends of the ligature hanging out at the lower angle of the wound. In 1821, Nathan Smith, of New England, tied the pedicle with "strips cut from a kid glove;" he cut the ligature off close to the knots, and dropped the pedicle into the abdominal cavity.

Neither Chrysmar nor Nathan Smith knew anything of McDowell's operations. Were the teachings of Hunter and John Bell working upon other minds, as well as upon the mind of Dr. McDowell? The last named sent to Mr. John Bell, of Edinburgh, an account of his cases. Mr. Bell being then in Italy, his colleague, Mr. Lizars, received the report. It is probable that this record was received in 1818. For six years Mr. Lizars kept it to himself. He attempted ovariotomy four times, and succeeded in one case, the patient surviving the operation seventy days. In one case he opened the abdomen by an incision reaching almost from the ensiform to the pubis, and thrust his hand into an empty belly. He requested every one of his students to put his hand into the abdomen, and finally exclaimed, referring to an army officer present, "Where is the military gentleman?" and had him make the same manual exploration. Mr. Lizars then closed the wound, *and it healed by first intention.*

Owing to the fact that Mr. Lizars's results were bad, twenty years elapsed before ovariotomy was again attempted in Scotland. In 1845, Dr. Handyside performed it. Another halt of seventeen years occurred, bringing us up to 1862, at which date but one success had been attained in Scotland. In that year Dr. Thomas Keith did his first operation.

Let us now cease the pursuit of Dr. McDowell's operation, as it was reported to Mr. John Bell, which report the latter did not live to see.

Up to the year 1843, I find the records of only eighteen completed ovariotomies in America. In this year, Dr. Alexander Dunlap, of Springfield, Ohio, and Dr. John L. Atlee, of Lancaster, Pa., did their first cases, the latter removing both ovaries. Eleven years later (1855), Dr. Kimball, of Lowell, began operating. These three are now the only living pioneers of the army. May they live long to enjoy the distinction!

The operations in the United States were already numerous, and the stability of the operation secured. This was before Sir Spencer Wells did his first ovariotomy.

It is estimated by Peaslee that up to the last quarter of 1863, over three hundred ovariotomies had been done in this country. At this date, Dr. Keith was only beginning in Scotland; the operation was performed for the first time in Russia, and was only a year old in Italy. Twelve years after the death of Dr. McDowell, in 1842, Dr. Charles Clay of Birmingham, England, did the first operation in that country; prior to this time, Jeaffreson, Walne, King, and West had each removed, by abdominal section, parovarian cysts. In 1851, Baker Brown began operating in St. Mary's Hospital, London; his results were not good, and the intense opposition of his colleagues drove him from the hospital; he then founded "The London Surgical Home," where his results compared favorably with those of any other surgeon of his time. *It was mainly due to his action that the practice of performing ovariotomies in large hospitals, where isolation is impossible, ceased.*

From Baker Brown, Nélaton learned the operation by personal observation, and returning to France, related, in a public lecture, how he had seen Brown do five cases, three of them in a single day; and thus through the influence of Brown on Nélaton, the opposition to ovariotomy in France was largely diminished. In 1854, Baker Brown taught Sir Spencer Wells the operation, and in 1857, Sir Spencer did his first operation. In 1864, according to Sir Spencer Wells, the operation was completely established in London, and, we may add with pride, in every country in the civilized world.

But while the surgical world recognized the operation, there was a diversity of opinion with regard to the treatment of the pedicle. From the date of Dr. McDowell's first operation up to 1821, when Dr. Nathan Smith operated, the ends of the ligature were brought out at the lower angle of the wound; Dr. Smith was the first to cut the ends off. For sixteen years afterwards no other method was offered. In 1837, Stilling, of Cassel, in the province of Hesse-Nassau, Germany, used the cautery, and suggested stitching the pedicle to the wound.

Nine years barren of new suggestions again elapsed, when, in 1846, Dr. Handyside, of Edinburgh, Scotland, carried the ligatures through the cul-de-sac of Douglas into the vagina. In 1848, Stilling treated the pedicle outside of the peritoneal cavity. Two years later, in 1850, this method was inaugurated in London by Mr. E. W. Duffin. The introduction of the extraperitoneal method of treating the pedicle by Stilling, in 1848, began a long and serious conflict which has happily died out with the method. Maisonneuve, of Paris, in 1849, had twisted the entire pedicle in one case, and Martin, of Jena, had stitched the pedicle to the wound. About this time Langenbeck stitched the pedicle to the wound, and covered it with skin from the margin of the incision.

Eight years later, in 1850, Dr. John L. Atlee, of Lancaster, Pa., introduced the écraseur to divide the pedicle. He was imitated by a number of prominent operators, notably by his brother, the late Washington L. Atlee, Sir Spencer Wells, Dr. Keith, Professor Pope, of St. Louis, U. S., and Professor Billroth, of Vienna. This year proved unfortunate for the operation, for during it Mr. Johnathan Hutchinson invented the clamp which perpetuated the extraperitoneal mode of treating the pedicle. In 1860, Sir James Y. Simpson secured the pedicle within the cavity of the abdomen by acupressure needles passed through the abdominal wall. About 1865, Koeberle, of Strasburg, invented his serre-nœud, or wire constrictor, with which he grooved the pedicle prior to applying the ligature.

In 1864, Mr. I. Baker Brown, of London, reverting to Stilling, of Cassel, established the use of the cautery, *a method rejected in London, taken up by Dr. Keith, and now credited through him with the best statistics yet attained by any operator.* In 1868, Masslovsky, a Russian, amputated the pedicle by double flaps, one on each side, and stitched the flaps together. In 1869, Dr. McLeod, of Glasgow, Scotland, by means of two pairs of strong forceps, twisted the pedicle entirely off. During this year, Dr. Peaslee invented a scabbard and knife by means of which the pedicle was secured, the ligature traversing the scabbard. After forty-eight hours the ligature was cut by introducing the knife into the scabbard, when both ligature and scabbard were withdrawn. In 1870, Dr. Thomas Addis Emmett reported eighteen cases in which he had secured the pedicle by means of silver wire.

Up to the present year (1885), every conceivable thing has been done with the pedicle. It has been tied entire; tied in sections; been twisted off; burnt off; crushed off; cut square off; cut off in flaps; left inside; left outside, and been made to slough off. The extraperitoneal method of treating the pedicle is gone. The question is now resolved into the merits af the ligature cut short, the Dr. Nathan Smith method, or the clamp cautery, as introduced by Mr. I. Baker Brown, of London, in 1864. If the clamp as devised by Mr. Jonathan Hutchinson was a bad instrument, and according to Mr. Tait, reduced the statistics that Sir Spencer Wells should have attained, it must have similarly affected the results of those who have employed it in the United States. Recently ligation and the cautery have given almost equal results.

The operation of Dr. McDowell in so far as it relates to the treatment of the pedicle, is, therefore, triumphantly where he placed it, despite the ingenuity of the surgical world, having undergone but a single alteration, namely, Dr. Nathan Smith's improvement of cutting the ligature short I have not been able to learn anything as to the extent sponges were used by the pioneer operators. When Dr. Keith was about to do his first operation, he had the water to be used boiled the night before, and he made everything scrupulously clean; during the operation he was surrounded by old practitioners.

After removal of the cyst, he thrust a big sponge into the abdomen, and brought it out full of fluid. As he was about to repeat this, one of the doctors seized his

arm, and exclaimed, "For God's sake don't do that again." While he hesitated, the others argued that any fluid left in the body would be a nice protection to the intestines. He closed the wound. Subsequently the patient did badly. He at once opened the wound and let out a pint of dirty fluid, and the patient recovered. From that time he advocated careful sponging after the operation, *and he was the first to insert a flat sponge under the wound while the stitches were being placed.* Koeberle, who also began to operate in 1862, *introduced the compression forceps and drainage, first by short and later by long glass tubes.*

I here show you the Baker Brown cautery clamp, used by Dr. Keith, the compression forceps of Koeberle, *also the modification by Sir Spencer Wells*, and the drainage-tubes so much in use by operators in Great Britain.

The technique of McDowell's operation is, probably, complete, *and its future will depend on the subject, the place of application, and the care taken to protect the patient from extraneous sources of danger.* It may be compared to a mighty oak, each decade of years having added to its greatness until its far-reaching branches furnish shelter for the thousands of men and women who require abdominal section. Its ramifications are hysterectomy for fibroids, hepatotomy, cholecystotomy, normal ovariotomy, the Hegar-Tait operation for the removal of both ovaries and tubes, nephrectomy, exploratory incisions, gastrotomy, and enterotomy. It still continues to grow, and the task of pointing out the leaves that have been added to its foliage during the last year requires our efforts ere they fall about the roots and contribute themselves to the growth of the parent tree.

Valuable lectures and papers have been given by Dr. Keith, Mr. Lawson Tait, Mr. Savage, Sir Spencer Wells and Mr. Bryant, all in the *British Medical Journal.*

The results of valuable experiments on lower animals have been published by Prof. C. T. Parkes, of Chicago. Many successful cases of the Hegar-Tait operation done by our countrymen, and the surgeons of Great Britain, have been published in various journals.

Mr. Thornton has been successful in gastrotomy for the removal of a large foreign body, and has had seventeen successful cases of nephritic surgery, ten of these being nephrectomy by abdominal section. Drs. Keith and Bantock continue to do supravaginal hysterectomy with unparalleled success, and it is premised that, if their success continues, it will elevate their method of operating beyond the reach of controversy. They both adhere to the extraperitoneal treatment of the stump, while the continentals practise the intraperitoneal method.

The recent visit of Mr. Lawson Tait to the United States, has given a great impetus to the Hegar-Tait operation for the removal of diseased tubes, and for the removal of ovaries and tubes for the cure of fibroids of the uterus.

For the purpose of encouraging the conservative abdominal surgeons, *those who look carefully to the environment of their patients*, I point with great pleasure to the fine statistics of Dr. John Homans, of Boston, and of Dr. Robert Battey, of Georgia, whose early initiation of normal ovariotomy was suggestive eventually of the Hegar-Tait operation which included the tubes.

Ovariotomy and its offshoots comprise almost, if not the entire field of abdominal surgery. The establishment of the parent operation brought out the others, if not for the first time, it revived and established them after they had been practically abandoned. "The seed was sown by Bell and Hunter, carried by McDowell, and planted in Kentucky;" its first growth was slow, but gathering strength from the passing years, its top has risen high, and its great branches cover a wide space, where unfortunate men and women of every land and clime gather to find relief from suffering and to acquire new leases of life.

The carbolic spray is still a matter of dispute. In Great Britain, Mr. Thornton adheres to it as of old, Drs. Keith and Bantock, and Mr. Tait will have none of it. The latter said to me, "I sold out all my right, title, and interest in Listerism, with my tea-kettle to Battey."

So far as I know, the best statistics yet obtained in ovariotomy in the United States belong to Dr. Battey, of Georgia, and Dr. John Homans, of Boston, Mass., both of whom operate under the carbolic spray, and in apartments kept especially for abdominal operations. I make special mention of the fact that these gentlemen use the carbolic spray, for the reason that Dr. Emmet says in his last edition, p. 715, "I do not know of any prominent operator in this country who now uses the spray," evidently an oversight.

I do not use the spray myself, but look upon the entire Lister system, less the spray, as firmly grounded in the surgical mind. Cleanliness and Listerism can never be separated, for "Listerism is the gospel of cleanliness;" without the latter you cannot have the former.

The year has wrapped up in its eternal folds one whose name is synonymous with the surgery of women; one whose reputation is immortal, who in America at least, stood next to McDowell; beloved by his own countrymen honored by the entire surgical world. No eulogy of mine can increase his fame. I speak of *the great, the good, the pure, the noble, the generous* Marion-Sims. Like McDowell, he possessed a genius for origination, and will share with him the admiration and plaudits of future generations.

MEDICAL PROGRESS.

Posterior Tarsotomy in Clubfoot of Long Duration.—At the meeting of the French Surgical Congress, held at Paris, April 6, 1885, M. Gross, of Nancy, read a paper on posterior tarsotomy in clubfoot of long duration. Various operations are preferred by different surgeons to remedy this deformity. Poinsot and Beauregard prefer cuneiform incision. Lucas-Championnière practises ablation of the astragalus. Ollier advises a mixed operation—excision of the cuboid, of the astragalus, and of the anterior part of the calcaneus. In order to make intelligent choice between the methods proposed, the pathological anatomy of the parts affected must be considered, and a study of the osseous lesions in varus demonstrates that ablation of the astragalus may be an efficient means of correcting the deformity. Sometimes ablation must be supplemented by incision of the plantar ligament. M. Gross exhibited plaster moulds showing the condition of the foot after the operation, and demonstrated that although some internal curvature still existed, the equinism was corrected, and while

the axis of the foot was inclined toward the inner border, the firmness of the tibio-tarsal articulation is perfect and still retained a certain degree of mobility. Nevertheless, ablation of the astragalus does not suffice in every case, and in varus equinus, after such operation, there always remains a deformity which can only be remedied by excision of a portion of the calcaneus and cuboid. In other cases, excision of the external malleolus will serve to correct the adduction; also section of the tendo Achillis. Excision of the astragalus is, however, the preferable operation.

M. Gross held, in conclusion:

1. That posterior tarsotomy is to be preferred as an operation for varus.

2. That with antiseptic precautions the operation is not dangerous.

3. That the solidity of the foot is assured.

4. That the tibio-tarsal articulation remains mobile, and that the movements of the foot depend chiefly on the condition of the muscles.

5. That return of the deformity is not to be feared.—*Gazette Hebdomadaire de Medecine et de Chirurgie*, April 10, 1885.

Indications for Operative Interference in Deep Wounds of the Abdomen, Particularly in Traumatism of the Intestine without Lesion of the Abdominal Walls.—Dr. Charasse, at the meeting of the French Surgical Congress, held April 6, 1885, concludes a paper on the surgery of deep abdominal wounds by an enumeration of the following principles:

1. Laparotomy should be practised in every case of rupture of the intestine without lesion of the abdominal walls.

2. The operation should be performed as early as possible, and before peritonitis has become severe and alarming.

3. If the rupture is small, one suture should be made, and a drainage-tube introduced; if it involves the whole intestine, or half of its circumference, an artificial anus should be established.

4. The operation is one of incontestable utility, the death-rate in such accidents having been exceedingly high. It is not and cannot be harmful, even when confined to a simple exploratory incision.

5. Contraindications are a pronounced state of collapse, as indicated by a temperature of 95° to 96⅘° F.; concomitant lesions of the spleen, pancreas, kidneys, and liver (the bladder excepted).

Cancer a Germ Affection.—A. Ledoux-Lebard, in a paper recently published, advances the theory that cancer is a parasitic disease. In proof of the position assumed he cites the experiments of Langenbeck, Fallin, Lebert, Cohn, and others, in which inoculation with cancerous tissue was practised, some giving positive and others negative results. Ledoux-Lebard considers actinomycosis a variety of cancer, and arrives at the following conclusions:

1. By its clinical, etiological, and, especially, its anatomo-pathological characteristics, cancer presents marked affinity with tuberculosis, a parasitic disease. And hence, there is reason to suspect its parasitic nature.

2. Certain forms of cancer (actinomycoses), belonging to the sarcomatous variety of tumors, are of a parasitic origin. It is, therefore, reasonable to suppose that other varieties are also of parasitic origin.

The paper is followed by an extensive bibliography.—*Archives Générales de Médecine*, April, 1885.

Osteo-sarcoma of the Clavicle; Resection of the External Three-fourths of the Bone, followed by Cure, with Conservation of all the Movements of the Arm.—Dr. Polaillon reports a case of osteo-sarcoma of the clavicle, in which the distal three-fourths of the bone were removed with resulting cure and conservation of all the motions of the arm. The patient was a girl 16 years of age. Six months previous to the operation the tumor first made its appearance, and, yielding to no treatment, gradually increased in size. The skin was entirely normal; there was but little pain on pressure. No pain was experienced either day or night. Effort made to write for a long time caused some pain. Quick movement of the arms also caused pain. Elevation of the arms was very painful, and almost impossible. The cervical and axillary glands were not enlarged. Examination showed that the tumor was movable with the clavicle, and that it probably had no relation with the deeper structures. Operation was performed under the carbolic spray. To isolate the tumor the fibres of the deltoid and trapezius, inserted in the clavicle, were cut. The clavicle was cut through immediately external to the insertion of the sterno-cleido-mastoid muscles, and disarticulated from the scapula. Antiseptic dressing, under a compress of wadding, was applied. In two days the dressing was renewed. In two weeks all the sutures and drainage-tube were removed. The health of the patient was excellent.

The 25th of March, 1885, less than two months after the operation, the absence of the clavicle was scarcely noticeable. The contour of the shoulder was preserved, and careful observation necessary to detect any difference between the two sides of the body. The arm was easily put and held in a horizontal position and the hand placed, without difficulty, on the back or top of the head.—*Gazette Médical de Paris*, April 4, 1885.

Deadly Pistol Wound, and Embolus by the Ball.—Dr. Schmidt, in the *Centralbl. für Chirurgie*, 1885, No. 8, p. 131, reports a case of suicide by pistol, in which post-mortem examination revealed the following: The ball traversed the sixth intercostal space in a course from below upward and from before backwards, and penetrated the left lung at a point corresponding to the fifth rib on the left side. After traversing the lung a distance of nearly three inches, the ball perforated the anterior wall of the left pulmonary vein, without, however, passing through it; the posterior wall being simply eroded. Search for the ball resulted in its discovery in the femoral artery. Its presence here Dr. Schmidt explains by supposing that, having entered the pulmonary vein, it was carried by the current of blood into the left auricle, thence into the ventricle, and from the ventricle as an embolus into the femoral artery. The valves of the heart were found in a normal condition.

No similar case seems to have been reported in medical literature.—*Gaz. Méd. de Paris*, March 14, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 9, 1885.

THE TREATMENT OF CROUP.

THE terms croup and diphtheria have a never-failing interest to the practising physician, and there are probably no diseases concerning which he is more eager for information than these. It cannot be said that the ideas entertained with regard to these conditions, either as to their clinical history or morbid anatomy, are altogether unconfused, and contributions which promise greater definiteness from either aspect are always welcome. We have endeavored to keep our readers informed by noticing from time to time the most important facts, new or old, bearing upon the subject, as adduced in papers and in discussions before societies in this country and abroad, and have now to call attention to a recent valuable paper by DR. J. LEWIS SMITH in the *American Journal of the Medical Sciences* for April, 1885, and entitled "Membranous Croup; Diphtheritic Croup; True Croup."

Dr. Smith applies these terms to any pseudo-membranous laryngitis or laryngotracheitis, from whatever cause. The majority of cases are caused by diphtheria, but others are the result of cold, measles, pertussis, scarlatina, typhoid fever, and irritating inhalations; the rate of frequency being in the order named, and in all instances the morbid anatomy, clinical history, and required treatment are, according to Dr. Smith, so nearly identical that attempts to differentiate the disease as due to diphtheria or other cause, have been futile and unsatisfactory in districts where diphtheria occurs.

It will be seen that Dr. Smith does not ignore a croup due to cold, but says that the anatomical characters, clinical history, and required treatment are the same, and that in New York physicians scarcely recognize any other form of membranous croup than that caused by diphtheria. We do not think that this is exactly true of Philadelphia, for although it is a fact that the morbid anatomy is identical, and, it may be, the treatment demanded, it is generally recognized in Philadelphia that the adynamia in diphtheritic croup is much greater than in croup due to cold, and that the results of treatment, and especially of operative treatment, are correspondingly less favorable. At the same time we think Dr. Smith's classification a good one, and hope it may be generally adopted.

The differences in the false membrane in croup from cold and in diphtheria, are differences solely due to peculiarities in the mucous membrane on which it happens to be deposited. Thus there are no differences in that of the tracheal membrane from either cause, but the membrane formed in the fauces in diphtheria differs from that of croup from the same cause, as well as from that in croup from cold, in being more of the nature of a coagulation-necrosis, the coagulable material infiltrating the squamous cells, which die simultaneously with the infiltration, while in the larynx the membrane lies more upon the surface of the columnar cells.

With regard to treatment, which, for the reason given, he makes the same for all forms of croup, Dr. Smith evidently favors early tracheotomy,—that is, early after membranous laryngeal stenosis is established. He admits, however, that prompt measures, which, if deferred to a time in which such stenosis is established, are useless, may be of service in averting a degree of laryngitis indicated by simple hoarseness, which, if continued, might eventuate in irremediable obstruction. Such are keeping the air of the apartment moist by the croup kettle or by pans, over the fire, of hot water, to each of which is added a lump of lime, or better by steam atomizers. As an inhalation, he deems lime water, slightly turbid and containing about one and a half per cent. of liquor potassæ, as efficient and unirritating a solvent for false membrane as any of the alkaline mixtures. It also renders thinner and more easily expelled the mucopus, which collects in large quantities in the bronchial tubes, and is expectorated with difficulty on account of its viscidity.

Since its first introduction, Dr. Smith has also used with most satisfactory results, for dissolving pseudo-membranes, trypsin, and especially pencilling the fauces every half hour with a solution made by adding to six teaspoonfuls of water a teaspoonful of a mixture of one drachm of Fairchild's extract of pancreas and three drachms of sodium bicarbonate. A solution of trypsin prepared by Fairchild, and used with the atomizer, promises good results.

With regard to the calomel treatment, Dr. Smith admits that it probably exerts a salutary action

either on the exudative process or the pseudo-membrane, without being able to state precisely how it acts. In the ordinary form of diphtheria he would not advise the use of calomel, or would limit its employment to one or two doses of six to ten grains in the commencement of the disease, and in robust cases, but in the treatment of croup he would prescribe it in larger doses and for a longer time; but he does not order it after the first or second day, preferring other remedial measures which are efficient and less likely to produce injurious results. Our readers will be interested to know that a case of recovery is reported in which a child 28 months old took 20 grains of calomel dry on the tongue every two hours until the third day, when 720 grains had been taken, another of 3½ years in which 170 were administered, and a third, 130 grains in ten grain doses after a first dose of twenty grains.

Of the emetics, Dr. Smith considers sulphate of copper one of the best, in doses of two grains repeated, but that in ordinary cases probably the best is turpeth mineral—the yellow sulphate of mercury—in doses of two or three grains of the powder.

The value of the germicides Dr. Smith believes to be still *sub judice*, but gives their use, more particularly corrosive sublimate, due consideration, and refers to several cases in which the latter agent seemed to be followed by happy results. The well-known tolerance of children for the drug explains why it is that a child aged 9 years took $\frac{1}{40}$ of a grain every one and a half hours, and in one day nearly half a grain till the fifth day, when a little more than two grains had been taken. Similar cases are narrated, in one of which a child 2 years and 5 months old took $\frac{1}{48}$ of a grain every second hour for three days. Dr. Smith reccommends from the $\frac{1}{60}$ gr. to $\frac{1}{48}$ gr. every hour or two, but says, also, that it does not seem necessary or prudent, in ordinary cases, to continue the use of the bichloride more than three or four days, in large and frequent doses.

Supporting measures are also required, particularly when the croup is diphtheritic in origin, and among these the tinctures of the chloride of iron, potassium chlorate, quinine, brandy or other forms of alcohol, have their place. All these measures, however, especially if not promptly adopted, are inadequate in a large majority of cases, and surgical interference must be had The indications for it are, according to Dr. Smith, a gradual increase of the stenosis and consequent dyspnœa, notwithstanding constant and judicious use of remedial agents, and a manifest suffering from want of air, as shown by restlessness and the expression of suffering in the patient's features, with or without lividity of the surface. When these symptoms appear the duty of the physician to relieve suffering should prompt to operative treatment, even if the important object of saving life be disregarded.

The two operative measures employed are tubage and tracheotomy, with regard to which we may have something to say in a future issue.

If, now, we compare Dr. Smith's treatment with that of Jacobi, as published in his article on diphtheria in the volume of the *American System of Medicine* just issued, we find first with regard to steam, which Dr. Smith would appear to recommend for all cases of croup, that Jacobi says it can only be expected to increase the secretion from the mucous membrane, and thereby throw off the subjacent membrane, when there is a natural tendency to it—that is, where there are a great many muciparous follicles under a columnar or ciliated epithelium. This is the condition in the pharynx, but in only a small portion of the larynx, in the trachea and bronchi, but not on the vocal cords. Again steam in an overheated room, and without pure air, liable to be as injurious as steam in pure air is beneficial to many. Jacobi has repeatedly seen children with croup become less cyanotic after their removal from an atmosphere of vapor, and he can readily see that pure atmospheric air would be more agreeable and wholesome to a child with stenosis of the larynx than an atmosphere laden with steam.

Water, according to Jacobi, is serviceable in various ways. Taken in large quantities, it not only causes copious perspiration, but the same effect is produced on the mucous membrane. Cold and ice applications are not mentioned by Smith, and there is no single measure which we regard so useful. But, according to Jacobi, these, too, have their limit. They are not well borne by very young infants, and the beginning of recovery contraindicates their use, as does also the absence of fever. In such cases, while unlimited internal stimulation is required, the hot bath or hot pack, and hot injections into the bowel will be found beneficial.

Jacobi is not enthusiastic over the solvents for membrane, including lime water, glycerine, lactic acid, pepsin, papayotin, chinolin, and pilocarpine, doubting whether there are sufficient time and opportunity to produce a curative effect. Trypsin had not been introduced when he wrote his article.

Turpentine inhalations, recommended by Edel, are not referred to by Dr. Smith. Jacobi favors their use, floating a tablespoonful of the oil on water, which is kept boiling on a stove or over an alcohol lamp, care being taken that none is spilled on the flame. Ammonium chloride, for its softening and liquefying effect, may be used internally or burned over alcohol or gas. Calomel, for its constitutional rather than its abortive effects, is recommended by Jacobi, 8 to 12 grains in divided doses, and for the same purpose the oleate of mercury rather than the blue ointment, by inunction.

Jacobi's views as to the mode of administration of

the chloride of iron are such that, if they are correct, an important modification of the more usual plan will be necessary. He has not the least doubt that the failure of the remedy may be attributed, in most cases, to the fact that the doses are too small and too seldom administered. Accordingly, he would give 5 to 15 drops, properly diluted, every fifteen minutes or half an hour. Gargles containing this substance are of no service, because they do not remain sufficiently long in contact with the parts. Its direct application is needlessly irritating, while its frequent administration, in the manner described, secures sufficient local action, for which, as well as for its general effect, it is administered.

THE RADICAL CURE OF HYDROCELE.

AFTER Volkmann's operation for hydrocele, which consists in freely opening the sac, and stitching its edges to the scrotal tissues, the fluid reaccumulates in about 1.54 per cent. of all cases, from the failure of the apposed surfaces of the vaginal tunic to unite. With a view to obviate this untoward result, Julliard resects the vaginal tunic, saving, however, enough to cover the testicle and cord, and sews the edges together with catgut sutures. Of his 54 cases, there was recurrence in 1, or 1.85 per cent., so that his operation has not proved to be an improvement upon that of Volkmann on the score of infrequency of the failure of the procedure.

The latest operation that has been recorded is that of Von Bergmann, an account of which is published by his assistant, DR. BRAMANN, in the *Berliner klinische Wochenschrift*, No. 14, 1885. The hydrocele having been freely laid open, the parietal layer of the vaginal tunic is excised, the epididymis and testicle remaining covered by that membrane. The bleeding having been arrested, and the cavity irrigated with a three per cent. carbolic solution, the edges of the wound are approximated except at the most dependent part, at which point a drainage tube is inserted. The parts are then covered with sublimate gauze and cotton, and gentle compression exerted upon them by means of a carbolic bandage.

In the twenty cases in which the operation was practised, all pursued an aseptic and an almost afebrile course. In none was there suppuration or phlegmon of the scrotum, nor was epididymitis or orchitis met with, accidents which have not infrequently been observed after Volkmann's procedure. In from ten to twelve days the healing process had sufficiently progressed to enable the patients to resume their occupations, but in the majority of the cases there was a slight painless thickening in the region of the testicle, which disappeared in a short time.

So far as a conclusion may be drawn from the very limited test to which the operation of Von Bergmann has been subjected, it may be pronounced to be free from danger to life and the inconvenience of relapse; but whether this conclusion will be borne out by a more extended experience is very questionable. Thus, of 305 cases of Volkmann's operation which we have collated—and it is a simpler one than Von Bergmann's—4 died, and there was recurrence in 4, while, as we have seen, there was 1 recurrence out of 54 cases of partial excision of the vaginal tunic in the practice of Julliard. Our own opinion is that not a single one of these procedures should be resorted to in ordinary cases, but that they should be reserved for those cases in which the sac is much thickened, and for examples of recurrence after the injection of carbolic acid, which we regard as being the most promising, safest, and simplest of all the modern measures that have been suggested for the radical cure of hydrocele.

THE INTERNATIONAL MEDICAL CONGRESS AND THE AMERICAN MEDICAL ASSOCIATION.

THE action of the American Medical Association at its recent meeting, expressing dissatisfaction with the work of the Committee of Organization of the Ninth Session of the International Medical Congress, was unexpected, but it is now easy to see how it was brought about.

The Committee in undertaking its task, of course believed that it had been clothed with full powers, and, as far as authority from the American Medical Association is concerned, this belief appears to be justified by the resolutions under which the invitation was extended, and which were as follows:

"*Resolved*, That a committee of seven, of which Dr. Austin Flint, the President of this Association, shall be a member, shall be appointed by the President.

"*Resolved*, It shall be the duty of this Committee to extend, in behalf of the medical profession of the United States to the International Medical Congress about to meet at Copenhagen, a cordial invitation to have the next International Medical Congress meet at Washington, D. C., in 1887.

"*Resolved*, That the Committee shall elect its own officers, and that, in case the invitation is accepted, it shall proceed to act as an Executive Committee, with full power to fix the time and to make all necessary and suitable arrangements for the meeting of such Congress, and to solicit funds for this purpose.

"*Resolved*, That the Committee shall have power to add to its membership, to perfect its organization, and that, to meet the preliminary expenses of printing, postage, etc., the Chairman of this Committee is authorized to draw upon the Treasurer of this Association for an amount not exceeding four hundred dollars."

The Association acted on the hypothesis that, inasmuch as it had voted that an invitation be extended "in behalf of the medical profession of the United States," to the Congress to hold its Ninth Session in Washington, which had been accepted, therefore, the authority vested in it to organize the Washington Congress. The action of the Association in formally disowning the subsequent

work of the Committee of Organization must, of course, cause embarrassment, and great care is necessary to prevent unpleasant results, especially since the important appointments made in the course of preliminary organization have been widely published, both in this country and in Europe.

The Committee has acted on the theory that the International Medical Congress is a permanently organized scientific body, in which the medical profession of the United States has a right to be represented as a whole, that the men to be selected to organize the Sections should be men of scientific reputation both at home and abroad, and that if a man is thus well known, his place of residence is a secondary matter. The Association, on the contrary, prefers the State as a unit of organization to the United States, and wishes to have the Congress organized on essentially the same plan as the Association itself. This we believe to be a mistake, due to an erroneous view of the nature and objects of the Congress, but the mistake has been made, and the only thing now is to do the best that can be done under the circumstances, and to this end we are confident that wise and conservative counsels will ultimately prevail.

It is of course impossible to predict the action which the Committee of Organization will take in this matter. It is safe to say, however, that it will do nothing without due consideration, keeping in view its responsibility to the Executive Committee of the Copenhagen International Medical Congress, and its duty to the medical profession of this country as well as to that of Europe, to secure, if possible, harmonious action, and to prevent the country from being disgraced by a failure to meet the obligations incurred by the invitation which has been extended and accepted.

At the best, there must be, now, delay in the work of organization, but there is time enough to permit of this, and we hope that our professional brethren abroad will not jump to a hasty conclusion, and suppose that the dissensions which have been stirred up among us are so great that it will be better to change the place of meeting of the Congress.

LACTIC ACID AS A DESTRUCTIVE OF DISEASED TISSUES.

Professor Von Mosetig-Moorhof, of Vienna, induced by numerous observations upon the destructive action of concentrated lactic acid upon fungous granulations, has most successfully employed that agent in lupus vulgaris, superficial epithelioma, and papillomatous growths. When brought in contact with diseased tissues, the latter, in the course of a few hours, are converted into a loose, black pultaceous mass, the cells, stroma, and vessels being completely destroyed, without the slightest effect having been exerted upon the adjacent healthy parts, through which the agent possesses manifest advantages over ordinary escharotics.

The mode of applying the remedy is as follows: The parts, having previously been carefully cleaned, are covered with absorbent cotton wet with the fluid, over which a piece of impermeable material, as rubber cloth, is placed, and the whole confined with a roller; or a soft paste, made by the addition of pure silicic acid, is spread upon gum tissue, and secured in place. At the expiration of about twelve hours, the dressings are removed, and water applied for one or two days, when the application is renewed. The treatment is continued in this way until all the morbid tissue has disappeared, as is shown by commencing cicatrization The application is by no means painless, but it is readily borne.

The resulting scar is soft and smooth, but as yet Mosetig is unable to speak as to the final result with regard to recurrence. He, however, thinks that lactic acid is indicated more especially in those cases of lupus and rodent ulcer in which the patient objects to the use of the spoon, and in cases of epithelioma which are beyond the reach of the knife. The remedy certainly deserves a fair trial, as it is the only one of which we have any knowledge that acts solely upon the diseased tissues. Mosetig's paper may be found in the *Centralblatt für Chirurgie*, No. 12, 1885.

ABDOMINAL SECTION IN RUPTURE OF THE CYST IN EXTRAUTERINE PREGNANCY.

Authorities differ as to the proper treatment in case of rupture of the cyst in extrauterine pregnancy. Lawson Tait, whose views upon this subject were presented to our readers a few months since, strongly advocates immediate abdominal section with removal of fœtus and of the fluids that have been poured out in the abdominal cavity, and arrest of hemorrhage by ligation of bleeding parts. On the other hand, Dr. W. W. Jaggard, in a paper recently read before the Chicago Medical Society, strongly advocated palliative measures in such condition. Dr. Jaggard, in the course of his argument, suggests it as possible that recovery after ectopic gestation is not an uncommon event, quoting Schroeder, who states that he so frequently sees cases of tubal pregnancy, in which the diagnosis is positive, pursuing a favorable course, that he considers recovery as the regular termination. He further regards the prognosis of the operation of abdominal section as very unfavorable, among other reasons, because of the patient being in a condition of more or less profound shock, and because of her acute anæmia, while the anatomical conditions of the parts are not easily made out even in post-mortem examinations of those who have died from ruptured gestation cyst.

The palliative treatment is also advocated by Karl Braun, Schroeder, Martin, Wells, Thomas, and Emmet.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Thirty-sixth Annual Meeting, held at New Orleans, April 28, 29, 30, and May 1, 1885.

(Specially reported for THE MEDICAL NEWS.)

FRIDAY, MAY 1ST.—FOURTH DAY.

THE Association was called to order at 10.30 A. M. by VICE-PRESIDENT DR. J. S. LYNCH, of Maryland.

The Committee of Arrangements reported a few additional entertainments.

The following were announced to have been appointed, under the resolutions adopted on Wednesday, as the additional members of the Committee of Arrangements for

THE INTERNATIONAL MEDICAL CONGRESS:

Dr. G. A. Ketchum, of Mobile, Ala.
Dr. D. A. Linchicum, of ——, Ark.
Dr. R. Beverly Cole, of San Francisco, Cal.
Dr. Chas. Denison, of Denver, Col.
Dr. ——, of ——, Conn.
Dr. L. P. Bush, of Wilmington, Del.
Dr. A. Y. P. Garnett, of Washington, D. C.
Dr. R. D. Murray, of ——, Fla.
Dr. R. Battey, of Rome, Ga.
Dr. E. P. Cook, of Mendota, Illinois.
Dr. F. M. Beard, of Vincennes, Ind.
Dr. ——, of ——, Iowa.
Dr. D. W. Stormont, of Topeka, Kan.
Dr. W. H. Wathen, of Louisville, Ky.
Dr. J. W. Dupree, of Baton Rouge, La.
Dr. S. C. Gordon, of Portland, Me.
Dr. J. S. Lynch, of Baltimore, Md.
Dr. A. H. Wilson, of South Boston, Mass.
Dr. A. R. Smart, of Hudson, Mich.
Dr. George F. French, of Minneapolis, Minn.
Dr. J. M. Taylor, of Corinth, Miss.
Dr. N. F. Essig, of Plattsburg, Mo.
Dr. R. C. Moore, of Omaha, Neb.
Dr. J. W. Parsons, of Portsmouth, N. H.
Dr. William Pierson, of Orange, N. J.
Dr. Ellsworth Eliot, of New York.
Dr. ——, of ——, N. C.
Dr. N. C. Scott, of Cleveland, Ohio.
Dr. J. V. Shoemaker, of Philadelphia, Pa.
Dr. W. E. Anthony, of Providence, R. I.
Dr. R. A. Kinloch, of Charleston, S. C.
Dr. F. L. Sim, of Memphis, Tenn.
Dr. William McLaughlin, of Austin, Texas.
Dr. W. C. Dabney, of Charlottesville, Va.
Dr. ——, of ——, Vt.
Dr. G. Baird, of Wheeling, W. Va.
Dr. N. Senn, of Milwaukee, Wis.
Dr. Robert Murray, U. S. A.
Dr. J. B. Hamilton, U. S. Marine Hospital Service.
Dr. F. M. Gunnell, U. S. N.

The Committee was called to meet at once.

DR. QUIMBY, of New Jersey, offered the following:

Resolved, That the Committee appointed in pursuance of a resolution adopted by this Association, April 30, 1885, to constitute an addition to the original Committee of seven previously appointed to invite and make arrangements for the meeting of the International Medical Congress, to be held in Washington, D. C., in 1887, be, and the said Committee is, hereby authorized and empowered to select a Chairman and a Secretary, and to fill all vacancies that may occur by death or inability to attend in the committees, and to appoint the officers of the Congress. Adopted.

PRIZES.

DR. R. HARVEY REED, of Ohio, offered the following:

Resolved, That a committee of three be appointed by the President, whose duty it shall be to devise a system for the awarding of honors to those who may desire to present original papers at the next meeting, and that the said committee shall report through the *Journal* of the Association. Adopted.

THE RESIGNATION FROM THE JUDICIAL COUNCIL

of Dr. Brodie was read and the resignation accepted.

STATE BOARD OF MEDICAL EXAMINERS.

The Section on State Medicine presented the following:

Resolved, That the Section on State Medicine heartily recommends the appointment in each State of a State Board of Medical Examiners and Licensers.

That the Committee appointed by the Association shall construct and forward to each State Society the form of a bill, the passage of which by the Legislatures these Societies shall be requested to urge strongly.

DR. KELLER, of Arkansas, asked that his resolution in regard to

CREMATION,

offered three years ago, be now taken from the table and considered. On motion, it was referred to a special committee to report next year.

The Nominating Committee reported the following additional

NOMINATIONS:

Trustees of the Journal.—Drs. J. M. Toner, of Washington; J. H. Hollister, of Chicago; E. M. Moore, of Rochester, N. Y.

Committee of Arrangements.—Dr. Legrand Atwood, of St. Louis, Chairman.

Judicial Council (to fill vacancy occasioned by resignation of Dr. Brodie).—J. K. Bartlett, of Wisconsin. Adopted.

THE ADDRESS IN OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY,

was read by DR. J. A. WHITE, of Virginia. After referring to the difficulties of reviewing, in a proper manner, the advancements that have been made in any single branch of the medical sciences, he gave a critical review of the ophthalmological work of the past year; notably, the efforts made for the improvement in the treatment of detached retina. He also recommended the substitution of enucleation by evisceratio bulbi, which was originated by Dr. Henry D. Noyes, of New York, but was comparatively unknown until Alfred von Graefe brought it prominently forward. The important work of Landolt in determining the converging power; the improved indications for the use of jequirity; and the value and application of cocaine,

with an explanation of its physiological action, all received due attention.

The main consideration of the paper was the reflex neuroses of the nose, such as reflex cough, sick headache, hay asthma, etc., in which, with a full review of the present aspect of that question, the author produced facts, in many instances somewhat at variance with the idea that engorgement of the nasal mucosa is essential to the production of the reflex phenomena.

Dr. J. H. Pope, of Texas, then delivered

THE ADDRESS IN DISEASES OF CHILDREN.

He said that there have been no special advances in the department which he represented, unless it be in the improvements in certain methods of treatment, and in remedies. A good many so-called specific remedies have been introduced, and their value cannot be determined at so recent a date. Among other advances has been the use of disinfectants. Notably among these is the bichloride of mercury. Dr. J. Lewis Smith, of New York, has called especial attention to his results from its use in diphtheria. Some of the cases which he has reported are remarkable. In some of them tracheotomy appeared almost unavoidable, but by the persistent use of bichloride of mercury the dangerous symptoms were averted.

As regards the pathology and etiology of children's diseases, there cannot be said to have been any advance. He, however, stated that in his experience a new view of the causation of rickets could be advanced. He had observed that it occurred more frequently in children who were nourished at the breast until long after the proper time for weaning than in any other class. Too long nursing then was one of the most frequent causes of the affection. He expressed, in conclusion, strong regret that the Section on Disease of Children is not better attended at all the meetings. This fault was not perhaps so patent at this meeting as at a number of previous ones, when compared with the attendance, but there was still not the number present that should have been.

Dr. Quimby, of New Jersey, reported that the committee appointed to consider the suggestion of the President that a section on forensic medicine be added to the present list of sections, had considered the matter and now recommended that such a section be formed, to be styled, a

SECTION ON MEDICAL JURISPRUDENCE,

and that the constitution be so amended as to admit of this addition to the sections already in existence.

The Address on Oral and Dental Surgery was read by title, the author, Dr. W. W. Allport, of Illinois, being absent.

THE REPORT OF THE COMMITTEE ON NECROLOGY

being called, Dr. J. M. Toner, the Chairman, stated that since the establishment of the *Journal* he had reported promptly through it all the deaths of members. He asked further that the members of the Committee on Necrology, in each of the States, should report promptly either to him or to the editor of the *Journal* all deaths of members as they occur.

Dr. Eugene Smith, of Michigan, stated that at the last meeting of the Association a resolution was offered by Dr. Seiler, of Philadelphia, providing for the

DIVISION OF THE SECTION ON OPHTHALMOLOGY, OTOLOGY, LARYNGOLOGY, AND RHINOSCOPY,

into two separate bodies, one to be known as the Section on Ophthalmology, the other as the Section on Otology, Laryngology, etc., and moved that it be now taken up for action.

The motion being carried, Dr. Smith moved that it be permanently tabled, such a division being clearly inexpedient and unnecessary. The motion was unanimously carried.

A motion was then made to take up the remaining resolutions laid on the table at the last meeting.

Dr. Von Klein's (Ohio) resolution providing for the requirement of a

HIGHER EDUCATION

in order to become members of the American Medical Association, and other requirements intended to elevate the standing of the profession, was then called up.

The Secretary stated that a letter had been received from Dr. Von Klein, requesting that his resolutions be laid on the table for another year. It was the opinion of the Association that they could be acted upon at once, and they were tabled indefinitely.

The resolution of Dr. Cochran, of Alabama, that it is the sense of the Association that it is not expedient for the members of

THE NOMINATING COMMITTEE

to nominate any of its own members to offices of the Association, was taken up and discussed at length, and finally laid on the table.

A VOTE OF THANKS

was tendered by the Association to the entire profession of New Orleans, and particularly to the Committee of Arrangements, who have by their attentions and kindness enabled the members to enjoy thoroughly this meeting of the Association. Also to Dr. and Mrs. T. G. Richardson, Mr. and Mrs. Cartwright Eustis, and the New Louisiana Jockey Club, all of whom have added greatly, by their hospitality, to the enjoyment of the Association.

Dr. M. H. Henry was announced as a

DELEGATE TO THE BRITISH MEDICAL ASSOCIATION,

and it was further resolved that other members desiring to become delegates could be elected by the vote of the President and Permanent Secretary.

THE PRESIDENT-ELECT,

Dr. Brodie, was then introduced, and accepted the trust in a few words of appreciation of the favor.

The retiring President, Dr. Campbell, thanked the Association for their consideration and assistance during the session just ended.

Adjourned.

Section on the Practice of Medicine, Materia Medica, and Therapeutics.

Tuesday, April 28th.—First Day.

The Section was called to order at 3.40 P. M., Dr. H. D. Didama, of New York, Chairman, presiding.

Dr. W. A. Love, of South Carolina, stated that if he

was in order, he would move that the resolution from the South Carolina Medical Society on the

DISCOVERY OF THE ANÆSTHETIC PROPERTIES OF ETHER,

which was referred to this Section by the Association, be entrusted to a special committee, with instructions to report at this meeting, if possible; if not, at the next.

Adopted.

The Chairman appointed Dr. W. A. Love, of South Carolina; Dr. H. J. Bigelow, of Massachusetts; and Dr. R. J. Dunglison, of Pennsylvania.

Dr. L. Duncan Bulkley, of New York, read a paper on

THE TREATMENT OF CARBUNCLE WITHOUT INCISION.

He related the case of a gentleman, aged 56, large and florid, who suffered for several years with eczema of the left foot. He was also diabetic. Following upon this eruption was a large carbuncle. He applied to this tumor, thickly spread on the woollen side of lint, the following ointment:

R.—Ergot. fl. ext.	℥ij.
Zinci oxidi	℥ss.
Unguent. aq. rosæ	℥ij.—M.

Covering this was cotton-batting, to prevent blows or injury. He was given sulphite of calcium ¼ gr. every two hours, and occasionally the following:

R.—Magnesiæ sulphat.	℥iv.
Ferri sulphat.	℥j.
Acid. sulphurici dil. . . .	℥iij.
Syr. zingiber.	℥j.
Aquæ	ad. ℥iij.—M.

S.—Teaspoonful in water through a tube three times daily.

At bedtime, Dover's powder was administered to give rest when required. The result of the treatment was cessation of pain, rapid resolution, and a cure, except some induration, in eighteen days. The man continued at his work.

He summed up his paper as follows:

1st. Avoid any irritation, as pressure, blows, etc.

2d. Avoid warmth and moisture, as in poultices.

3d. Avoid incision.

4th. Do not use stimulants.

5th. Protect the inflamed parts with the ointment given above. The solid extract of ergot may be used if desired. Spread the ointment at least one-third inch thick.

6th. Use sulphite of calcium every two hours for its effect upon suppuration.

7th. Employ good, nutritious food, and fresh air.

8th. A sedative, if desired, and occasionally the laxative and refrigerant tonic as above.

The advantages are:

1st. Short time required for recovery. 2d. Cessation of pain. 3d. No scar. 4th. No operation. 5th. No detention from business.

Dr. Hibberd, of Indiana, said that up to a year ago he had tortured his cases with poultices, incisions, and the orthodox measures generally. Since then he had used in every case oleate of morphia. He had this rubbed gently into the base of the tumor, and gradually encroaching upon the tumor itself, every three hours. The pain always ceased within twenty-four hours, and in ten to fifteen days the patients were well, except a little induration.

Dr. Savage, of Tennessee, three years ago began the use of cantharidal collodion applied in a ring one-half to one inch broad around the base. This forms a blister and eases the pain at once. He makes a small incision, also, if pus has formed. In one case he applied a cantharidal plaster over the whole tumor and extending beyond it, with excellent results; the patient a farmer, was following the plow in a week. He gives internally calcium sulphite, one-fourth of a grain, four times daily.

Dr. Bulkley said that he uses this form of treatment in large and small tumors. He lets them run their course, protecting them as much as possible and allows nature to do the opening. In using calcium sulphite, it is important to be sure that it is fresh; the gelatine-coated preparation is preferable. Exposed to the air, it becomes gypsum. He had not used oleate of cocaine.

Dr. A. F. Pattee, of Boston, read an article on

THE PERCUTEUR: ITS USE IN DISEASES OF THE NERVOUS SYSTEM.

This instrument had been introduced by Dr. Granville, of England, to carry out his theory of nerve vibration and excitation in the cure of disease. In the instrument exhibited electricity was used to give motion to the hammer. By this hammer percussion was practised along the course of diseased nerves or the spinal cord. Several cases were detailed in which improvement followed.

Dr. R. Harvey Reed, of Ohio, read a paper on

HYDATID TUMOR OF THE BRAIN.

He stated that hydatid cysts are caused by either the echinococcus or the cysticercus cellulosa; that the former are the embryo of the tænia echinococcus and the latter of the tænia solium. He then followed with a description of a cycle of life of these parasites as he understood them, and closed with a detail of his four cases. The size of the cysts varies according to the locality and the space allowed for expansion. No very great damage results from these cysts if they occur in the cellular tissue. In muscle tissue the danger increases with the depth. Those deposited in the posterior chamber of the eye give serious trouble. In the brain they are rare, are ultimately fatal, and the symptoms are very obscure. He had charge of four cases, in all of which he had held autopsies and in two of which he had diagnosed hydatids before death.

A travelling doctor, age 46, first came to Dr. Reed in 1880, complaining of being easily fatigued both mentally and physically. Later he began to suffer from vertigo, which increased; his head would fall forwards; if he attempted to walk he staggered; very nervous; appetite bad; bowels regular; urine normal; stupor supervened, increased, and death followed. At the autopsy an hydatid tumor was found.

Dr. ——, of Iowa, was inclined to doubt the correctness of the diagnosis had not the statements been proved by the microscope. Cases of this nature are rare in this country, and many physicians had never seen a case. It would be difficult for the parasite to

find its way into the brain, and it is strange that in none of the cases were any of the other organs, especially the liver, affected.

DR. WHITTAKER, of Cincinnati, did not think these cases could serve as statistics until Dr. Reed furnished trustworthy and satisfactory evidence that the tumors were hydatid cysts. Certain cysts occurred in the brain, some of an apoplectic nature, which resembled in many particulars hydatid cysts. He would ask who made the microscopical examinations, and what the results were?

DR. REED could not explain how so many cases should occur in Ohio. It is just as easy for the embryo to get into the brain as anywhere else. He had examined many cysts from the rabbit, in which animal they are frequent, and he is familiar with the microscopical appearance of the tumors and the hooklets. He had examined two of the tumors, and demonstrated their hydatid nature. One of the tumors had been sent to Cleveland, where it was lost, the other had been stolen.

Several members, among them Dr. Didama, and Dr. Hibberd, objected to Dr. Reed's statements of the natural history of the tæniæ and the stages of development. The Chairman gave the generally accepted views on this point.

DR. WHITTAKER, of Cincinnati, read a paper on

AN ATTEMPT AT A RADICAL TREATMENT OF TUBERCULOSIS.

The attempts were made with subcutaneous or parenchymatous injections of a solution of bichloride of mercury into the lung at the site of the disease. He used a preparation consisting of common salt 10 parts to 1000, and corrosive sublimate 1 to 1000. He administered the injections every day, amounting to about one-eighth of a grain in a syringeful of water. Though he watched the cases carefully the results were negative.

WEDNESDAY, APRIL 29TH.—SECOND DAY.

The Secretary read DR. AUSTIN FLINT'S paper on

A UNIFORM NOMENCLATURE OF PHYSICAL SIGNS WHICH OCCUR IN CONNECTION WITH THE RESPIRATORY SYSTEM.

The Secretary conveyed Dr. Flint's regrets at his enforced absence, and his request that his paper be read.

The paper was a provisional report of the Committee appointed at the meeting of the International Medical Congress, in London in 1881. The Committee had been composed of English, American, French, and German members, and it was decided that work should be assigned to five subdivisions in accordance with the nationalities above mentioned. Five lists were thus drawn up with much care and study, and were exchanged. The result of their work has already appeared in THE MEDICAL NEWS, of Sept. 6, 1884, p. 273.

Heretofore terms were very loosely applied, and carelessly selected—in some cases signs were named after authors or discoverers. They should be chosen by analytical study, by analysis, and comparison of physical signs. The most important elements to be considered in establishing a nomenclature of physical signs are: 1, intensity; 2, pitch; 3, quality; 4, distance; 5, moisture or dryness; 6, succession or continuity. The only solid foundation for such a study are clinical observation and autopsies.

The Secretary read a paper by DR. A. T. KEYT, of Cincinnati, on

CARDIOGRAPHY,

which was defined to be the art and science of graphic representation of the heart's action by means of an instrument based on the same principle as the sphygmograph, and applied to the heart's point of impulse upon the chest. It is less known than its sister instrument, but was applied as early as 1880, by a French observer, and is worthy of attention. The application of the cardiograph was illustrated by diagrams and some cases.

DR. N. S. DAVIS addressed the Section on the

RELATION OF CHEMICAL FACTS TO THE QUESTION OF CONTAGIOUSNESS OF PHTHISIS PULMONALIS.

The determination of such a question as the one before us, he said, should rest on the completeness of clinical history and observation, with a careful study by instruments of precision of all the secretions and fluids of the body. If the bacillus tuberculosis is found in some excreta, we are at once told that the case is phthisis, and the bacillus is the cause. Are these statements necessarily correct? Grant that the bacillus is found in all tubercular matter and not in other matter, and grant that such tubercular matter, if inoculated, is always followed by tuberculosis, is it necessarily the case that the bacillus is the cause of the disease and the disease itself contagious? Is it not just as fair to presume that the bacillus is simply an accompaniment of the diseased process found with it, but not the cause? Is it not just as legitimate to say that it got there after the beginning of the disease, but not as a cause? But some form of bacteria accompanies every form of deterioration. The microscope must be called in to assist in settling this point. It has shown that the bacillus is not present in all cases. But if a microscopist, however expert, finds some tubercular matter without the bacillus, they say his observations are imperfect. According to this, Koch must examine every specimen of such matter, or the result will be questioned.

If tuberculosis follows the inoculation of tuberculous matter, or the bacillus in animals easily made tuberculous, then three probabilities may be asserted: 1. The bacillus may be the cause; 2. The matter may be the cause; or, 3. The excreta may be the cause. Inoculation with the bacillus *alone*, without any other matter, has never been accomplished, and doubts must always accompany the results of the experiments until some one catches one of these little organisms by the tail and inserts it alone in the subject. One great fault of medicine is jumping to conclusions from one, two, or three data. We are told if we fail to find bacilli maybe the spores are there. As to spores, he would say that years of microscopical study have shown him that one can see anything with the instrument he sets out to find. Where do spores come from? If a body of a healthy man be exposed twelve hours in a high temperature an abundance of spores will be found. All organic matter undergoing decay is accompanied by some form of spores. May not the atoms of bioplasm which develop into

high forms, as cells, in the process of deterioration change in germs.

He has gathered up much material reviewing the clinical facts of cases supposed to have resulted from contagion. Of the millions exposed to infection he ventured to say that not one in a thousand manifests any indication of the disease. In the Hospital for Consumptives, in which there has been an average of fifteen Sisters of Charity as nurses since 1850, not one has died of phthisis. Of the internes, of whom there are usually four, not one that had not any indications of the disease prior to his entrance has died of consumption. And the story is the same in all hospitals. When we adduce such facts we are given histories of cases where husbands infect their wives, or vice versa. These are only coincidents. We are further told that bacilli are floating in the air. If so, and the bacillus is the cause of consumption, why has not the human race been annihilated? We are told that it requires a predisposition or starting point of deterioration. If so, then logic would say that the deterioration or predisposition was the disease, and the bacillus was only present as other germs.

Dr. Lynch, of Maryland has been engaged in investigating this question, and had attended the meeting at Washington for this purpose. The conclusion at which he had arrived was that the bacillus is not a factor in the cause of phthisis. It is found wherever there is any cellular matter. In every pathological state some bacteria are present, but they do not produce specific disease if carefully separated from the matter in which they exist. Ten young men inoculated themselves with the gonococcus without any result.

Dr. Whittaker, of Cincinnati, believed that tuberculosis is contagious, and that the bacillus is the cause. He believed that more than half of us have tuberculosis, but only a few develop into consumption and die.

Dr. Shoemaker read a paper on *The Hypodermatic Injection of Oils in the Treatment of Diseases;* and Dr. R. J. Nunn, of Savannah, read one on *The Mineral Foods, and How to Give them.*

Thursday, April 30th.—Third Day.

Dr. J. H. Hollister, of Chicago, read a paper on

cholera and its treatment.

1. Its origin; 2. Its pathology; 3. Its manner of propagation; 4. Its means of control; 5. Its treatment. The origin was still more or less in doubt, but most probably on the Ganges. It first appeared in London in 1669, and in Paris in 1793. In Madras it was endemic, and under certain meteorological conditions became epidemic. In America it is not endemic. It is only communicated from foreign countries. It is not spread by air or ocean currents, but is always brought in infected ships from infected ports. It moves inland only along lines of travel. It never appears in localities absolutely isolated. The comma-bacillus is the practical point of discussion. Is it the cause of cholera? The French Commission in Egypt reported adversely to such an opinion, and Dr. T. Lewis, of Calcutta, states that the so-called comma-bacillus, or something similar to it, is found in the saliva of healthy persons. The crucial test, inoculation and production of the disease, has not been performed. The conditions for the life and growth of the poison outside of the system are: 1. Warmth; 2. Moisture; 3. Decaying organic matter.

Dr. Austin Flint, who was to have opened the discussion, sent a short paper, in which he stated his belief in the specific character of cholera and in the comma-bacillus as the cause. Then, without developing them, he raised the points of the importance of quarantine and other means of prevention of cholera and its control when in progress.

It may be disseminated by air and water, but are there not other means? Do choleraic dejections contain the agent, and is it in those of cholerine? He believed that cholera might be stamped out as in New York, in 1867, where house-to-house inspections were so valuable. It was important to treat the premonitory diarrhœa, to remove filth, and afford good hygienic measures. In therapeutics, which are wide, nothing compares with opium up to the stage of collapse.

Dr. N. S. Davis said that he was a total disbeliever in the idea of importation. He had seen cases develop in the city totally independent of each other, and before any such thing as cholera was thought of. It is one thing to follow the official record and another to be right there yourself. It was in Chicago six weeks before it became known. He had reported a case of cholera nearly two months before the authorities discovered the disease, but his statement had been pigeonholed. In July, 1866, it started in Chicago; a rainy season in August washed the city clean, and the disease died out. In October it became hot and sultry, and it broke out again in the filthiest part of the city. The treatment of cholera is cleanliness.

Dr. Lynch had very little belief in the bacillus as a cause. Dr. Flint deprecates opium in collapse. In cholera nostra, with rice-water discharges, blue, cold surfaces and contracted skin, he uses morphia and atropia with immediate success. He would use it in cholera.

Dr. Jones, of New Orleans, believed in the germ theory as applied to cholera, that it is portable, and depended upon bad sanitation. It came down the river in 1832, and driving out yellow fever, caused six thousand deaths in twenty days.

Dr. Taylor, U. S. Army, thinks the disease contagious, but is doubtful as to the part played by the comma-bacillus. Isolation, in his opinion, is an absolute prevention. Nothing equals opium in the early stages, but it is contraindicated in collapse.

Dr. Whittaker, of Cincinnati, thought the disease imported and a germ disease. No chemical agent increases in the body as does the poison of cholera. Koch did not claim that the comma-bacillus is the cause of cholera; it is present in all cases.

Dr. Jerome Cochrane, of Alabama, read a short paper on

hemorrhagic malarial fever,

and stated some of his conclusions as follows:

1. This form of malarial fever originates only in malarial regions, though it may exhibit itself elsewhere.

2. The poison is the same as that in remittent and intermittent fevers.

3. It may show itself in the following forms: *a*, intermittent; *b*, remittent; *c*, congestive; *d*, quasi-continued.

4. The congestive form is almost necessarily fatal, the prognosis in the remittent and the quasi-continued forms is bad, the intermittent form is less fatal.

5. The negro is comparatively exempt.

6. Only those persons suffering under malarial cachexia are attacked.

7. One attack is not protective.

8. It begins usually in the afternoon or at night with a chill, followed by fever, bilious vomiting, discolored urine, jaundice.

9. The fever, except in the remittent and quasi-continued form, is not usually high.

10. Skin harsh and dry.

11. Bowels constipated, liver torpid.

12. Vomiting, early nausea, matter yellow, green, black, or even blue.

13. The black vomit is usually changed bile and in the beginning of the case.

14. Icterus begins with chill, and deepens rapidly.

15. Characteristic red urine, profuse at first, begins with chill. In fatal cases there is suppression.

16. This red urine is albuminous with granular casts. Color is due to blood-pigment hæmoglobin, not corpuscles.

17. The post-mortem appearances are similar to those of other malarial affections with enlargement of the kidneys added.

Cases reported	642
Deaths	188
Per cent.	24.60

Blood-corpuscles in the urine are accidental. The serum of blisters is colored the same way.

As to treatment:

1. The superabundance of bile renders the use of mercurials of great service. Some physicians use small, frequently repeated doses. Others like large doses—in one instance, a doctor was in the habit of giving 60 to 70 grains at a time.

2. Warm drinks are of service in promoting emesis, to get rid of the large amount of bile thrown into the stomach.

3. Sweating to reduce the harshness of the skin, and promote its action for this purpose, heat to the surface, hot drinks, and occasionally diaphoretics are used.

4. Management of the kidneys is a disputed point. The majority are in favor of letting them alone. Even in suppression of urine, trust to the compensatory action of the bowels and skin.

5. Quinine was formerly looked upon as the sheet-anchor in this affection. It exerts less control here than in any other form of malaria, and is losing gound.

DR. GHENT, of Texas, had treated forty-seven cases with five deaths. He thinks the red color due to blood-corpuscles. He uses calomel first, last, and always.

DR. TAYLOR, U. S. Army, had an experience similar to Dr. Cochrane's. But he had always found micrococci in the blood of these cases, and always blood-corpuscles and albumen in the urine. It is very fatal. Quinine will control the fever to a certain extent, but nothing more. Calomel and bicarbonate of soda in small doses are of great value.

DR. JOS. JONES, of New Orleans, thinks most cases of so-called hemorrhagic malarial fever, or hæmaturia, are really melanuria. The fibrin is increased as in inflammations. There is red matter in the urine in all fevers. In melanuria, in addition to blood-corpuscles, there is also bile, as proved by testing with nitric acid. Serum of a blister is so colored. The origin of this disease is congestion of the kidneys, and the consequent pouring out of blood in the tubuli, just as in congestion of the brain. The rest of the pathology is due to the want of functioning of the kidneys because of this fact. The prime cause is malaria. He is prepared for good effect from calomel, since the pathology includes an increase of fibrin in the blood, but he would not abandon quinine.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

TUESDAY, APRIL 28TH.—FIRST DAY.

DR. R. S. SUTTON, of Pittsburg, Chairman, called the Section to order.

DR. WM. H. WATHEN, of Louisville, read a paper on the

TREATMENT OF THE SECUNDINES IN ABORTION AND LABOR,

of which the following is an abstract:

Three methods have been urged: (1) The expectant method; (2) The immediate removal; (3) A course, intermediate. During the first two months of pregnancy no placenta exists, and the egg, together with the decidua, is usually expelled in abortion *en masse*. Even in case of retention of membranes, during this period, no operative interference, of a radical character, should be instituted, as the fœtal envelopes are comparatively innocuous, and the danger from trauma is relatively great. From the third to the end of the seventh month, it is advisable to remove the secundines immediately, irrespective of the condition of the cervix as regards dilatation.

The retained placenta in premature labor, or labor at full term, should always be removed at an early period. If the os is dilated, the fingers or curette suffices; if the os is not dilated, he employs a modification of the steel dilator of Scanzoni. The cervix can be dilated by this means to a width of two and one-half inches, and the secundines can be removed by the finger, curette, or forceps. Instead of the curette, a piece of copper or iron wire properly curved may be used. The separation of amnion from chorion, without rupture of bag of waters, as recently pointed out by Dr. Sawyer, may occur. This is a subject to which text-books do not allude. In the third stage of labor, if the placenta was not spontaneously expelled within thirty minutes, it should be removed. He had no confidence in the Strasburg method of treatment of the third stage. The old method of the application of the *vis a fronte*, by traction on the cord, and Credé's method of the application of the *vis a tergo* by expression, should be combined.

DR. JAMES R. CHADWICK, of Boston, said it was impossible to formulate a universally applicable rule. The treatment during the first two months should be governed by the history of the case. If the woman was a "bleeder," immediate operative interference should be instituted; if she had had previous abortions, it was advisable to temporize. Placental forceps were absolutely worthless; the best instrument for the removal of the secundines, as insisted upon by Dr. Sinclair, of

Boston, was the finger. The finger was also the best dilator.

Dr. Green, of Kentucky, pursued the intermediate course, as illustrated by the history of a case of abortion in the fourth month, with retention of fœtal envelopes.

Dr. Sinclair, of Boston, agreed with Dr. Chadwick that manual dilatation of the cervix is the best method. When the os is contracted, the fibres will usually yield to the finger in from six to eight minutes. He is in favor of immediate removal of the secundines.

Dr. Carroll, of Texas, referred to the fact that the retention of a small shred of decidua or of a clot of blood is sufficient to cause alarming hemorrhage. He would not hesitate to use an Ellinger's dilator in case of non-dilated cervix, but thought the finger a better instrument.

Dr. Wathen closed the discussion by saying that he advised the use of his own modification of Scanzoni's dilator only in extreme cases in which the finger had already been employed without effect.

Dr. W. W. Potter, of Buffalo, N. Y., reported the following case of

PARAMETRIC ABSCESS:

Mrs. B., 38 years old, the mother of three children, experienced sudden pain, 17th March, 1874, in the region of the right ovary, accompanied by nausea. On vaginal examination, the right broad ligament was tender. Temperature 101°; pulse 110. Hot vaginal douche, morphine and atropine hypodermically, quinine per rectum, were suggested. The symptoms continued unabated until the 28th, when she was etherized. An incision was made into the cul-de-sac of Douglas, per vaginam, and three pints of fetid pus liberated; a drainage-tube was inserted. The cavity of the abscess was washed out with antiseptic solutions of the bichloride of mercury and carbolic acid. The condition of the woman continued to be desperate until an emulsion of iodoform was injected, when she began to improve, and was restored to her original condition about May 1st, thirty-three days after the operation.

Dr. Potter called attention to the following points of interest in connection with the case:

1. The rapidity of the formation of the parametric abscess in the non-puerperal state. 2. The rapid closure of the abscess cavity by granulations. 3. The large amount of pus (three pints) evacuated. 4. The beneficial effect of the iodoform emulsion. 5. The possible influence of cotton-root and gin, advised by a friend of the patient, as an etiological factor.

After a careful review of the pathology and etiology of abscess in the pelvic connective tissue, Dr. Potter advised the vaginal operation for the evacuation of pus, the cleansing of the cavity by the curette, as suggested by Byford, when necessary, and subsequent daily irrigation of the abscess cavity by the physician himself.

CHRONIC PERIUTERINE ABSCESS: ITS TREATMENT BY LAPAROTOMY,

was the title of a paper by Dr. Christian Fenger, of Chicago, which in his absence was read for him by Dr. W. W. Jaggard, of Chicago. It was based upon the observation and treatment of three cases of chronic periuterine abscess.

I. Technique of the Operation.—Before making the abdominal incision, the site of the bladder should be marked out by the introduction of a sound. If adhesions have formed between the sac and abdominal wall, the operation is extraperitoneal and simple. Such cases are exceptional. In the majority of cases, when the abscess is lateral or posterior to the uterus, it can be reached only by opening the peritoneal cavity—that is, by laparotomy, for which preparation has always to be made, since it is impossible to make a clear diagnosis beforehand as far as this point is concerned.

When the abdominal cavity has been opened, it is usually possible to come right down on the sac of the abscess. If covered by omentum or intestines, these have to be pushed aside, and all possible adhesions ligated or detached. The upper surface of the sac, together with the uterus and appendices, will generally form a convex, red, smooth, more or less regular tumor, to the side of which, outward toward the brim of the pelvis minor, loops of intestine or omentum generally adhere; as it is not desirable to extirpate the sac, these parts need not be disturbed, if only a surface of two inches in diameter is clear—that is, space to admit of a sufficient opening being made into the sac, and of a sufficient margin round the opening for a double row of sutures to unite the edges with the anterior wall of the abdomen. When the upper surface of the sac is thus clear, or has been cleared, the next step is to find some way into the sac, with due regard to the prevention of the escape of pus into the abdominal cavity. To this end, it is necessary to pack two or three large disinfected sponges around the sides of the cleared space, at the same time preventing any loops of intestine from slipping out through the abdominal incision.

As a soft or fluctuating point on the surface of the tumor, especially when the abscess communicates with the rectum or bladder, or, more rarely, with some remoter part of the intestinal canal, cannot always be found, an exploratory puncture with the needle of a hypodermic syringe has to be made, at the point and in the direction where, from the previous examination, we expect the abscess to be, or where the tumor feels less resistant than in other places. If pus is withdrawn, proving the existence of an abscess, it is advisable to effect as perfect an evacuation of the contained pus as possible. An aspirator should be ready, so that the aspirator needle may be introduced along the needle of the hypodermic syringe, which is left in the cavity as a guide.

The aspirator needle is left in the cavity as a guide for the knife in the incision into the sac. This incision should be made by the thermo-cautery; the small, knife-shaped burner of Paquelin answers the purpose very well. It is well to have a small sponge ready to thrust into the sac as soon as the incision is made, because some pus is likely to flow out as soon as the sac is opened. The edges of the incision are firmly grasped with the large artery forceps of Billroth, and dragged forward to check hemorrhage; sponges, saturated with ten per cent. solution of zinc chloride, may be introduced into the cavity; or, if necessary, the inside of the cavity may be scraped out with the sharp spoon or curette (Byford).

If counter-opening is desired, a strong curved forceps should be pushed down to the bottom of the sac till it can be felt through one of the vaginal cul-de-sacs,

through which an incision is then made, by one of the assistants on the end of the forceps. The forceps is then pushed through the opening, and opened so as to dilate the latter. A heavy drainage-tube is now grasped by the jaws of the forceps and drawn up from the vagina through the sac and out of the abdominal incision.

The next step is then, after carefully cleaning the peritoneal surface of the sac, to unite the latter to the part of the abdominal wound nearest to it by a double row of sutures. Silk is used for sutures. The deeper row, about one-quarter of an inch from the edge of the opening into the sac, and not penetrating the whole thickness of the wall of the latter, unites the peritoneum of the sac with the peritoneum of the anterior wall of the abdomen. These sutures must be sufficiently near to each other (less than one-quarter of an inch apart) to close up the peritoneal cavity hermetically. The outer row of sutures passes through the entire thickness of the abscess wall, along the incision into the sac, and through the whole thickness of the abdominal wound, thus uniting the edge of the skin with the inner wall of the abscess cavity.

The question as to whether or no drainage-tubes should be inserted into the abdominal cavity, depends entirely, as in all other laparotomies, upon the amount of detached adhesions. But in laparotomy for abscesses, it is more desirable not to have a drainage-tube in the abdominal cavity, because of the danger of secondary infection from the fetid abscess cavity through the abdominal drainage-tube, as it is practically impossible to effect a perfect seclusion between the abdominal tube and the tube leading into the abscess. Such a necessity may, however, arise, and then the best course possible under the circumstances is to be pursued.

Heavy antiseptic dressings should be applied over the abdomen, and also an intra- and extra-vaginal dressing sufficient to cover the drainage-tube in the vagina. Iodoform is especially valuable when communication with the rectum makes it possible that feces will come into contact with the abdominal wound. The dressing should be changed at least once a day, and the sac washed out with an antiseptic solution; a saturated solution of boracic acid is preferable, as there is then no danger of poisoning.

The question as to the safety of performing the whole operation at one sitting, in opposition to the method of Volkmann in the treatment of abscesses of the liver (union of the surface of the sac with the anterior abdominal wall, before the sac is opened), will depend, to a certain extent, upon the skill of the operator. Lawson Tait's record of thirty operations, each at one sitting, without a single accident, may be considered as a definite answer.

A tangible difference between a periuterine abscess and an abscess in the liver exists. The liver participates in the respiratory movements; the periuterine abscess does not. The wall of an abscess of the liver is friable, and furnishes a very insecure substratum for the application of sutures, while the walls of the periuterine abscess are thick and solid.

Regarding effective drainage of a periuterine abscess, the counter-opening through the vagina appears inexpedient from the experience of Lawson Tait and the reader of the paper. If, in the course of the after-treatment, rise in temperature and the accumulation of pus in the lower part of the sac should demand it, a counter-opening in the vagina can be made.

II. Laparotomy as Compared with other Operations.—The value of the operation of laparotomy was compared in detail, with Schroeder's vaginal operation in cases in which the circumuterine abscess does not point downward, and, in fact, does not point anywhere. After a careful discussion of the advantages and disadvantages of both methods, the author of the paper was very decidedly of the opinion, advanced by Lawson Tait, that in circumuterine abscesses, which can only be reached from vagina or suprapubic region, laparotomy is the operation of election.

III. Points in Diagnosis.—Bandl is hardly correct when he states (Die Krankheiten der Tuben und die extrauterin Schwangerschaft) that the diagnosis of suppuration and formation of abscess in the pelvis is generally not difficult because they are indicated by increase of evening fever, rigors, and nightsweats. The author has twice observed cases in which, without fever, rigors, or nightsweats, more than one pint of pus was present. Exploratory puncture through the vagina, by means of a fine aspirator needle, while not entirely harmless as insisted on by Dr. Emmet, gives reliable information, and is comparatively safe.

Exploratory laparotomy is preferable to suprapubic exploratory puncture. The escape of one drop of pus into the peritoneal cavity may be sufficient to start up a general acute peritonitis. Especially is this means of diagnosis advisable when a suprapubic tumor is recognizable.

In the author's three cases the abscess had ruptured into the rectum, and the diagnosis was simple.

It is dangerous to wait too long in cases of suspected periuterine abscess on account of the danger of amyloid nephritis. In conclusion, the author paid a compliment to Lawson Tait, the first advocate of free laparotomy in cases of this kind.

Dr. Engelmann, of St. Louis, thought that Dr. Emmet very correctly laid stress upon the fact that inflammations of the pelvic connective tissue were not confined to the puerperal state. As regards operative procedure, laparotomy ought to be the *last* resort, but not a *late* one. It is frequently impossible to make a diagnosis before the exploratory incision is made. He had lost one case from septicæmia in his earlier practice as the result of the imperfect *technique* of the operation.

Dr. Gordon, of Portland, Me., thought that in from one-half to two-thirds of all cases of pelvic cellulitis the physician is responsible for the production of the condition. The introduction of the uterine sound, application of iodine, nitrate of silver, and carbolic acid to the endometrium were apt to injure the genital structures if not carefully performed. Prophylaxis was more important than cure.

Dr. Reed, of Ohio, thought Dr. Gordon's statement entirely too sweeping. He narrated the histories of three cases occurring in his own practice; two died; one made an incomplete recovery.

Dr. Quimby, of New Jersey, had one case in which the diagnosis was obscure. Dr. Gordon Buck's operation—incision from anterior superior spinal process of ilium to Poupart's ligament, introduction of finger under the ligament, introduction of pledget of lint—was performed, and the patient recovered.

DR. CARROLL, of Texas, desired to enter a protest against Dr. Gordon's etiology of pelvic abscess; it may be so in Maine, it is not the case in Texas.

DR. W. W. JAGGARD, of Chicago, referred to Dr. Byford's criticism of Dr. Fenger's operation. When an abscess discharges through the rectum it is usually possible to dilate this orifice so as to secure free drainage. The communication between abscess and bowel could be dilated with the finger or cut. Schroeder has operated successfully in cases of chronic periuterine abscess, after perforation of the bladder, by the high section.

DR. SUTTON, of Pittsburg, closed the discussion. He had recently performed laparotomy for pelvic abscess, and the patient recovered. In cases in which the walls of the cavity cannot be united to the anterior wall of the abdomen, it is advisable, after evacuation and scraping of interior, to fill with iodoform and close. As regards the diagnosis, if no dull space exists above the symphysis always try aspirator needle.

DR. GEORGE F. FRENCH, of Minneapolis, read a paper entitled

HOW SOON AFTER EXPOSURE TO SEPSIS MAY THE ACCOUCHEUR RESUME PRACTICE?

The term puerperal fever embraces a group of essentially diverse affections, some of which are non-contagious; but the septicæmic variety of the disease is that which alone engages us in this discussion, and he expressed the belief that the evidence that this fever is caused by the contagia of erysipelas, scarlet fever, and septic dirt, is as demonstrable as any proposition of Euclid. In order to obtain all possible light on the duty of the practitioner to the obstetric patient, he addressed, in October last, letters of inquiry to some of the most distinguished medical men in this country and in Europe, of which the following is the substance:

"How soon after exposure to sepsis, may the accoucheur safely resume practice? My purpose is to controvert the opinion which obtains in the profession, that time is an essential element in the cleansing process. I have had an experience which emboldens me to make abdominal section on the day following exposure. I greatly desire to know whether your own experience warrants me in pursuing such a course."

In reply, Thornton, Savage, and Hegar write that they believe time is essential—to be accompanied, of course, with careful cleansing. While Emmet, Battey, Marcy, Goodell, and Thomas in our own country, with Martin, Schroeder, Nussbaum, Volkmann, and Esmarch in Europe, write that they believe time to be entirely non-essential and that thorough disinfection can be at once accomplished. The present weight of evidence goes to show that the materies morbi of contagion is a non-gaseous particle, capable of being acted upon and demonstrably susceptible of destruction. Some kinds of contagia have been isolated and their property of self-multiplication demonstrated. It has been exactly determined how such contagia are affected by different agents. The presence of other contagia is inferred from analogous diseased conditions and by disinfecting the supposed source of this latter contagion the morbid effects have been interrupted. Experiments show that the resting spores of the bacilli, the most difficult to destroy of all forms of life, can be killed by a corrosive sublimate solution 1:5000.

Fermentation and putrefaction occur only when the specific germ lives—and filth undergoing fermentative change is most conducive to the spread of infectious diseases. Particles of contagia most frequently find lodgement on our hands and particularly under the finger-nails. It is always possible after the ordinary use of a nail-brush or knife, to remove particles of dirt in which the microscope reveals living germs of possible infection. On this account he cuts his nails short and swab under them with a blunt instrument covered with cloth and wet with some disinfecting liquid. He formerly used for this purpose 5 per cent. carbolic acid, but this made the flesh crack—so he now uses instead corrosive sublimate solution 1:2000. For hang-nails, cracks, and abrasions he uses collodion.

All instruments are kept scrupulously clean as well as disinfected, and the nurse is regarded as one of the instruments. The June number of the *Centralblatt für Chirurgie*, of 1880, contains a most impressive contribution to this subject by Volkmann. In his letter to me, dated Halle, Dec. 5, 1884, he says: "I hold the same views to-day as at that time. A surgeon who disinfects himself well, can, immediately after making a post-mortem, undertake any operation known to surgery. Every morning from six to eight during the summer I am obliged to give the students operations on the cadaver; and from ten to three I am busy in the hospital, operating, and dressing wounds. I have never yet infected a patient. In the winter I have no operations on the cadaver. Comparing my results in the clinic, I can assure you that the mortality in summer is not greater than in winter."

To show his confidence in the possibility of absolute disinfection, he made the following experiments.

June 21, 1884, after laying open a dissecting abscess of the thigh in a pyæmic patient, and stripping the limb with both hands till they were offensively drenched with the pus, he carefully disinfected himself, and three hours later attended Mrs. M. in confinement.

July 22, in dealing with a case of pyonephrosis, before penetrating the kidney he came upon a foul perinephritic abscess. Passing through this the kidney was incised, explored, and its grumous contents scooped out with the finger. The hand was so long engaged in this work, that a more complete purulent saturation could hardly be conceived. In the afternoon of the same day he confined the wife of a physician, having stated to him the full extent of his morning exposure. In both cases the convalescence was perfectly normal.

Feb. 11, 1885, he purposely infected his index finger with the ichor of an erysipelatous case and after a corrosive sublimate washing, inserted it in a fresh wound from which he had just excised a tumor. He might multiply instances of this kind. The following characteristic letter, received from Prof. Esmarch, epitomizes the subject under discussion.

"If you have thoroughly disinfected yourself, you can immediately enter upon obstetric practice. Time does not destroy septic dirt."

DR. S. PAINE, of Texas, reported

AN INTERESTING CASE OF SUBSEROUS FIBROID TUMOR OF THE UTERUS.

The patient, white, forty-three years old, native of Louisiana, began to have pains in the abdomen and

pelvis about two years ago; menorrhagia and leucorrhœa. A tumor was demonstrable, which grew so rapidly that all the abdominal viscera were encroached upon, and respiration was interfered with. The diagnosis of subserous fibroid tumor of the uterus was made. Squibb's aqueous extract of ergot, rubbed up in glycerine and water, was exhibited in large quantities, through one year, hypodermatically, with the effect of causing almost entire disappearance of the swelling. As much as ten grains, three times daily, were exhibited. No tendency to spasms, gangrene, or other expression of ergotism, was observed. The cardiac rhythm was slowed.

DR. NELSON, of Chicago, thought that Dr. Paine's case could be multiplied. Before the formation of omental adhesions ergot will, in many cases, control the growth of the tumor. The great mistake in the exhibition of ergot is that it is generally given in too small doses through too short a period of time.

WEDNESDAY, APRIL 29TH.—SECOND DAY.

DR. R. J. NUNN, of Savannah, Ga., read a paper on

THE MULTIPLE SPECULUM UTERI, AND AN IMPROVED DRESSING FORCEPS.

The speculum is of the antero-posterior bivalve variety, like Cusco's; it has the extension motion of Graves's, and, like it, can be reversed for a Sims's. The upper blade consists of two superposed leaves capable of lateral motion. Two lock-nuts fix this blade immovably in any position when such fixation is desirable, as when using the instrument as a Sims's. The arrangement of parts adopted gives great powers of expansion and self-retention.

The dressing forceps has a downward and backward curve in the direction in which the jaws open. It has a spring catch, forming a useful polypus forceps, etc., and between the pivot and the jaws the shank of the forceps is formed into a scissors.

DR. S. M. HEALEY, of Cumberland, Md., then described

A NEW SPECULUM AND A NEW VAGINAL IRRIGATOR.

The speculum is a self-retaining Sims's speculum; it is secured *in situ* by a sacral pad, with bands of steel, connected together by ball-and-socket joint. The instrument was applied to a patient in the presence of the members of the Section.

The vaginal irrigator is a long, conical, corrugated glass tube, with a rubber diaphragm, containing two perforations for the insertion of a delivery and an escape tube.

DR. GEO. J. ENGELMANN, of St. Louis, read a paper on

THE IMPROVED TECHNIQUE IN GYNECOLOGICAL OPERATIONS, MINOR AND MAJOR.

He called attention to the various models of Simon's specula, as more efficient instruments for operation in the lithotomy position than the instrument of Sims. He employs continuous irrigation with hot water, 115°–125° F., during all his operations. He uses semicircular needles and strong silk thread, which has been disinfected. The operative *technique*, thus briefly sketched, has received no mention in any American text-book. Dr. Engelmann claims the following advantages for this method:

1. Cleanliness, or asepsis. 2. Field of operation is clear. 3. Rapidity of operation. 4. Hot water acts as an efficient hæmostatic.

The irrigation with hot water is an idea of his own, and he has used it for seven or eight years. The method of operating, with the exception of the hot water, is that extensively practised in Europe.

DR. HENRY O. MARCY, of Boston, read a paper on

THE "ROLE" OF BACTERIA IN PARTURITION,

the underlying thought of which was that normal labor is a physiological process and as such aseptic, hence antiseptic injections are unnecessary, and, beyond the securing of cleanliness, meddlesome and dangerous. When the labor departs from the normal character, then new factors are introduced. In instrumental labors, and where the hand is introduced into the cavity of the uterus, exposures are of necessity not unlike those incidental to any surgical operative procedure. The uterus in most labors is subject to lesions where infection may easily be superinduced and when thus infected, Dr. Marcy showed that the puerperal state made most favorable conditions for rapid development of microörganisms, a favorable soil for growing most dangerous seed. He laid the utmost emphasis upon the use of all antiseptic precautions, and urged precisely the same thoughtful attention to all details as in a major surgical operation.

DR. HEALEY, of Maryland, held that sepsis occurs in every labor, and milk fever was evidence of the fact.

DR. GORDON, of Maine, said that he did not believe in antisepsis, but he did believe in cleanliness. Lister had recently lost two cases from septicæmia. Cases of poisoning from carbolic acid and the bichloride of mercury had been recently reported. He was known as the hot-water surgeon, on account of the frequent employment of large quantities of that agent. He had no objections to hot vaginal injections after parturition, on general principles; he did object to medicated solutions.

DR. ALEX. J. STONE, of Minnesota, thought that Dr. Marcy misrepresented Dr. Thomas in the statement with reference to the sites of purulent resorption. The placental area, the cervix, and the vulvo-vaginal canal were the regions through which the resorption of pus usually occurs. Extensive lacerations of the cervix occur quite as frequently among multiparæ as in primiparæ.

DR. HUNTER, of Minnesota, closed the discussion by saying that it was too late, at the present day, to appeal to the *vis medicatrix naturæ*. The experiments in the cultivation of germs, and the clinical observations in Vienna, Prague, Berlin, and other large cities, established the prophylactic value of antiseptic injections beyond peradventure of doubt.

DR. A. REEVES JACKSON, of Chicago, read a paper entitled

VAGINAL HYSTERECTOMY FOR CANCER.

A surgical procedure, to be beneficial, should relieve suffering and prolong life. If it fail to effect either of these results, it is useless. If it destroy more lives than it saves, it is injurious, and should be abandoned.

A table based upon 256 cases of vaginal hysterectomy, compiled by Dr. P. F. Mundé, showed a mortality of only 24.6 per cent.; while the results of the operations

performed by Martin, Schroeder, and Ohlshausen, *all of whose cases are published*, show a much higher rate of mortality, namely, 38.6 per cent. in 101 operations. This discrepancy is explainable by the fact that such tables as that of Dr. Mundé are based upon incomplete returns—the successful cases being published, and the unsuccessful ones suppressed. Figures will not lie if they have a fair chance. If the whole truth in relation to this matter were known, the mortality of the operation would be found much greater than it now appears. Taking even the foregoing most favorable report, vaginal hysterectomy has actually destroyed nearly one hundred years of life. If all the cases were published, the amount of destruction would appear much greater. There is nothing to offset this. It has yet to be shown that a single life, otherwise doomed by the disease, has been saved by the operation. The history of the operation does not afford ground for hope that improved methods in its performance will materially better the results. Schroeder's greatest success was obtained in his first 8 cases, with a mortality of 8.7 per cent.

The dangerous character of the operation is not the gravest charge against it; it does not benefit those who recover. The disease recurs in all, sooner or later, and their sufferings, which have at best only been interrupted, are as severe as before. In short, the patients gain nothing, and die, on the average, sooner than if let alone.

Of all the methods of treatment which have been used for uterine cancer, hysterectomy has given the worst results, both immediate and remote; and the statistics seem to show that it has killed more rapidly than the disease itself.

Schroeder, Mundé, and others think that vaginal hysterectomy should be restricted to cases in which the cancer is limited to the cervical mucous membrane, or to the body of the uterus. These limitations are proper, but impracticable. It is impossible, in the present state of our art, to make the subtle diagnostic distinctions which they imply. There are no means by which the extent of cancerous involvement can be known in any given case. The unreliability of Schroeder's method by digital touch alone, is shown clearly by the rapid and numerous recurrences of the disease which have followed his own operations.

When cancer affects the cervix uteri, extirpation is improper because unnecessary. Supravaginal amputation, with a mortality only one-fourth as great, does all that can be done by total removal.

The diagnosis of cancer of this body is always difficult, and frequently impossible in the only stage in which extirpation can be proper or useful. Here, too, the disease is of much longer duration and less painful than when it attacks the cervix, so that a highly perilous operation is not justifiable. The so-called "palliative" operations are not only less fatal in all forms and locations of the disease, but more lasting in their good results than the "radical" operations.

Conclusions: 1. Any operation for cancer which does not completely remove the disease will be followed by recurrence.

2. During life the diagnosis of the extent of cancerous disease originating in any part of the uterus is at present impossible, hence no operative procedure can afford a guarantee of complete removal.

3. In view of this necessary doubt, no operation is justifiable which greatly endangers life, provided other and safer methods of treatment are available.

4. Vaginal hysterectomy has sacrificed the lives of more than one-third of those who have been subjected to it, the mortality of the operation when done by those of greatest skill and experience being over thirty-six per cent.

5. Other methods of treatment, attended by not more than from one-sixth to one-fourth the mortality of vaginal extirpation are equally efficient in ameliorating the symptoms and retarding the progress of the disease, and these have been followed by as good or better ultimate results. Hence they should be preferred.

6. Hysterectomy does not avert or lessen suffering; it destroys and does not save life. It is, therefore, not a useful but an injurious operation, and being such, it is unjustifiable, and ought to be abandoned.

Thursday, April 30th.—Third Day.

Dr. W. W. Jaggard, of Chicago, read a paper on

the ring of bandl.

Conflicting views as to the changes which occur in the cervix uteri during pregnancy and labor have been urged from the latter part of the eighteenth century up to the present day.

The object of the paper was to sketch very briefly the outlines of our knowledge upon this important subject, especially since the views of Bandl have been grossly misrepresented. The old theory, of Roederer and Stein, Sr., displaced by the doctrine of Stoltz, in 1826, is coming to the front again, as the result more particularly of the anatomical studies of Braune and the researches of Bandl. Bandl's doctrine is substantially that promulgated by Carl Braun, in 1857. Professor Sales, in 1869, 1874, and 1877, approximates the position of Braun, Braune, and Bandl.

It is inconceivable that the little, thin-walled, nipple-like process, the cervix of Müller, could be so distended as to receive the entire head of the child, as shown in Braune's drawing, and still be capable of functional activity. If this proposition is regarded as demonstrated, the greater part of the cervix, as shown in Braune's drawing, must have been filled out by the egg during pregnancy, and the cervix of Müller must play a very insignificant rôle. The cervix of Müller forms a part, from two-fifths to one and one-fifth inch long, from the os externum upwards, of the cervix of Braune. The cervix, as shown by Braune's drawing, is the lower segment of the uterus of the older observers, plus the little tube described by Müller. After a careful review of recent evidence upon the topic, Dr. Jaggard said that it is impossible, in the present state of our knowledge, to assert dogmatically that the ring of Bandl and the anatomical internal os are identical, but that the weight of probable evidence, at present at our command, is very decidedly in favor of such a view.

Dr. Gustav Zinke, of Cincinnati, then read a paper on

Emmet's operation: when shall it and when shall it not be performed?

He summarized his conclusions as follows:

1. It is evident that the operation has been performed unnecessarily for symptoms similar to but other than

those arising from lacerations of the cervix. Further, that it has been done imperfectly, even without preliminary treatment, in many more; and the failure to give relief, as reported by several, is due to these two causes.

2. That from our present knowledge we cannot, at this time, arrive at any definite conclusion, from the fact that many of the so-called consequences of lacerations of the cervix uteri are not settled beyond doubt.

3. That every one engaged in this department should carefully select his cases, and try every known means to give relief before resource is had to operation.

4. The operation should never be performed *eo ipso* in cases of simple fissures or lacerations of first and second degree.

5. In cases of eversion and disease of the cervical or corporeal cavity, or both, although attended by hyperplasia and displacement, it has been observed that all the symptoms abated and the parts returned to their natural condition, and that no laceration was discoverable after alleviative measures were instituted first, which alone caused the parts to return to a normal condition.

6. There are some cases of extensive lacerations of cervix that seldom give rise to any inconvenience, and that, therefore, an operation should be deferred until symptoms arise that will call for its performance.

7. The operation, although indicated, should never be performed until, by preparatory treatment, the parts have been brought into a healthy condition.

8. Near, and during, the climacteric period the operation should be postponed as long as possible, and the patient not exposed to any risks, since in many cases all the symptoms subside under proper treatment, and never return on account of senile involution.

9. The operation is justifiable in cases of lacerations of the third and fourth degree, without complications, if there is a history of malignant disease in the family.

10. The operation may be performed with perfect propriety in young women, as a preventive, if the laceration is bilateral and extends up to the cervico-vaginal junction, or beyond it, even though there are no pathological changes; indeed, it seems to be the duty of every one who observes a lesion to that extent, to urge the operation.

11. The operation is justifiable in any degree of laceration, and in rare instances even in fissures, when there exist cicatricial tissues, productive of reflex disturbances, annoying in character, and not tractable to any other treatment.

12. The operation is absolutely indicated in all extensive tears of the os, in which the cervix is everted, its mucous membrane and Nabothian follicles diseased, and especially if there be granular or cystic degeneration present, provided, the parts have first been restored to a healthy condition by palliative treatment.

DR. HARVEY, of Indiana, said there was frequently very much less pain in extensive than slight laceration. When there is extensive eversion, the parts are covered in time with cicatricial tissue, and are relatively non-sensitive. When a fissure exists in the cervix, it is productive of much the same reflex symptoms as a fissure *in ano*. Moreover, while upon a cursory examination, the laceration may be apparently slight, if the lips are everted it will be found that the laceration has taken on larger proportions higher up. For these cases of slight lacerations—fissures, so to speak—cauterization and deep incision will not suffice; they require Emmet's operation.

DR. WATHEN, of Kentucky, said each case must be an individuality. The preparatory treatment is the best test as to the urgency of the indication for operation. Some cases do not require operation; such cases are cured by the preparatory treatment.

DR. GORDON, of Maine, said that Emmet had made the remark over and over again that epithelioma of the cervix had never occurred in any of the cases coming under his observation without an antecedent laceration. But, although admitting laceration to be a potent factor in the production of cancer, he did not advise closure of the laceration in every case, irrespective of its condition. Dr. Emmet was clearly inconsistent. Dr. Gordon had operated 225 times, with 1 death. He agreed with Dr. Harvey in his remarks. Dr. Gordon does not believe in such long preparatory treatment; as said by Peaslee, chronic inflammation is a misnomer. Inflammation is a process rarely lasting over seven or eight days; subsequently, there exist the products of inflammation merely—*i. e.*, chronic congestion. He had treated successfully cases refused admission at the Woman's Hospital of New York, because there was too much inflammation.

DR. KING, of Missouri, thought there was greater danger of the development of cancer in case of slight lacerations than in larger ones.

DR. CARSTENS, of Detroit, thought that all lacerations should be operated upon. An ulcer on either lip of the buccal orifice is excised if it does not heal spontaneously; the same line of reasoning ought to apply to lacerations of the cervix.

DR. BATTEY, of Georgia, was never impressed with the opposite character of the argument which would unite laceration of the cervix and epithelioma as cause and effect: with equal force, labor itself might be urged as a factor in cancer. He had seen extensive lacerations cured by local treatment.

DR. SUTTON, of Pennsylvania, said that he had operated in cases of lacerated cervix merely to satisfy the patient. Epithelioma occurred in the cervices of virgins; he had seen numerous cases of this kind in Marten's clinic at Berlin.

DR. S. C. GORDON, of Portland, Maine, read a paper entitled

REASONS FOR AND RESULTS OF SOME CASES OF TAIT'S OPERATION.

At the last International Medical Congress, Sir Spencer Wells, in commenting upon a paper presented by Koeberle, of Strasburg, said: "As to castration of women for nervous diseases, we might just as well go about the country cupping men for similar diseases as to do what is being done, in removing ovaries of women." In reply to Dr. Gordon's direct question, he said, "I believe that in no case should the ovaries of a woman be removed unless we can demonstrate beyond all doubt that there is actual disease." In reply to the question, "Do you mean by demonstration only that which can be made by touch?" he said, "Yes, most emphatically." Dr. Gordon then related detailed histories of several cases in which one or both ovaries or

tubes had been removed. Improvement of all symptoms was observed in each case and in some of them a radical cure was effected. Dr. Gordon concludes that a close analysis of subjective symptoms, through a long period of time, is frequently adequate to establish the diagnosis of disease of ovaries and tubes, and indicate operation when absolutely nothing of a positive character can be ascertained by physical exploration. Sir Spencer Wells's well-known aversion to Mr. Lawson Tait probably influences his judgment to an undue degree. Some of these subjective signs are premenstrual pain, irregularity of menstrual function, alternate pallor and flushing of face, an extraordinary mahogany-bronze color of the complexion resembling that of Addison's disease. Dr. Gordon observes no antiseptic precautions. He is clean, and uses hot water.

Dr. B. E. Hadra, of San Antonio, Texas, presented a paper entitled

INTRAPERITONEAL ADHESIONS CONSIDERED IN RELATION TO BATTEY'S AND TAIT'S OPERATION.

He concludes from the detailed consideration of four cases, taken as types, that intraperitoneal adhesions may exist high up in the abdominal cavity, between various portions of the intestines, and that in all cases of abdominal section, after examination of the uterus and annexa, the hand should be made to search for such adhesions.

Dr. Battey, of Georgia, thought that any aversion to Lawson Tait upon the part of Sir Spencer Wells would not influence his judgment. Both Sir Spencer Wells and Mathews Duncan had told him in London, a few months since, that the scope of Battey's or Tait's operation is limited; the former operator had seen but two cases, the latter but one case, in which the operation was deemed expedient.

It is necessary, in estimating the results of the operation, to allow a sufficient interval of time to elapse. The immediate effect is always favorable. Almost any operation which draws blood will do the patient, if she is a woman, good. But then there comes a reaction, and she feels the improvement is imaginary. Cheer her up. Wait for the expiration of one and a half to two years before reporting your cases. The results of the operation are uniformly favorable.

With reference to the introduction of the hand to search for adhesions, as suggested by Dr. Hadra, he had little doubt that some good is effected. But this may arise from (1) traumatism, (2) imagination, (3) the actual severing of incarcerating bands. These bands, however, may form again.

Dr. Sutton, of Pennsylvania, called attention to the importance of always telling the patient that merely an exploratory incision is to be made, and then of being prepared for any emergency that may arise.

Dr. Harvey, of Indiana, called attention to the influence of Battey's and Tait's operation in causing involution upon chronic hypertrophy or hyperplasia of the cervix, and indeed of the *corpus uteri*.

Dr. Wathen, of Kentucky, thought that the line of diagnosis advocated by Dr. Gordon is pernicious in its tendencies. Objective diagnosis is more reliable, although it must not be relied upon exclusively.

Adjourned.

AMERICAN SURGICAL ASSOCIATION.

Sixth Annual Session held in Washington, D. C., April 21, 22, 23, 24, 1885.

(Specially reported for The Medical News.)

Friday, April 24th.—Morning Session.

First in the order of exercises was the discussion of the paper of Dr. Senn, entitled

AN EXPERIMENTAL AND CLINICAL STUDY OF AIR EMBOLISM.

Dr. J. Collins Warren spoke in strong terms of admiration for the labors of the author, and particularly upon a subject of so great importance as that of air embolism. He, however, thought the subject of greater importance in a practical sense to the obstetrician than to the surgeon. With regard to the cause of death, various theories have been advanced in addition to that adopted by Dr. Senn, but he thought it sufficiently explained by calling it an inflation of the right side of the heart. The phenomenon has been compared to fat emboli, and the cause of death attributed to the action of the air in the capillaries of the lungs. The comparison is not a proper one, however, because we may have the lungs well filled with fat emboli with very little disturbance to the circulation. One lung may be almost filled with an exudation, as in pneumonia, without producing the death of the individual. But when the heart has in its cavities a substance like air, which it is unable either to compress or expel, it must immediately become exhausted. A large amount of air may be introduced into the circulation if it be done slowly so as to allow it to form a froth with the blood. He had once opened a vein while operating upon the neck, and had distinctly heard the hissing sound of air entering the vein, but no evil symptoms followed. The danger is greater when a large vein or sinus is opened and a larger amount of air permitted to enter in a short time. In operating in the axilla, he had noticed a sound made simply by the suction of air into the loose cellular tissue of the region, which so closely simulated the sound of air entering a vein that he was at first confused. Speaking of the erect posture as favoring the entrance of air, he recognized the authority for such a suggestion, but thought a much more plausible cause is the tension of the respiratory muscles produced when the patient experiences pain and takes a sudden deep respiration. As an illustration of the ease and rapidity with which air may be forced into the circulation, he cited the case of a woman who applied to an abortionist in Boston. An instrument was introduced into the uterus and air pumped through it, causing death in fifteen minutes. The autopsy revealed the right side of the heart full of air. Air was also found in the capillaries of the lungs as well as in the capillaries of the general arterial system. In such a case the air is very readily drawn into the enlarged uterine sinuses by the ordinary movements of respiration.

Dr. Gordon, of Portland, Maine, reported a case in which air was introduced into the circulation in the operation of aspirating a pelvic abscess. Before coming under his care, the abscess had been twice aspirated without the discovery of pus. He, however,

succeeded in withdrawing a large amount of pus at the first aspiration, and repeated the operation a week after, with the same result. The aspirator that he used was one with a bottle attached to act as an exhaust-chamber, capable, as he remarked, of killing at either end. The bottle could be either filled or emptied according to the direction in which the stopcock was turned. When the third aspiration was about to be made, the operator was assisted by a young and inexperienced resident physician, who attended to the preparation of the instrument. Instead of exhausting the chamber, he had charged it with air. After the introduction of the needle, the stop was turned; the woman instantly gave a scream, put her hand over the region of the heart, and in a minute was dead. Just what occurred, it was impossible to tell, no autopsy being permitted. It was probable, however, that the cavity of the abscess having been previously nearly exhausted, the enlarged veins of the vicinity had been left with their mouths nearly or quite open, so that with the great pressure the air was forced into them. From the rapidity with which death was produced in this case, he concluded that preventive treatment is, in the human subject at least, better than curative, for it would have been impossible to have taken any measure for the restoration of this patient. Again, complete anæsthesia renders the accident less likely to occur, inasmuch as it quiets respiration to such an extent that the aspiratory force is much diminished.

Dr. C. B. Nancrede expressed his admiration for the work of Dr. Senn, and regretted that he had nothing new to offer on this important, but much neglected, subject.

The subject of air embolism is an old one. It was first recorded, however, by Duchenne. The elder Larrey had noticed it several times on the field of battle, from sabre-wounds of the neck. With regard to experiments, it should always be remembered that animals are not human beings. This statement was made without prejudice against experimental investigations, and only in the belief that in some animals death occurs with much greater certainty than in others. The horse was one of the least likely to be killed by air embolism, because of the large size of its pulmonary capillaries. It is an interesting fact, in this connection, that the same quantity of water, if introduced into the circulation, will cause almost as severe symptoms, although these are more likely to pass off after a short time. Again, in the experiments of Dr. Senn and others a much larger quantity of air was introduced than could possibly enter during an operation, hence the results could hardly be compared. Death from a small amount of air is not due, he thought, to paralysis of the heart, but to obstruction of the pulmonary circulation. If, however, a large quantity of air gains entrance to the heart, it is churned back and forth from auricle to ventricle, and does not pass into the general circulation, hence aspiration of the heart cavities may be of benefit in removing the spumous blood. Tension of muscles is capable of holding the mouths of veins open to a greater extent than the tension of fascia, as is the case with the platysma in the neck. A case was then reported of sudden death from air embolism following amputation. The stump had sloughed and gas had developed under the dressing, giving an easy means of its entrance to the circulation. This he considered a mode of death not always recognized. As remarked by the last speaker, the preventive treatment of these cases is of much more importance and more likely to be successful than the remedial, simply because we cannot always be present when the accident occurs, or, if present, it requires some minutes to get an aspirator ready for use. In operations about the axilla or neck, the greatest care should be taken to prevent the entrance of air into the divided vessels.

Should air have entered, what can be done? Experience has shown that if the patient can be kept alive for a short time by artificial respiration, he is likely to recover, and artificial respiration will cause a disappearance of most of the dangerous symptoms. This can be practised in all cases, and it is the most convenient method we have. It should be practised with the patient in the recumbent posture, the head low and the limbs slightly elevated. Where the accident occurs during an operation, the vein should, if possible, be tied; but if this cannot be readily done, a spongeful of water should be squeezed into the wound, and the cardiac action maintained by stimulants. Another remedy of value is the hypodermic injection of atropia, because of its power of enlarging the pulmonary capillaries. In one case he thought the patient had been saved for six days by the administration of this remedy. Patients who have recovered from the accident, however, have all shown symptoms of secondary pneumonia, which has to be treated on the same principles as an ordinary case of pneumonia.

Dr. P. S. Conner, of Cincinnati, then read a paper on

THE ETIOLOGY OF TRAUMATIC TETANUS.

In it were reviewed the various theories that have been advocated as to the cause of the disease, and the leading arguments for and against them. The opinions expressed were mostly conservative, but favor was expressed for the humoral theory.

In conclusion the essayist said, it can only be assumed that it is in the secretion of the wound that the irritant is developed. The idiopathic cases are those the explanation of which is the most difficult upon this or indeed upon any theory. There is abundant material for the chemical development of the poison both in the fluids that are poured out and in the decomposition of the tissues. Even in a physiological fluid—urine—Gautier was able to find a ptomaine capable of tetanizing animals. Does not the danger of a punctured wound of the hand or foot lie in the pent-up fluids rather than in the nerve injury, and should not the pus, the pieces of clothing, the bits of wool, that have been found in some of the reported cases, and not the lacerated nerve-fibres, be considered as the exciting causes? The veins and lymphatics of the nerve themselves may readily be the channels through which the morbific matter may be carried in, and the anatomical fact that a relation exists between the sensibility of a nerve and the number and closeness of its associated lymphatics may go far in explaining why tetanus is so frequently associated with slight wounds of parts endowed with high sensibility, as the fingers and toes.

Is it not then from very careful chemical and microscopic examinations that we may hope to receive the information we desire upon this obscure affection?

Will it prove to be a peculiar toxic material developed in the breaking-down, dying, and dead tissues, or a specific organism that will allay tetanus with anthrax, erysipelas, and septicæmia, an organism entering at the open wound or carried in with the vulnerating body. Whatever it may prove to be, if it is discovered at all, we shall hear no more of hypothetical personal predispositions, or parts of least resistance, and the treatment will be directed either towards preventing the entrance of the microörganism or the sustaining and quieting of the patient until such time as the one shall be eliminated or the other have completed its life-history.

(This paper will be published in full in an early number of The Medical News).

Dr. E. M. Moore asked the author's opinion with regard to the remarkable prevalence of tetanus a few years ago among boys who used the toy pistol, and whether he thought it due to a peculiar chemical effect of the fulminate upon the tissues.

Dr. Conner replied that nothing, so far as he was aware, had been given that throws any light upon the subject. All the cases that he had seen from this cause were cases in which there was a considerable amount of contusion and laceration, the wad lodged, and the fluids pent up. In other words, they were cases which lent strength to the humoral theory. In the only case which he was called upon to treat, the injured member was kept constantly under hot water for forty-eight hours and no tetanus had developed.

Dr. Nancrede called attention to the fact that a difference of locality amounting to but a few miles made a great difference in the prevalence of the disease, as had been recently stated by a New York writer. At one point on Long Island the disease is of comparative frequent occurrence, while at a place but a few miles distant it is practically unknown under any circumstances. This could be best explained, he thought, by reference to the humoral theory.

Dr. T. F. Prewitt did not consider the experiments of Arloing and Trippier, referred to in the paper, as bearing any evidence against the humoral theory inasmuch as the blood from a horse suffering from tetanus would have to be injected into the blood of another in very large quantity to produce the disease, as would be the case in poisoning by strychnia.

Dr. J. Ewing Mears reported a case in which tetanus had developed after amputation of the arm. Post-mortem examination showed that it was due to the inclusion of the median nerve in a ligature. He further expressed surprise at the rarity of the disease as a result of wounds of the hand and foot in the late war.

Dr. J. R. Weist remarked that there was a discrepancy in the statement that tetanus had not occurred as a result of wounds of the hand during the war, as he had observed one case that followed a gunshot wound of the finger, coming on within twenty-four hours after amputation had been performed. During the last year he had seen three fatal cases of tetanus; all were from wounds, two were railroad injuries, and one caused by the falling of a window sash.

Dr. L. McLane Tiffany reported that tetanus as a result of toy-pistol wounds had been of remarkable frequence in Baltimore. He thought some importance should be placed upon the part wounded, and this differed with differences of race and other peculiarities; thus, the negro is peculiarly liable to suffer from the disease in consequence of injuries to the head and neck. One of his associates had made a careful chemical study of the fulminate of the caps used in the toy pistols, but had discovered nothing. He had not seen a case of tetanus from this cause that recovered.

Dr. Mears called attention to a case he had reported three years ago, from the toy pistol, in which chemical examination had failed to reveal anything. He considered the frequency of the disease in connection with this accident due to the character of the cartridge used, the manner in which it is placed in the pistol, and the fact that it is discharged in the hand, causing the fragments produced by disrupture of the cartridge to enter the flesh.

Dr. David Prince advised free incision for the purpose of permitting the escape of discharges and particles of foreign matter.

Dr. Nancrede reported several cases arising from various injuries. Only two cases recovered, and they had been treated by trephining the fractured bone which was the cause of its development, and removing the fragments, the operation being followed up by the administration of large doses of chloral. The child had, however, for several weeks the most pronounced risus sardonicus. The other case recovered after amputation of the finger. He had seen the musculo-spiral, the median, and the radial nerves stretched, with the result of temporary improvement. He had made neurotomy for it with the same unsatisfactory result. He had kept the patient under anæsthetics for hours, alternating between ether and chloroform, when ether seemed to lose its effect. He had seen calabar carried almost too far; everything appeared to give relief. One of his colleagues had obtained a recovery from the inhalation of nitrite of amyl alone. In one case he had seen good results from it, but the treatment was changed without his consent, and the patient died.

Dr. T. F. Prewitt reported several cases from the toy pistol. In one case from injury of the right arm he had obtained good results from the administration of large doses of bromide and chloral with five drop doses of Fowler's solution every three hours. In a few days the patient went into a typhoid state, in which he remained three weeks. He had an exceedingly dry tongue, but no diarrhœa. When he recovered it was discovered that the flexor muscles of the left foot were paralyzed. In another case in which the symptoms were mild, the same treatment was employed, and the man recovered. While it was doubtful whether every case could take such large doses of Fowler's solution, he thought a tolerance for it was developed in this disease.

Dr. Moses Gunn reported a case in which stretching of the median nerve was followed by recovery with permanent paralysis. Another case of nerve-stretching was attended by complete recovery. In another case following amputation, the administration of the calabar bean appeared to be the element of cure. It is an old view that if a case can be kept alive for ten days it will recover; looking at this from another view, it is in those cases in which the disease exhibits a milder form and comes on more gradually that the patient lives for ten days and finally recovers. The fatality is in direct ratio to the acuteness of the attack.

DR. T. W. BRIGGS thought there must be in all cases a peculiar predisposition to the disease. When the individual is in that condition, the slightest injury will be followed by the disease. He then reported a case in which the removal of an ulcer of the knee was followed by the disease and death within three days, although the wound had been carefully closed and no cause could be determined.

DR. CONNER, in closing the discussion, remarked that while he did not deny the theory of a predisposition, one fact was opposed to it, and that was that those persons who have the predisposition may be wounded over and over again without the development of tetanus. He thought there was nothing special in the character of the fulminate used in the toy pistol further than that it is a powerful one, driving the wad deeply into the tissues, where it soon becomes saturated, obstructs the discharge of fluids, and affords abundant opportunity for decomposition. It requires but an infinitesimal quantity of the septic matters produced by decomposition to produce the most alarming results. In explanation of the peculiar liability of the negro to contract the disease from wounds of the head and neck, he suggested that there is something peculiar in the free secretions of the skin of the negro that may be more liable to decomposition than those of the white man. Dr. Tiffany had further called his attention privately to the susceptibility of the negro to cerebro-spinal meningitis, a disease closely allied to tetanus. All the statements that had been made, he thought, favored the humoral theory. The cases that recover do so as a result of the administration of remedies which allay the irritability and tide the patient over the period of danger until the spontaneous elimination of the disease may occur. In his experience the disease had followed major rather than minor injuries. With regard to nerve injuries as a cause of the disease, he considered the point made in the paper of importance, namely, that the more sensitive the nerve the greater the lymphatic circulation, and, therefore, the corresponding liability to the absorption of septic matter. In conclusion, he expressed the hope that in the near future investigations will be made toward the discovery of the microörganism to which the disease is due.

Dr. C. T. Parkes, of Chicago, was unavoidably absent and his paper on

A CASE OF CHOLECYSTOTOMY,

was read by Dr. Moses Gunn.

The patient had suffered for several years from severe symptoms of the disease. The general health was, however, good. Some icterus was, however, present, and examination revealed a bulging of the right hypochondrium, due both to distention of the gall-bladder and enlargement of the liver. An oblique incision was made just above the prominence supposed to be the gall-bladder. After pushing aside the enlarged liver, the cyst was found very much distended. The bile was drawn off, an opening made in it, and the edges of the incision stitched carefully to the edges of the abdominal wound. No calculi were found. Four days were allowed to pass before the wound was dressed. It was found then that the enlargement of the liver had disappeared, and probing removed seven calculi. When the wound was next dressed, three days after, five more stones were removed. Three weeks after severe pain and the failure during the interval of the bile to pass into the intestine, rendered a second opening necessary. This time a probe was passed down the common duct into the intestine. After this the stools had a bilious character, and regular recovery followed. Two months later, the fistula had to be enlarged on accont of the recurrence of pain, the calibre of the duct appearing not sufficiently large to permit the proper passage of the bile. In conclusion, the author expressed the opinion that the case had been one of obstruction of the common duct, and that the stones which were found after the operation were not in the bladder but in the ducts, and did not pass into the gall-bladder until its distention was removed.

(This paper will be published in full in *The American Journal of the Medical Sciences* for July.)

DR. MEARS remarked that this disease is more frequently treated by the physician than the surgeon, but he thought the time had come when more attention should be given to the surgical treatment. Cholecystotomy is called for in more affections than those referred to in the paper. There are both intrinsic and extrinsic conditions which call for it; conditions in the gall-bladder and conditions in its ducts. The conditions most frequently requiring operative procedure are chronic inflammatory affections of the lining membrane of the duct; tumors making pressure upon the duct, malignant disease of the structures of the duct and around it; suppuration, the abscess in or around the duct requiring evacuation; and finally, impacted gall-stones either in the bile-duct or in the common duct. The cases that have been reported, which are contained in an article in *The American Journal of the Medical Sciences* for October last, number 35; of these eight or ten died. Stones were not found in all, but other conditions seemed to indicate the necessity of the operation. It is important, he thought, to be sure of the diagnosis before operative measures were adopted. With reference to the point at which the incision should be made, he thought it better not to go so high as in this case, because the tension of the liver on the delicate cyst is too great, and inflammatory conditions sometimes make it impossible to push the liver aside. Some consider the point where the least hemorrhage will occur the best, but the hemorrhage is seldom of any consequence. It was objected that this operation does not give assurance of a permanent cure, but that the disease is apt to return. On this account the entire removal of the gall-bladder has been advised. This is objected to, however, on account of the possibility of the existence of some relation between the presence of the gall-bladder and the discharge of the bile into the intestine, and that the destruction of this relation is apt to cause disturbance of considerable severity.

DR. TIFFANY referred to the difficulties of diagnosis and the frequence of mistakes. Further, it is a matter of interest to study the behavior of an organ when its ducts are occluded by a foreign body. Organs which are bilateral, as the kidney, are much more intolerant of obstructions than those which are unilateral. Where one ureter is obstructed, the opposite kidney is exceedingly prone to take on inflammation, but the duct of the liver, or of the pancreas, may be occluded and the subject live with comparatively little inconvenience.

He considered that catheterization of the gall-ducts promises good results.

Dr. Prewitt narrated a case in which he found the patient suffering great pain and in collapse. He could distinctly feel the gall-bladder full of stones through the abdominal wall. The patient died in a short time without recovering from the collapse. In the case of a negro woman the gall-bladder was very large, extending below the umbilicus. He aspirated and drew off a pint of a mucous fluid with very little indication of bile in it. In some cases gall-stones may remain in the gall-bladder for the greater part of the lifetime of the individual, doing very little harm. If they are discovered, he did not advise operation unless they should produce grave symptoms. In one case he had seen a woman who had suffered for years from obscure symptoms which were considered hysterical, in an attack of acute obstruction of the bowels. Operation was proposed and consented to, but before it was attempted the patient went into collapse. The autopsy revealed that a gall-stone had penetrated into the jejunum, causing the obstruction. He further believed the case of Prof. Hodgson, of St. Louis, who died from perforation of the gall-bladder, to have been one of this character, the stone being so small as to escape detection at the autopsy. He opposed the making of too low an incision.

Dr. S. W. Gross had collated 42 cases of operations upon the gall-bladder for concretions or dropsy, an examination of which may prove of interest in our efforts to arrive at correct conclusions regarding the proper management of these conditions.

Of 36 cases of cholecystotomy, 28 recovered, and 8, or 22.22 per cent., died—3 of exhaustion and hemorrhage, 2 of shock, and 1 each of escape of bile into the peritoneal cavity, suppression of urine, and acute peritonitis. He stated that the operators were Tait in 15 cases, Keen in 2 cases, and Kocher, Ransohoff, Gardner, Eddowes, Savage, Bobbs, Sims, a surgeon quoted by Tait, Courvoisier, Trendelenburg, Koenig, Boeckel, Naire, McGill, Meredith, Parkes, Savage, Taylor, and Wright, each in 1 case. In the case of Wright, the patient was thought to be the subject of renal calculus, so that the incision was made through the loin, and a stone extracted from what at first was presumed to be the enlarged ureter. On death from peritonitis, the kidney was found to contain a stone. In 4 cases, the gall-bladder was sutured and returned into the belly. Of these 1, or 25 per cent., died as the direct result of the procedure, as against 8 deaths out of 31 cases in which the viscera was stitched to the wound, the mortality being 22.58 per cent. In the case of the surgeon mentioned by Tait, the sutures appear to have given way and permitted the escape of bile into the peritoneal cavity. That suturing the bladder is not so dangerous as Tait assumes is shown, not only by the comparatively insignificant rate of death, but by the case of Meredith, in which, on death from suppression of urine, the stitches were all right, and the gall-bladder contained nearly eight ounces of bile. Were he himself called upon to do the operation, he would certainly employ sutures and return the organ.

In 6 cases the gall-bladder has been excised, 5 times by Langenbuch, and once by Courvoisier. One of Langenbuch's patients died, because of the existence of an ulcer in the cystic duct, which was overlooked on account of the presence of large masses of fat, which permitted the bile to escape into the peritoneal cavity. Hence, the mortality of cholecystectomy is 16.66 per cent., or 6.19 per cent. less than that of cholecystotomy, which shows that is not so absurd a procedure as Tait declares it to be. Finally, in 1 case Von Winiwarter successfully established a communication between the duodenum and the gall-bladder. This operation, or cholecystenterostomy, has not been repeated on the human subject, although Dr. Gaston, of Atlanta, has experimented with it on dogs.

In the present state of our knowledge, based upon the foregoing data, he would prefer cholecystotomy in recent cases, but would not hesitate to extirpate the gall-bladder if its coats were ulcerated, or if ulceration were threatened.

Dr. J. Ewing Mears next read a paper on

PHOSPHORUS NECROSIS OF THE JAWS,

in which he discussed chiefly the local and constitutional character of the disease, the value of early treatment in arresting it, the value of a certain agent (turpentine) which is antidotal in character, and, finally, the prevention of the disease. After a brief résumé of the history of the disease, he reviewed all the more important conditions that have a bearing upon the affection and the susceptibility of certain persons to it. This susceptibility varies greatly with different individuals. A majority of the employés of match factories are females, varying in age from eleven to twenty. Some of these work only a few weeks, while others are able to endure it for years. Most of the cases are among those in the packing-room. The effects of phosphorus on the system were also described at some length. Very few of the symptoms given as the physiological or toxicological effects of phosphorus were found at all prominent in these cases. Beyond the evidences of bronchial and conjunctival irritation, none was prominent. Constipation was more frequent than diarrhœa. No aphrodisiac effects were observed, and no change in the menstrual flow. Pain over the liver, nausea, and sick headache, are described by many, while well-defined catarrhs have not been noted. One of the primary effects of the poison is the disintegration of the red blood-corpuscle and the fatty degeneration of the blood-vessel walls. With this degeneration of the walls, the liability of the poison to affect the periosteum and the mucous membranes is great. He had seen hemorrhages from mucous membranes that appeared blanched and bloodless. Professors von Bieber and Geis, in 1847, concluded, from original experiments with phosphorus on rabbits, that the poison must come into direct contact with the periosteum in order to produce necrosis, and that those free from carious teeth were free from the disease. The last opinion, he received with some hesitation, because he had seen persons with carious teeth who were not affected after long exposure; persons who had had teeth extracted without ceasing their employment and without the development of the disease, and in the case previously referred to the disease did not develop until three months after the exposure had ceased. The only early symptom was the feeling, on the part of the patient, that his teeth were lengthened. Importance was placed upon the accumulation

of tartar about the necks of the teeth, and its penetration below the surface of the gums, resulting in constant irritation. This irritation renders the phosphorus more likely to attack the alveolus, especially upon exposure to cold or wet. Comparing the effects of phosphorus and arsenic necrosis, he pronounced the former local, the latter general.

The repair from phosphorus necrosis varies with different cases. Usually it pretty completely envelops the necrosed bone and encroaches well upon the articulation. In one case, in which operation was refused and the disease went on for six years, the sequestrum was completely enveloped by the new bone. But the permanent character of the new bone formation has been called into question by Mr. Salter, who claims that sooner or later the new bone will be absorbed. While absorption sometimes occurs, he did not think it necessary, and believed that its occurrence depends to some extent upon the time at which, and the method by which the sequestrum is removed. Although it would seem that the pressure of dentures upon the new-formed bone would hasten its absorption, this is not the case, but rather the reverse. The frequency of the disease in the lower jaw as compared with the upper, he attributed to the difference in histological structure and blood-supply of the two bones. Further, his experience had been the reverse of that of Mr. Heath that phosphorus necrosis is less frequent in cancellous bones than in compact ones.

The symptoms of the disease are at first intermittent, but soon become continuous. The first and second stages soon pass, giving way to the suppurative stage. In that stage, the teeth become loose, and pus exudes from the alveoli; the gums become detached, and the alveolar border becomes visible. The discharge is of a very offensive character. In the lower jaw, the pus usually burrows to the most dependent poin , discharging at the lower margin of the jaw, and in one case it was discharged at the lower margin of the clavicle. When the condyle of the jaw is affected, great pain is experienced in the ear. The difficulty of taking food, the pain occasioned by the attempt to do so, and the swallowing of the offensive discharges all tend to deteriorate the health of the individual, and unless interference is made death may occur.

The treatment divides itself into primary, intermediate, and secondary. It is rare that the patient presents himself for primary treatment. The treatment, however, relates to the condition of the teeth, and the administration of antidotal remedies. Teeth too much diseased to be saved should be extracted, others should have temporary fillings until able to bear permanent. The gums should be bathed in alcohol, tincture of myrrh, phenol, etc. The vapor of turpentine is reputed to overcome the effects of the vapor of phosphorus.

When the stage of suppuration has developed, cleanliness should be enjoined and solutions of iodine and carbolic acid should be thrown around the parts. Also a 7½ per cent. of iodoform gauze should be used to receive the discharge, and to prevent its mixture with the secretions of the mouth. Poultices and warm applications should not be used, and nothing should be done to retard the growth of new bone. The sequestrum should not be removed unless the necrotic action has ceased and the development of new bone has reached a stage sufficient to retain the shape of the jaw. The sequestrum should be removed from the mouth, care being taken not to fracture or tear away the lamellæ of new bone. After removal of the sequestrum, the cavity should be filled with a 7½ per cent. of iodoform gauze. The strength of the patient should be maintained with iron and quinine and concentrated food. The prevention of the disease should be accomplished by control of the employé. The emission of the fumes of phosphorus should be prevented as much as possible, and they should be removed as quickly as possible. The vapor of turpentine should be employed either in large baths or in small reservoirs suspended around the neck of the workmen. In addition to this, cleanliness and frequent inspection of the teeth should be enforced.

DR. E. M. MOORE inquired whether phosphorus necrosis differed materially from ordinary necrosis of bone, and whether in young cases the articulation escaped. He asked further how long the speaker had been accustomed to wait for the formation of new bone before operating; if much contraction of the arch occurred; and whether when the bone removed includes the joint, a useful articulation was formed by the regenerative process.

DR. MEARS replied that his attention had never been called directly to the first question. In regard to the second, all his patients had been of such an age as to represent the adult formation of bone, and that the joint was therefore involved. The period of time that should elapse before operation varies with the case; as a rule, at least four months are required for the new bone to become sufficiently firm. Contraction of the arch is not to be feared except where the entire jaw is removed. To prevent this, it is advisable to remove only one side of the jaw at a time, waiting until that side has become firm before attacking the opposite side. The new joint is, as a rule, perfect so far as function is concerned.

DR. MEARS next exhibited an *Apparatus for the Inhalation of Ether*, the advantages of which were the regularity of the flow into the cone, and the ease with which the ether could be disengaged by heat.

Some miscellaneous business having been transacted, DR. MOSES GUNN, President-elect, was conducted to the Chair, and he accepted the presidency in a few words expressive of his gratification at the honor, and his sensibility of the importance of the position.

DR. W. T. BRIGGS, in retiring from the Chair, congratulated the Association on the success of the session, which he then declared adjourned.

LOUISIANA STATE MEDICAL SOCIETY.

Annual Meeting, held at New Orleans, April 21, 22, 23, 1885.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from p. 508.)

APRIL 23D, THIRD DAY.—MORNING SESSION.

MISCELLANEOUS BUSINESS.

THE Secretary read a communication from the Rapides Medical and Surgical Association, asking the Society to hold its next meeting at Alexandria, and one from the

Bienville Association, requesting the Society to meet at Arcadia. These communications were referred to the Nominating Committee.

Dr. Tebault moved that a Nominating Committee, to consist of one member from each Parish represented, be formed. Carried.

Dr. Lyon moved that "the thanks of the Society are due, and are hereby tendered our Recording Secretary, Dr. P. B. McCutchon, for his faithful performance of his duties during the past two years." Adopted.

THE COMMITTEE ON NECROLOGY

reported the death of four valued members of the Society during the year 1884.

In Ascension, Dr. A. C. Love, July 29; in De Soto, Dr. R. T. Gibbs, in July; in New Orleans, Dr. J. C. Faget, December 9; and, lastly, Prof. S. M. Bemiss, M.D., in whose death on November 17, the profession of this State and of the country at large mourns the loss of one of its most eminent and gifted members; distinguished as a teacher, as a sanitarian and philanthropist, as well as for his learning and social qualities, which endeared him to friends and acquaintances.

Dr. M. Schuppert read extracts from his paper on the *Physiological Action of Chloroform*, with experiments on animals.

THE NOMINATING COMMITTEE

presented the following report, which was adopted:

President.—Dr. Samuel Logan, of Orleans.

Vice-Presidents.—Dr. E. S. Lewis, Dr. C. J. Bickham, Dr. T. J. Woolf, Dr. A. A. Lyon, Dr. William Kelly, Dr. O. P. Langworthy.

Annual Orator.—Dr. H. D. Bruns.

Place of Meeting.—New Iberia.

Dr. Rudolph Matas then read a valuable paper on

THE NATURE OF THE CONTINUED FEVERS OF LOUISIANA WHICH RESIST QUININE.

In Austria, Germany, and France, where malaria is not especially prevalent, the indiscriminate use of quinine is, to say the least, extravagant, quinine being administered in those countries not so much as a specific or antidotal agent, but simply as an antithermic. The immediate use of quinine at the onset of an obscure fever of low temperature would there be censurable, but in Louisiana, where malarial fevers of an insidious and malignant character so extensively prevail, the object of the therapeutist is not so much to lower a temperature, that might be insignificant in itself, but to prevent any further development of pyretic phenomena by antagonizing or neutralizing the poison—the paludal poison, which might be acting as the pyrogenic agent. Hence, Dr. Matas held that the teaching of Nothnagel was not applicable to Louisiana and other malarious countries, and that the general practice of immediately prescribing quinine at the onset of a fever of obscure etiology was safe and correct.

Dr. Matas stated that his aim was to discuss those pyretic states in which it was comparatively worthless as an antipyretic.

These conditions might be classed in the order of rebelliousness as follows: 1. Yellow fever; 2. Typhoid fever; 3. The so-called typho-malarial fever; 4. Dengue; 5. The so-called "continued malarial fever;" 6. The simple continued fever; 7. The malarial remittents with organic complications or "bilious fever."

After a cursory review of the etiological factors in these diverse pyrexiæ, he concluded that the reason why the cinchona alkaloids fail to produce any effect is simply due to the fact that in each one of these conditions the causative factors are agencies which are not neutralized or antidotally affected by the alkaloids, the beneficial action of quinine being specifically restricted solely to cases of uncomplicated malarial fevers.

The major part of the paper was devoted to the study of the so-called "continued malarial fever," which was recognized under various confusing and misguiding appellations by practitioners. In this condition, which he regarded as an absolutely independent entity, quinine is a thoroughly impotent agent. The differential diagnosis between this fever and typhoid and malarial fevers was elaborately treated and copiously illustrated by graphic thermometric observations. Special stress was laid in the absence of enteric and ataxic symptoms in this condition as differentiating it from typhoid. Quinine had been administered, thirty grains per diem, in many cases for one week with the view of testing its relations to malaria, but no effect whatever had been produced. The new antipyretics, salicylate of soda, kairin, and especially antipyrin, had been tried with remarkable antithermic results, the numerous charts presented by Dr. Matas attesting to his observations. The fever, however, was never arrested in its course, an abnormal elevation of temperature persisting, during two, three, four, and five weeks, but under the vigilant administration of the antipyretics and a supporting treatment, the dangerous effects of excessive tissue change had been greatly eliminated. The prognosis is favorable in all the typical cases of the continued fever.

The great difficulty in the differentiation of this fever from the malarial fevers at the beginning of a case, is the lack of a positive differential test. Periodicity is certainly no criterion of malaria; the blood morphological changes which are special to malarial poisoning which may furnish a microscopical test for this agent, are practically valueless at the most needed moments. The inoculations recently performed by Gerhardt, Ciarrochi, Mariotti, and other Italian observers, may perhaps furnish a future test for the malarial poison, but this is highly improbable.

The quinine or therapeutic test, though imperfect, furnishes clinically the readiest and most practical means of determining the nature of a case. After prolonged observation, the speaker believed that, as a general proposition, it is safe to assume that any essential fever (a fever free from organic complications) which remains unaffected after a thorough and systematic administration of quinine, is not a malarial fever.

In conclusion, it was stated that more accurate and detailed observations are needed to complete the satisfactory study of the fevers of this section. The word "malaria" is repeated too frequently in our medical vocabulary, and appears too often in our diagnoses. It is a convenient word, but, like the *regnum protisticum* of some naturalists, it serves merely to designate a

scientific *limbo* wherein numerous species are patiently waiting redemption.

Dr. Austin then read a paper on the *Inversions of the Gravid Uterus.*

Evening Session.

The second Wednesday in April, 1886, was selected as the *time for the next meeting.*

The newly elected President announced the new Committees, and after passage of appropriate resolutions of thanks, the Society adjourned to meet in New Iberia, La., on the second Wednesday in April, 1886.

CANADA.

(*From our Special Correspondent.*)

Toronto General Hospital.—During last winter's session, four hundred and fourteen students have been attending the practice of the Toronto Hospital. The average daily number of in-patients was over two hundred. Special gynecological wards have been lately opened under charge of Drs. Temple and U. Ogden. The training-school for nurses in connection with the hospital is in a prosperous condition, and has thirty-four pupils.

Summer Sessions.—The tenth summer session in connection with McGill University opened on the 13th of April, and continues for three months. The courses are mostly practical, and given in the Montreal General Hospital. This year the two rival schools in Toronto have combined to form a teaching faculty for the summer session in the Toronto General Hospital. All the lectures will be given in the hospital. The session begins on May 1st, and lasts ten weeks.

Yellow Fever Inoculations.—We are indebted to Dr. Domingos Freire for a copy of the *Rio News*, of April 5th, in which he publishes the following important statement concerning his yellow fever inoculations.

With the intention of giving your readers some ideas which I trust will be of interest, relating to the inoculations practised in the city with the attenuated liquid culture as a prevention against the dangers of contracting yellow fever and of which I have by order of the Imperial Government the charge, I beg to give you the following details.

Having had printed in different languages (Portuguese, German, Spanish, Italian, French, and English) notices relating to the subject, of which the enclosed are specimens, after their distribution in the most conspicuous and convenient parts of the town and in places where they in all probability would be useful, I gave the necessary instructions to my assistant, Mr. Charles Browne, to proceed with the work.

From December 22d last year, up to March 22d instant, or in the period of three months, 1109 persons of different nationalities, and whose ages ranged from one month to sixty years, were submitted to subcutaneous injections in the deltoid region of the arm with the said liquid. All, with the exception of one or two cases, experienced elevations of temperature varying from 37.5° C. to 40° C., *frontal headache*, pains in the articulations, general indisposition, and in some, slight epigastric oppression—symptoms which ceased after twenty to forty hours and without any medical intervention. In many cases these injections were practised in houses where a few hours before deaths had taken place from yellow fever; nevertheless in the cases specified and under disadvantageous hygienic circumstances, not one single serious accident has happened. I beg to add that these inoculations were chiefly performed in my presence and in the company of the two medical gentlemen commissioned by the Spanish government specially to study this disease in Brazil.

Every care has been taken in giving publicity in one of the principal newspapers, as to the names, ages, professions, conditions, residences, time in Brazil, etc., and this will be continued in order to facilitate the necessary examination by those who may be so inclined.

New York State Medical Association.—The second scientific meeting of the Fifth District Branch will be held at the Morgan House, Poughkeepsie, at 2.30 P.M., on Tuesday, May 19, 1885. The following papers will be read:

"Three Cases of Ligation of the External Carotid; in Two, Both Vessels were Tied Simultaneously," by J. D. Bryant, M.D.

"Diphtheria and its Treatment by Calomel," by S. J. Murray, M.D.

"Hypertrophy of the Prostate Gland," by J. G. Porteous, M.D.

"Treatment of Cerebral Hemorrhage and Embolism by the Internal Use of Carbonate of Ammonia," by R. C. Van Wyck, M.D.

"Report of a Case of Rheumatic Metastasis to the Brain, ending Fatally," by C. S. Wood, M.D.

Jefferson Medical College.—It is understood that Dr. Wm. H. Pancoast has informed the Trustees and Faculty of his intention to resign the Professorship of Anatomy in this school at the expiration of the next term.

University of Pennsylvania.—At the Annual Commencement of the Medical Department, held on May 1st, the degree of M.D. was conferred on 108 graduates.

THE EPIDEMIC OF TYPHOID FEVER AT PLYMOUTH, PENNA.

BY LEWIS H. TAYLOR, M.D.,
OF WILKESBARRE, PA

THE borough of Plymouth, situated upon the banks of the Susquehanna River, three miles below the city of Wilkesbarre, in the State of Pennsylvania, is a mining town of some eight or nine thousand inhabitants of various nationalities. The main street of the town is parallel to the river and upon alluvial soil, while a large portion of the inhabitants live upon higher ground extending some distance toward the sloping mountain beyond.

The general health of the inhabitants has in past time not been worse than that of their neighbors in surrounding cities, but about the second week of April, of the present year, an epidemic of fever, of great virulence, broke out, and so sudden was the onset, that within a very few days nearly a thousand people were stricken with the dread disease. The ravages were not confined to any class of people, nor to any section of the town, but the dwellers in the mansion as well as in the hovel were alike attacked; the house upon the hillside being not more free from the scourge than that situated in the valley.

The epidemic appeared so suddenly, following upon a few days of warm weather, and the symptoms of those first attacked were so severe, that some diversity of opinion as to the true nature of the disease seemed to exist among the attending physicians. It was variously declared to be typhoid fever, malarial fever, typho-malarial fever, and typho-malarial-meningitis; but in a very short time its true nature was made manifest, and the doubt no longer existed that a true epidemic of typhoid fever was hanging over the doomed borough of Plymouth. The scourge spread with frightful rapidity, from fifty to one hundred new cases appeared daily, until nearly one thousand persons, as above stated, were affected.

Various theories as to the cause of this outbreak were put forth, the most prominent being that it was due to the accumulated filth of the town, which being acted upon by the warm rays of the April sun, had suddenly become noxious, but inasmuch as all classes of people were attacked, the clean as well as the filthy; and all parts of the town affected, the highlands as well as the valley; thoughtful minds naturally turned to the water supply as a possible cause of the invasion. But Plymouth is supplied by a stream of great purity, which comes leaping down the mountain side a distance of several miles, and is distributed through the various streets by pipes running from the lower of four successive reservoirs, formed by huge dams of masonry across the stream. Occasionally, however, when the water in this stream is quite low, the pipes are supplied with water pumped directly into the mains from the Susquehanna River. This was the case from March 20 to March 26, but as the river water at this point is known to be reasonably pure, this fact did not seem to present sufficient explanation of the cause of so widespread an epidemic.

That the mountain stream supplying the town with water might have become polluted by fecal matter was first suggested by Dr. R. Davis, of Wilkesbarre, in an article published in the *Record of the Times* about May 1st. The publishing of the article excited considerable interest, and, as great consternation prevailed among the people upon the subject of drinking water, a committee of physicians, consisting of Drs. J. A. Murphy, J. L. Miner, and myself, was requested by the Plymouth Water Company to make a thorough investigation of its reservoirs and stream, to ascertain, if possible, whether any source of water pollution had existed, and whether the same was now operative. A very careful examination of the stream, with its several reservoirs, was made on May 6th, and specimens of water from different points procured for chemical examination.

The Committee found the stream supplied with an abundance of pure water, and no source of contamination at *present* existing, but between the third and fourth reservoirs, however, in the only house situated upon the stream, and within forty feet of its banks, they found a patient convalescent from typhoid fever. This patient visited Philadelphia on December 25, 1884, and while there contracted the disease. He returned to his home in January, and was quite ill with genuine typhoid fever for many weeks, having suffered from a relapse of the same after he had partially recovered. On March 18th and 19th, he suffered from attacks of hemorrhage from the bowels of so severe a type that his life was despaired of.

During the course of his illness the dejecta passed at night, without any attempt at disinfection, were thrown out upon the snow toward, and within a few feet of, the stream supplying the town, while that passed during the daytime were emptied into a privy, the contents of which *lie upon the surface of the ground.* That this was so done we have from the testimony of the two nurses in attendance, and it is not denied by other members of the household. These dejecta, thrown out from time to time, no doubt accumulated and remained innocuous upon the snow and frozen ground. From March 25th to March 31st, the temperature, as shown from actual records, was daily above the freezing point and sufficiently warm to melt large quantities of snow, while early in April we had frequent, light showers of rain with mild, warm weather. These

thaws and rains removed the snow, and with it the accumulated poisonous dejecta, directly into the water supply. Supposing this to have occurred between March 25th and April 5th, and allowing from ten to fourteen days as the proper period of incubation, we would expect, from this cause, an outbreak of typhoid fever to occur from the 5th to the 15th of April. The time of the proven contamination of the water supply, allowing the proper time as the period of incubation, corresponds so thoroughly with the onset of the epidemic, that the Committee could but conclude that in this explanation sufficient cause was found for the epidemic of typhoid fever in Plymouth.

The opinion that this disease, in the present case, came directly from the use of hydrant water from the reservoirs, and not from that pumped from the river in March, was strengthened by the following facts: Six hundred feet below the first reservoir from which the supply pipes start, there is found upon the banks of the stream a house in which two persons are sick with the fever. The family living in this house dip water directly from the stream overflowing from the reservoir, and have at no time used river, or hydrant water. A little further down the same stream stands a house in which hydrant water is used, and in this house the sickness prevails, while in another, situated but sixty feet away, and supplied with well water, all the inmates are free from the disease. A little further north of these houses there are found, on Temperance Hill, eleven families using well water. None of these have at any time been attacked. On the upper side of Lee Street almost every family using hydrant water is affected, while those living on the lower side of the same street all use well water, and none of them are sick.

The same relative state of affairs exists on Davenport Street. Ackley Street, which is supplied with a small pipe and back water, has but few sick, while on Franklin Street, supplied by the regular main, very many are affected. On Franklin Street one house supplied with well water was found in which two patients are ill, but of these the first to contract the fever was a girl of nine who had been attending the public schools, these schools being supplied with hydrant water. Many cases exist where well water is used, but it is found that the patients first attacked in such houses are those accustomed to drink water away from home.

Further investigation of numerous cases but confirms the opinion that persons who use well water habitually, and are suffering with the disease, are those who have been accustomed also to drink hydrant water away from home; the women and the children in such houses, except those who attend school, are not attacked.

Another striking instance was found which shows that the poison taken into the system did not come from the river water pumped into the pipes from March 20th to March 26th only. A lady came from the West to visit her sister, and arrived in Plymouth March 29th, and thus drank no river water, but she was taken ill on April 12th (about the time of the general outbreak); consequently the poison did not enter her system until after the river water had ceased to be used. A young lady from a neighboring State visited Plymouth late in March, remaining until April 2d or 3d, and is now ill with the disease at her home. A physician from a distance, spending a few days with a friend in the borough early in April, contracted the disease, and is now reported seriously ill in another part of the State.

If the river water were the cause of this disease, as is held by some, then we should have looked for an outbreak any time from March 30th to April 2d; in other words, from ten to fourteen days after the pumping of the river water began, but the fact is, no cases of the disease appeared until about April 10th or 12th.

The Committee did not pursue the investigation further, because they believed they had already found in the facts above mentioned sufficient explanation of the cause of the epidemic. They concluded as follows:

1st. That the present epidemic in Plymouth is undoubtedly one of typhoid fever.

2d. That its exciting cause was the use of water from the reservoirs furnished some time between March 25th and April 5th, and polluted by excreta from a typhoid fever patient living near the source of water supply.

3d. We do not believe that the said epidemic was caused by drinking river water. We are led to the second conclusion from finding what, in our judgment, is sufficient evidence of past pollution of the water supply near its source, and because it is well known that excreta from *one* typhoid patient have frequently poisoned the water supply of a whole neighborhood and caused an epidemic of such fever.

We have only to refer in corroboration of this to the epidemic of New Boston in 1843, cited by Dr. Austin Flint, and to the outbreak at Munich in 1860, and again in 1862; at Caterham and Red Hill in 1878; and especially at Nunney in 1872. We conclude it is not due to the river water pumped directly into the company's mains from March 20th to March 26th, first: Because we have found sufficient cause elsewhere; and, again, because (though not conclusive) river water is frequently used at Plymouth and Wilkesbarre, and constantly at Nanticoke, without causing such epidemics.

We find the present water supply in very good condition, and the specimens from the several reservoirs and taps of excellent quality and purity. We have carefully tested each specimen for organic matter and find none. The specimens, with one exception, are almost entirely free from sediment, of neutral reaction, tasteless, and odorless. The exception mentioned is that taken from an *unused* hydrant at the corner of Lee and Davenport Streets. This, under a high power of microscope (immersion lens) shows infusoria and inorganic matter with traces of vegetable matter. In the specimens from the reservoirs and taps used in town, there was no appreciable sediment.

Although we may expect new cases to arise from contamination of those already existing, we believe

the chief danger to be past, and the origina cause no longer existing.

The epidemic, as already mentioned, is widespread. A careful estimate gives the total number of cases in Plymouth and its immediate out 'rts as rather more than one thousand, while an actual count shows within the borough limits seven hundred and thirty still sick with the disease. Thus far, between eighty and ninety have died.

This most remarkable epidemic teaches us an important lesson at fearful cost. viz., that in any case of typhoid fever, no matter how mild nor how far removed from the haunts of men it may be, the greatest possible care should be exercised in thoroughly disinfecting the poisonous stools. The origin of all this sorrow and desolation occurred miles away, on the mountain side far removed from the populous town, and in a solitary house situated upon the banks of a swift-running stream.

The attending physician did not know that this stream supplied the town below with its drinking water. Here, if in any place, it might seem excusable to take less than ordinary precautions, but the sequel sadly shows that in all cases the most rigid attention to detail in destroying these poisonous germs should be enjoined upon nurses and others in charge of typhoid fever patients; while the history of this epidemic will but add another to the list of such histories which should serve to impress medical men at least, with the great necessity for perfect cleanliness, a lesson which mankind at large is slow to learn.

The Committee, in a supplemental report, recommended the Water Company not only to remove from the banks of its stream the offending privy, but also to remove privy and outhouses from its property on the banks of the fourth reservoir, lest these too, in the future, become a possible source of contamination.

The lesson of this epidemic should impress other Water Companies with the necessity of making a careful sanitary survey of their supply, and of removing from their streams, so far as may be, all possible source of contamination.

46 South Main Street, May 9, 1885.

Note.—Since writing the above a post-mortem examination of one of the unfortunate victims has been made, Police Surgeon French and Dr. E. O. Shakespeare, of Philadelphia, being present, which establishes beyond cavil the true nature of the disease, the characteristic lesions of Peyer's glands being found, the patient having died of perforation of the bowel. This simply confirms the diagnosis of nearly all the physicians of the neighborhood, that the epidemic was purely one of typhoid fever.

AN EPIDEMIC OF ACUTE CATARRHAL CONJUNCTIVITIS—"PINK EYE."

By H. F. HANSELL, A.M., M.D.,
CHIEF OF CLINIC OF EYE DEPARTMENT OF POLYCLINIC, OPHTHALMIC AND AURAL SURGEON TO SOUTHWESTERN HOSPITAL, ETC.

Within the past few weeks so many cases of acute inflammation of the conjunctiva have occurred in Philadelphia and surrounding country, as well as in several other Eastern cities, as to warrant the use of the term epidemic. Some have presented the features of the ordinary non-epidemic catarrhal inflammation, while others, on account of the violence of the inflammation, have had the appearance of Egyptian (purulent) ophthalmia, and seemed bordering on it. Saemisch[1] thus defines conjunctivitis catarrhalis (simplex) "in general a condition of abnormally diffuse hyperæmia of the membrane attended with increased mucous secretion." It is a more or less active exudative inflammation, developing suddenly, and frequently, without assignable cause, reaching its acme it twenty-four or thirty-six hours, receding nearly as rapidly, entirely disappearing in three or four days, and leaving no trace.

As is well known, most of the forms of conjunctival inflammation are contagious, hence their liability to occur in epidemics. Exactly how the contagion is communicated is not known. It may be by actual conveyance of the discharge from a diseased eye to a healthy one by means of towels, fingers, etc.—*material means*—and it undoubtedly is in some cases, for example, in a family of several persons where each one is successively affected; but the majority of cases owe their origin to contagion conveyed through the air—*ethereal means*. An epidemic could hardly be produced by material means, but, as in yellow fever, cholera, etc., by the ethereal dissemination of the poisonous germs or bacteria. The indirect cause of the conjunctivitis, that is, the direct cause of the epidemic, may probably be ascribed to a specific poison, which depends for its life and sustenance on moist filth, decaying refuse of all kinds collected during the winter, and which, liberated from its home by the warm rays of the spring sun, makes its way to our bodies, lighting up in one acute catarrhal conjunctivitis, in another typhoid fever, in a third acute tonsillitis, etc.

The recognition of this disease is not difficult. The inflammations most resembling it, and with which it is most apt to be confounded, are scleritis, episcleritis, and iritis; but, if its prominent symptoms are remembered—bright red conjunctival injection—involving the entire membrane, greatest on the lids and gradually growing fainter towards the cornea; the mucous discharge collected in flakes in the folds, the adherence of the eyelids to one another in the morning; the history—epidemic—its sudden appearance, rapid development, and almost entire absence of pain, its disappearance in a few days under the simplest treatment; and its binocular character, the affection attacking the second eye within a few hours of the first—and these signs are seen in every case—a mistaken diagnosis must be a rare occurrence.

The prognosis is always favorable. No serious complication is apt to arise. In severe cases the inflammation extends by contiguity into the tissue of the lids beneath the conjunctiva, and produces acute blepharitis. The adjacent connective tissue becomes infiltrated and œdematous, presenting the appearance of gonorrhœal ophthalmia. The secretion, although abundant, is never purulent. Œdema of the ocular conjunctiva (chemosis) may also be present, but is

[1] Graefe and Saemisch Handbuch der Augenheilkunde.

never very intense, nor does the inflammatory action extend to the cornea or iris. The former remains perfectly transparent and the latter reacts readily to light and mydriatics. A symptom which may give the patient considerable anxiety is the peculiar appearance of a gas-jet, or other small luminous object. It is distorted from its proper shape and surrounded by a ring of colors. This symptom is caused by flakes of mucus on the cornea, through which the patient sees the light. It disappears for a short time, or is changed after winking and is of no importance. An existing error of refraction may be discovered after the inflammation has passed away by the inability of the muscle of accommodation to resume its abnormal contraction, a good and not an evil result.

The *treatment* is entirely local and of the mildest character. A weak astringent wash, such as borax, gr. v, and ℥ss each of camphor water and pure water, or the same strength alum solution, used freely and frequently on a soft, clean sponge to the closed lids, and the application at night of Pagenstecher's ointment—hydrarg. ox. flav., grs. ʒj—or simple cerate will be proper for the majority of cases. If the inflammation shows a tendency to become chronic, touching the everted lid daily or every second day with silver nitrate, gr. ij—℥j, will speedily effect a cure.

My experience with abortive measures is not sufficient to warrant conclusions, but in one case I was able to prove the efficacy of a ten grain solution of silver. The patient, who was suffering from a severe attack in the right eye, was instructed to present himself immediately upon the appearance of the injection or sense of discomfort in the left. He did so. The silver was applied, followed by cocaine to mitigate the pain, and the next day the left was quite as well as the right. The injection had disappeared in twenty-four hours and did not return.

To prevent the spread of the disease all cloths, sponges, etc., used to cleanse an affected eye should be destroyed or thoroughly washed in a disinfectant solution. Precautionary measures, however, seem to be of little avail. In a private family consisting of a mother, four adult sons, and two servants, all were affected except one servant, although one of the sons who was the first attacked was warned to be exceedingly careful lest he should spread the disease to the others. Five of the six cases were binocular.

254 South Sixteenth Street.

EVACUATION OF AN OVARIAN CYSTIC TUMOR THROUGH THE INTESTINES.

By S. J. RADCLIFFE, M.D.,
of Washington, D.C.

Mrs. R. F., Irish by birth, aged 46 years, married late in life, no children, menopause occurred two years previously, apparently without constitutional disturbance, consulted me August 15, 1883, on account of a considerable colored watery discharge from the vagina and "lumps" in the lower part of her abdomen, one in either side, in each inguinal region, and deep-seated uneasiness, sometimes pain, almost continually felt in those parts.

She said she had been suffering in this way for several months, but felt some modesty in asking advice on the subject, hoping she would get better or relieved, and there would be no necessity for it. Finding her abdomen increasing in size, however, and the discharge continuing, she was compelled, as the only alternative, to make her complaints known.

I had treated her five years before while unmarried, for inflammatory rheumatism, and ever since that period she had always looked pale and cachectic. She kept about her usual occupations notwithstanding, was married, and undertook the duties of housewife with commendable alacrity, only consulting me occasionally for her old trouble of rheumatism, scarcely mentioning any abdominal pain or disturbance, or if so, it was considered of a fugitive character, and treated only in a general way.

She had greatly changed in appearance since I last saw her. She looked still pale, but wrinkled and old, and her flesh was soft and flabby, and she had shrunken like a person and looked fully sixty years of age. Though she had been a stoutly built woman, she did not move with her usual vigor and promptness, and had come to regard herself as a confirmed invalid. Her general external aspect was indicative of disease, while the functions of the heart and other organs of the body, independently of the uterus, were below normal.

On external inspection of the abdomen I found it enlarged, more so on the left side than on the right. On closer examination I discovered a large globular tumor, as large as a child's head, giving the appearance of about five months' pregnancy, of cystic outline, more or less elastic, easily defined, movable, but having some attachment to the contiguous parts, flat on percussion, occupying the left inguinal region, extending somewhat into the hypogastrium, and upwards to or above a line with the anterior superior spinous process of the ilium. On the right side a hard, firm, inelastic nodular tumor, broad, flattened, and of irregular outline, the surface as large as the palm of the hand, of a fibrous nature, bound down by adhesions and decidedly dull on percussion.

On vaginal examination I found the cervix large, swollen, and tender, bleeding to the touch; the uterus large and firm, and pressed down low in the pelvis, its mobility considerably diminished, especially noticeable by bimanual exploration, and by the probe, though the latter was employed very carefully for fear of exciting hemorrhage. The posterior vaginal cul-de-sac was almost obliterated from the pressure of the superimposed parts, and the position of the uterus was slightly oblique to the right, the os looking to the left.

Malignant disease of the uterus and its appendages was suspected—the tumor being probably fibrous or scirrhous in nature on the right side, and cystic or cysto-sarcomatous on the left side of the uterus, and of ovarian origin—and the fact was so stated to the husband of the patient, and also that medicine held out no hope for her relief. Consultation with a competent gynecologist confirmed this diagnosis, as well as the prognosis, and satisfied us that no surgical means would be of any avail in the case.

Her condition remained unchanged for five or six

weeks—the treatment in the meantime being merely palliative. Her abdomen then began to increase in size perceptibly, and the discharge from the vagina to increase, accompanied by some unpleasant odor. She suffered very much from nausea, and eructations of gas from the stomach, and it was difficult to nourish her, anorexia being a prominent symptom throughout. She consequently emaciated rapidly, but did not become so feeble as not to be able to turn or move herself in bed until towards the last. Her mental acumen did not suffer.

Three weeks before her death, which occurred about five months after my first examination, January 4, 1884, she began to have involuntary fetid stools, and one week later began to vomit without pain, straining, or effort, as if by reversed peristalsis, large quantities of a brownish, thin, soupy-looking, nearly odorless fluid, which continued at various intervals for an hour or more at a time. The intervals were not regular or constant, and depended upon no particular condition. The nausea was persistent, but its more or less intensity did not seem to govern the flow. With her head on the pillow the ejected matter would pass out siphon-like. The vomiting would begin and continue with varied force for some time, then cease, to be resumed the same day, or perhaps not until the next day or the day following. It was more continuous the last few days of life. The tumor or cyst in the left side began manifestly to diminish in size from the first vomiting, and gradually emptied, while at the time of her death—which took place from exhaustion—it had nearly disappeared, what remained being not larger or less than a small orange. The hard tumor on the right side was seemingly not affected by the vomiting. The external genitals became so swollen as to make further examination in that direction impossible. No examination was permitted after death.

Not having seen a similar case reported in any current literature, I deem it of sufficient interest to present it for record. Of the type of the disease there can be no doubt, nor can there scarcely be a question that its termination was as described. The mode of its ending was certainly unique, especially with reference to the evacuation of the tumor, this phase of the disease being the main point in which the interest of the case lies, and in the absence of an autopsy the course it pursued may be assumed as correct.

A very "remarkable case" is reported by Emmet in his *Principles and Practice of Gynæcology*, p. 810, Case LIX., of rupture between an ovarian tumor and the stomach. An operation had been begun for an ovarian tumor, and after the parts had been separated, he says "a condition was discovered unique and I may say startling, on account of the difficulties presented. The stomach, colon, and omentum were all adherent to the surface of the tumor and below the line of the umbilicus, while the whole upper portion of the tumor was covered by peritoneum, placed on the stretch by the displaced organs. The tumor was enclosed by viscera at every point within reach except just below the bladder, nearly to which the omentum extended. The empty stomach and colon lay on the surface of the tumor, resembling wet pathological preparations and were adherent by the whole surface in contact. Notwithstanding it was suggested that the tumor might be removed from above, . . . I closed the incision as soon as possible. The woman was placed in bed and began to vomit violently, apparently from the effects of the ether. Rupture took place between the stomach and the tumor, and in the course of several hours the tumor was entirely emptied of its contents. The fluid and semifluid substances were almost sufficient to fill two buckets." I quote this to show that rupture may take place between an ovarian cyst and the intestines or stomach by adhesions even in non-malignant or benign diseases of these parts.

Malignant diseases of the uterus and of the ovaries are not uncommon, and there is no fact better established than that they sooner or later end fatally. They always, however, attract the interest and tax the skill and patience of those who are called to treat them; and there is no class of affections more worthy of our study either pathologically or in the way of treatment.

1211 F Street, N. W.

MEDICAL PROGRESS.

Laparotomy for Intestinal Occlusion.—At a meeting of the Société de Chirurgie de Paris, held March 25, 1885, M. Jenner read the history of a case reported by Dr. Jeannel, in which laparotomy was performed for intestinal occlusion upon a man suffering from chronic enteritis. The patient was fifty-three years of age, and for two days had suffered from severe colic. Five years previously he had experienced an attack of enteritis, which became chronic, and had ever since persisted. When first seen by M. Jeannel his condition was extremely grave. The abdomen was retracted, and the region of the right iliac fossa was painful and swollen. Temperature 99.5° F.; pulse 80; urine scanty. No evidence of hernia. Diagnosis was made by exclusion of intestinal occlusion, and operation was decided upon and performed under antiseptic precautions. Incision was made in the linea alba from a little below the umbilicus to within two inches of the symphysis pubis. On opening the peritoneum no evidence of peritonitis was found. To facilitate examination, the incision was enlarged so as to permit the introduction of the entire hand. There was now discovered a portion of the small intestine, empty and retracted to about the size of the little finger, and about ten inches long, which was constricted by peritoneal adhesions extending from the abdominal wall to the iliac fossa, intestine, and mesentery. No constriction sufficient to explain the occlusion was discernible. M. Jeannel accordingly broke up the peritoneal adhesions, washed the intestine with carbolized water, returned it to the abdomen, and closed the wound with six deep and eight superficial sutures. The day following there was much flatus and one movement of the bowels. Notwithstanding the complications which supervened—inflammation of the wound and pneumonia—the patient survived and completely recovered, and no further trouble from peritonitis or intestinal occlusion was experienced.—*L'Union Médicale*, March 31, 1885.

Considerations upon the Pathology of the Stomach.—Heinrich Schellhaas, in the *Deutsche Archiv für Klin. Medicin*, April, 1885, in a study upon the pathology of the stomach, enumerates the following propositions:

1. Methyl-anilin-violet, tropäolin, carbol-ferric-chloride, are agents of positive value for the determination of free hydrochloric acid as well as of certain organic acids.

2. The several reagents were applied for the determination of the separate acids, with different results. For the estimation of free hydrochloric acid, methyl-anilin-violet and tropäolin are recommended, while for a test for lactic or butyric acid, ferric-carbol-chloride is to be preferred, but the other reagents must be applied as control tests.

3. The absence of free hydrochloric acid in dilatation of the stomach produced by pyloric carcinoma, is produced by the carcinoma *per se*; or the coexisting anæmia, the gastric catarrh, or the disease of the mucous membrane produced by the carcinoma, may be considered as causal.

4. Free hydrochloric acid may also disappear during fever, more frequently it fails (occasionally), or is found in combination with organic acids during attacks of nervous dyspepsia.

5. In dilatation of the stomach not occasioned by carcinoma ventriculi, the lactic or butyric acid frequently existing may nearly always in a short time be removed by washing out the stomach.

6. The danger of increasing dilatation by foods remaining in the stomach after digestion must be met by regular washing out of the stomach.

7. In patients with gastric affections in whom free hydrochloric acid is present, artificial experiments show that digestion is impeded as well in the stomach as in artificial apparatus for digestion, by the addition of ten per cent. alcohol.

8. Digestion which has already been disordered by carcinoma ventriculi appears to be entirely abolished by the addition of even the slightest quantity of alcohol.

Musical Murmurs in Valvular Disease of the Heart.—Dr. P. Pucci in reviewing a case in which these were heard, says:

1. Musical murmurs of the heart, though rarely heard, have long ago been noticed.

2. Their origin is due to the presence of a body which vibrates in the cavity of the heart, and the perforation of the valve reveals the presence of this vibrating body.

3. Oscillation of the venous blood may aid in rendering the vibrations more intense.

4. As to the mechanism of the origin of the murmurs, there is similarity between them and sibilant râles.—*Gazzetta degli Ospitali, Supplemento*, April 5, 1885.

Paralysis of the Bladder Consecutive to the Use of Carbolic Acid in Surgical Dressings.—Cartaz, in the *Gazette méd. de Paris*, 1884, No. 42, reports interesting cases of vesical paralysis due to the use of carbolic acid in surgical dressings. This is one of the various toxic effects of the acid, and has been observed by the writer only twice, occurring in the first instance after irrigation of the uterus with a two per cent. solution of carbolic acid after abortion. The paralysis disappeared on the substitution of corrosive sublimate as a disinfectant. The second instance was met with in the case of an aged woman with fracture of the neck of the femur. The dressings, which were daily changed, were treated with a five per cent. solution of carbolic acid In two weeks there was enormous distention of the bladder, and for forty-eight hours the woman had not urinated. By the catheter about a quart of dark-brown urine was evacuated. In four days the paralysis disappeared, the carbolic solution having been replaced by boracic ointment. There appeared no reason to doubt that in each case the paralysis of the bladder was caused by the drug in question, as in both patients the urine had the color characteristic of carbolic acid poisoning, and the symptoms of paralysis in each case disappeared on abandoning the use of the drug. Only two similar cases are reported, and in these vesical paralysis resulted from drinking a concentrated solution of the acid.—*Centralbl. für Chirurgie*, March 28, 1885.

The Succussion of Liquids in the Stomach.—Dr. A. Rubino gives the following *résumé* of his investigations on gastric succussion:

1. The sounds (succussion) in the stomach produced by digital impulse from light and rapid blows, are hydropneumatic in their origin.

The analogous sound obtained by Hippocratic succussion has the same significance, but is of less semeiological value than the first mentioned, which enables the exact determination of the volume of the stomach—a result impossible with the second.

2. The sounds of gastric succussion may be considered physiological when present under the following conditions:

(*a*) They should not be perceived when palpation is made below a horizontal line passing through the union of the cartilages of the ninth and tenth ribs.

(*b*) They should not be perceived more than two hours after ingestion of liquids, or more than six hours after partaking of mixed diet.

3. With these exceptions, gastric succussion is an index of a diseased condition consistent with gastric inertia, with or without gastric dilatation.

(*a*) When the sounds are heard in the normal region more than two hours after partaking of liquid food, or more than six hours after ordinary diet, it is a symptom of gastric inertia without dilatation.

(*b*) When the sounds are heard longer than normal and below the line indicated, it is a sign of dilatation of the stomach.

4. In some cases dilatation of the stomach may exist and, nevertheless, succussion sounds be not recognized; a condition sometimes observed in phthisical patients suffering from vomiting.—*Gazzetta degli Ospitali, Supplemento*, April 5, 1885.

Vaginal Extirpation of the Uterus.—Dr. Mario Giommi, on the 19th of February, operated upon a woman aged 36 years, for cancer of the cervix by the method of vaginal extirpation of the uterus. Notwithstanding strict antisepsis and every attention to minute detail, the patient was attacked the third day by peritonitis, to which she succumbed one week after the operation.—*Gazzetta Medica di Torino*, April 5, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 16, 1885.

PUMP-WELLS AND IMPURE WATER.

THE apprehension of an outbreak of epidemic disease during the coming season has had the effect of directing attention prominently to the great risk incurred by the use, for domestic purposes, of water contaminated by putrescent organic matter discharged into the soil from numerous sources always existing in inhabited places, and already, in a number of localities, measures have been adopted for averting this cause of danger to the public health. Of the 300 pump wells existing in Brooklyn in 1882, less than 100 remain at the present time, and as most of these have been condemned by the department of health as furnishing water which is unfit for human consumption, they will doubtless be soon abandoned. In St. Louis, the pollution, by the drainage from the numerous cesspits which still remain in that city, of well water used for domestic purposes has excited public alarm, and measures are being discussed for the remedy of the evil.

Col. Ludlow, the Chief Engineer of the Water Department of Philadelphia, has furnished the Board of Health with a list of over 1000 pump-wells and other local sources of supply in the city, which, from their surroundings, are deemed incapable of furnishing pure water. A large number of these wells have already been condemned and ordered to be abandoned, and, in all probability, similar action will be taken with regard to most of those yet to be examined. By far the greatest number of wells are located in the suburban wards, though in thickly populated localities; scarcely any of them are to be found in the old city proper. Originally, they were depended on as the only source of supply; but notwithstanding the city water is now, in most cases, made available, the people still prefer to use the well water on account of its clearness, coolness, and palatability, qualities which cannot be regarded as a test of the wholesomeness of a water.

It is a well-known fact that the ground-water underlying an inhabited district is almost invariably polluted. Leaching cesspools and privy-wells, leaking sewers and drains, stable yards, graveyards, and soakage from defiled surfaces, all contribute to its contamination. The domestic use of water derived from the drainage of a soil saturated with foul organic matter, particularly that of fecal origin, is known to be a frequent means of communicating disease, and the disgusting practice should be exposed, condemned, and prohibited wherever practicable.

The custom of disposing of sewage and of providing for a water supply upon the same premises is more common in towns and villages than in cities, and not infrequently local outbreaks of disease, such, for example, as typhoid fever, have been traced to this fault. The devastating epidemic of typhoid fever now prevailing in the mining town of Plymouth, Pa., is attributed to the use of water contaminated by typhoid excretions. Cholera may be propagated by this same filthy mode of infection. The active measures in sanitation which are being pressed at the present time throughout the country, should embrace, as a leading feature, the investigation of the water supply in every case in which there is a suspicion of its pollution. It should be borne in mind that the ground-water, from which shallow wells are fed, is almost invariably polluted in inhabited places, and that no precautions that may be taken in sinking wells can be depended upon as securing a safe supply.

UTERINE ERYSIPELAS AND ITS EXTERNAL AND INTERNAL IRRADIATIONS.

AT a recent meeting of the Paris Obstetric and Gynecological Society, a paper upon uterine erysipelas and its external and internal manifestations, by BERNUTZ, was presented, which appears in the April number of the *Archives de Tocologie*. In the three cases reported, the erysipelas had its origin in the uterine mucous membrane, and thence extended to adjacent parts; two of the patients had been recently delivered, while the other had not been pregnant for three years. One of the former was attacked ten days, the other the seventh day, after delivery, and in each the disease extended from the uterus to the vulva and adjacent parts. The third patient entered the hospital because of severe metrorrhagia, and was placed near a woman suffering with facial erysipelas. In this patient the erysipelas extended from the uterus not only to the external genital organs and adjacent parts, but also to the oviduct and thence to the peritoneum. While this patient had erysipelas in one ward, three puerperæ in an

adjoining ward, separated only by a vestibule, had septicæmia, all three dying.

In the discussion, Dolèris held that the inflammatory complications of surgical wounds, lymphangitis, and erysipelas in all its varieties, are found with very analogous characters in the newly delivered—that is to say, coinciding with septicæmia. In addition to clinical observations proving the close relationship between puerperal septicæmia and erysipelas, Dolèris called attention to the fact that he had, in 1880, first proved the morphological and physiological identity of certain septic germs found in the two diseases. But he justly remarks that nothing is so vague as the word septicæmia, nothing more difficult than to point out precisely the nature of the poison. The essential thing is not the determination, impossible in the present state of science, of a specific organism for each of the innumerable varieties of infection, but of the indisputable position of the role of the essential pathogenic element, the microbe; for it is from this position that useful prophylaxis and treatment come.

Pajot stated that he had seen two epidemics of puerperal fever, in one of which fifty-six women died and in the other forty-six attacked were all cured. He rejected quinine in the treatment of the disease, and while declaring himself a firm believer in the microbian doctrine, he thought that one should not forget the patient, the different individual predispositions, and even the influence of exterior conditions, temperature among others.

Guérin held that there could not be purulent infection nor septicæmia without microbes; he referred to the marvellous results obtained by the cotton dressing, which filtered the air, thus preventing septicæmia by closing the entrance to microbes. In regard to the use of quinine in septicæmia, he strongly advocated it, stating that there was a remarkable tolerance of the remedy by the disease, and that in one case he had given fifteen drachms in the course of the illness.

It has been held by many distinguished authorities that erysipelas and puerperal fever are identical in nature. That there is a close relationship between the two cannot be doubted when we remember the following facts: The prevalence of the two diseases at the same time in the same places; a fact by no means constant, but which has been frequently observed: the liability to septicæmia of a woman attended in her labor by an obstetrician who is also attending a case of severe erysipelas, or cared for by a nurse who comes from nursing a case of erysipelas; this liability also exists if the puerpera be in a hospital where erysipelas is present: women who have attended to the bodies of those who died of puerperal septicæmia have been attacked with erysipelas. Dr. Churchill, among others, has shown that in many instances the infants of women suffering with septicæmia are attacked with erysipelas. That these accidents may in many cases be prevented, now that the germ origin of each disease is prevailing in the professional mind, there is abundant reason to believe. If this doctrine had been known in the past, how many thousands of lives might have been saved! That some other diseases bear also a close relationship to puerperal septicæmia is also admitted—the germs may be different, but they may be in a common medium, and be conveyed by a common vehicle.

While writing these lines we have visited in consultation a multipara suffering with septicæmia. The physician who attended her has not seen a case of septicæmia for years previously, he has not now nor has he had recently a case of erysipelas, but the patient occupies a room in which two of her children were sick with diphtheria between one and two months since.

PELVIC SPINA BIFIDA.

In *Gaillard's Medical Journal* for March, 1885, Dr. T. Gaillard Thomas describes two extraordinary cases of spina bifida, occurring in women, aged, respectively, twenty-eight and nineteen years, in which the cavity of the sacrum was filled by an adherent cyst. In the first case nothing was done, and the patient was lost sight of; but in the second, operative interference occasioned death. Aspiration of the sac was attended with the escape of eight ounces of a clear, limpid, non-albuminous fluid, and was followed by severe headache, elevated temperature, and a rapid pulse. At the expiration of six months, the cyst was incised and its walls attached to the vaginal opening. Tetanus and other grave symptoms having set in at the end of twenty-four hours, Dr. Thomas suspected that he was draining a sacral spina bifida, and at once sewed up the opening, but death ensued in twelve hours more from heart failure. A post-mortem examination was not obtained.

Although there is no pathological proof in these cases that the sac was formed by the membranes of the cord projecting through a deficiency in the sacrum, the peculiar symptoms occasioned by the evacuation of the cyst in one, and a similar case narrated by Emmet in his *Principles and Practice of Gynæcology*, render the view that Dr. Thomas was dealing with a spina bifida extremely probable, and should put the practitioner on his guard in dealing with cysts in the hollow of the sacrum.

In the case of Dr. Emmet, that of a woman thirty-six years of age, a soft, fluctuating cyst filled the sacrum, and was firmly adherent to the sacral prominence. The aspirator evacuated a clear, limpid, non-albuminous fluid, and death occurred from uræmic poisoning at the end of several days. On post-mortem examination, a cyst, which contained upwards of three quarts of fluid, completely filled the cavity of the pelvis; the three lower bones of the sacrum were deficient on the right side; a funnel-shaped opening

communicated with the spinal canal; and a network of nerves was spread over the inner surface of the sac.

TUBERCLE OF THE TESTIS.

At the recent Congress der Deutschen Gesellschaft für Chirurgie, the proceedings of which may be found in the Berlin Medical weeklies for April, Volkmann, of Halle, read a most important paper on tubercular disease of the various organs and tissues, in which he took the ground, now generally accepted, that, whenever it is practicable, the removal of the diseased part should be practised with the view to prevent general infection.

In the discussion which followed the reading of the paper, there was, however, some difference of opinion in regard to the localization and treatment of tubercle of the testicle, which is worthy of notice. Volkmann himself teaches that, in young subjects, castration should be resorted to, in preference to cauterization, partial resection, and scraping, as soon as possible or before the cord is involved, and the disease has extended to the prostate or bladder. In many cases in his hands castration has been followed by a permanent cure, thereby showing that the affection was limited to the testis itself.

Von Langenbeck, on the other hand, was very positive in his statement that castration was unjustifiable in young persons; that good results were attainable by the employment of antiscrofulous remedies; that castration did not prevent recurrence; and that the enucleation of the diseased lobules was the only surgical measure demanded. Gueterbock stated that he had never seen isolated tubercle of the testicle, but that it was always associated with similar disease of the prostate, bladder, or kidney. He also was opposed to castrating children. Schede, however, held that castration is the best remedy to effect riddance of the disease; but he thought that in many cases the same end can be accomplished by free incision and scraping out the tubercular tissue.

Unless we greatly mistake, we fancy that the majority of surgeons hold the same views as Volkmann as to the infectious nature of tubercle, and support him as to the propriety of the operation of castration, no matter what age the patient may be.

OBSTETRIC PALPATION.

Comparatively little attention has been given in this country to the subject of obstetric palpation. American contributions to it have been very few, and we fear that in many of our medical schools obstetric teachers devote little time to its exposition, or omit all reference to it—treat it in fact, as all English text-books upon obstetrics do. Yet the importance of the subject cannot be easily exaggerated. It not only enables the diagnosis of pregnancy in many doubtful cases to be made, but may permit one to determine whether the pregnancy is single or multiple, and the presentation and position of the fœtus. Approximately at least one who is reasonably expert in obstetric palpation can decide the duration of the pregnancy, and in case some obstruction of the birth canal may render the induction of premature labor necessary, the time for this may be fixed by measuring the length of the fœtus, and thus approximating its size.

In a most admirable paper upon the subject read before the Philadelphia County Medical Society by Dr. Albert H. Smith somewhat more than a year ago—a paper that unfortunately has not been published—this eminent and experienced teacher, remarked in regard to obstetric palpation: For ten years past it has been carefully and systematically taught in every medical school in Europe, being held of as much importance in obstetric diagnosis as vaginal touch in gynecology, or auscultation in the affections of the thorax.

Probably one reason for the neglect of obstetric palpation by teachers has been that it was neglected altogether, or only imperfectly considered, in the text-books used in this country. A brief, clear exposition of the subject in a suitable manual, however, has recently been supplied by Dr. L. E. Neale, of the University of Maryland, who has translated Pinard's well-known treatise upon "abdominal palpation as applied to obstetrics." In a small volume of less than a hundred pages the medical teacher and the medical student can find the subject clearly, plainly, and succinctly presented. The time has gone when any obstetric teacher can fail to instruct his students upon this subject, and do justice to them.

IODINE IN THE NASCENT STATE IN UTERINE CATARRH.

The treatment of catarrh of the cervical canal is often tedious and unsatisfactory, and hence we take pleasure in mentioning a new and apparently quite rational method of meeting this affection. Dr. Brondel, in *Revue Médico-Chirurgicale des Maladies des Femmes*, mentions a case of sterility resulting from cervical catarrh, and the successful treatment of the disorder, and states that iodine is the only remedy which gives satisfactory results He considers that the best way of using the medicine is in its nascent state, as advised by Chéron. The method is as follows: Add two drachms and a half of iodide of potassium and fifteen grains of iodate of potassium to two ounces of water; then, by means of a rod wrapped with cotton dipped in the solution, apply it to the cervical canal; following this application by that of a solution of citric acid, two drachms and a half in two ounces of water,—similarly made. The citric acid solution immediately liberates iodine, and the latter in its nascent state is thus in immediate contact with the diseased part.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Thirty-sixth Annual Meeting, held at New Orleans, April 28, 29, 30, and May 1, 1885.

(Specially reported for THE MEDICAL NEWS.)

SECTION ON SURGERY AND ANATOMY.

TUESDAY, APRIL 28TH.—FIRST DAY.

DR. DUNCAN EVE, of Nashville, Tennessee, Chairman, called the Section to order.

DR. JOHN B. ROBERTS, of Philadelphia, read a paper on

FALSE DOCTRINES IN THE TREATMENT OF FRACTURES.

The first custom to which he referred was that of bandaging the limb previous to the application; this is unnecessary. The great point in the treatment of fractures is, not the kind of dressing that is used, but simply the keeping of the parts at rest. Very little ensheathing callus is formed if the parts are held in coaptation. This is proved by post-mortem examinations. The greatest point of dispute is when to begin passive motion. Where the fracture involves the joint, it is important that careful passive motion be commenced at as early a period as possible. Where the joint is not involved there is no need of passive motion and hence it may be delayed, and in his opinion should not be commenced sooner than the fifth week. Passive motion should never be made while acute arthritis is in progress. Again, splints are frequently worn too long. In simple fracture of the lower extremities, the patient should be able to go to his business within three or four weeks after the receipt of the injury, provided a gypsum or other light dressing be applied after the original dressing has been removed. In simple fractures of the fibula, one week of confinement is all that is necessary. In compound, or otherwise serious fractures, a much longer period is required.

Another erroneous view is that which opposes the conversion of simple fractures of the cranium into compound, where the case is obscure and an accurate examination cannot otherwise be made. The danger of the wound is rendered little if at all more serious, and a definite diagnosis can be made.

Another error is in the treatment of fractures of the nasal bones by the application of splints or adhesive strips. The proper method of holding the fragments in apposition is by transfixion with pins. Another error in this connection is the placing of canulæ in the nasal cavities to aid in holding the fragments in position. All of us would prefer breathing through our mouths to breathing through these filthy tubes, which soon become filled with mucus and very offensive, as well as giving rise to a nasal catarrh. Deformities of the nasal bones and cartilages have often become permanent from want of proper surgical treatment. The importance of this feature of the facial line renders its proper study necessary.

The important factor in the treatment of fractures of the clavicle is to apply such a dressing to the sternal end of the bone, as shall prevent it from sliding forward as it would do from the weight of the upper extremity. This is to be accomplished by extending the angle of the scapula, and not by the wearing of an axillary pad, which cannot succeed in holding the bone in position, unless the pad be so large as to render its use unadvisable.

The use of the angular splint for fractures about the surgical neck of the humerus is an error, because it cannot control the movements of the arm, and every such case acts upon the fracture and not upon the joint, since there is nothing to prevent the upper fragment from remaining quiet while the lower is in motion. It is better to use the thorax as a splint, and to place the arm across the chest, binding it in this position, and thus preventing a separation of the fragments, and using no splint on the outside. The fallacy of treating the fractures about the condyles of the humerus, extracondyloid, intracondyloid, etc., by using anterior and posterior splints is apparent when considered. The loss of the "carrying" function of the arm is a common experience. By this loss, I mean the loss of the obtuse angle which we all have between the humerus and the forearm.

In fractures about the middle of the forearm, interosseous pads are seldom required if the fragments are put into accurate apposition, and the arm carried in the prone position.

Another error is the use of the straight splint in fractures of the lower third of the radius. The inner surface of the lower end of the radius is concave and requires a convex splint. The straight splint will do very well for the external surface of the arm, but not for the internal. In many cases reduction without the application of any splint at all will give better results than the application of a splint of any pattern. The teaching with regard to the treatment of fractures of the metacarpal bones is not universal, but it is prevalent. In most cases the fracture can best be overcome by placing adhesive strips over the part attached to the fingers and to a splint placed under the hand, and, if desired, projecting a little beyond the ends of the fingers.

Finally, it is an error to rely upon measurements of the lower extremities for the estimate of the result obtained from our treatment of fractures. It is surprising that although the fact that the extremities differ greatly in length, has been repeatedly brought to the attention of the profession, it is an almost universal custom for surgeons to measure their broken limbs. Very often, too, where there is no natural difference, there is an apparent one from the position of the pelvis when the measurement is taken.

DR. W. F. PECK, of Iowa, stated that it had always been his experience, that it is impossible to pass a tube of any size, even a catheter, into the nasal cavity, when the bones are fractured. The best instrument for this purpose is a conical-pointed director. With reference to fractures of the condyles of the humerus, he had for fifteen years taught the importance of using no splints except for support. He then reported the case of a child whose fracture of the condyle of the left arm he had treated by simply placing it on a pillow at rest, and performing passive motion every day after the third. The result was perfect recovery without deformity.

DR. MUDD, of St. Louis, remarked that the motion of the fragments of a broken bone is largely limited by the tissues surrounding it, and hence the movements of the extremity will be made largely at the expense of the

fractured surface. Passive motion is an aid to the production of ankylosis if practised at any time before the parts have become solid enough to resist the muscular movements. The great point to be desired is the limitation of inflammatory action about the seat of fracture. Control that, and you control the amount of ankylosis of the joint. Put the fragments into good apposition, control the effusion into the joint, and prevent movement, and you get a good result. In fractures of the metacarpal bones, put the parts in position, put the pad near the joint, put on a splint, and bandage it firmly. This is enough to control the fragments. For sake of motion, the splint may be cut short.

Dr. E. P. Cook, of Illinois, stated that in fractures of the lower end of the radius, the application of the posterior splint is all that is necessary. One case of this kind he had treated by applying a closely fitting kid glove to the hand, and a close bandage over the fracture, with direction to lay the arm on a pillow in any position that was most comfortable. The result was perfect. But the question in his mind was whether he was justified in going on and treating all fractures in the same manner.

Dr. Roberts stated that he had not attempted to bring out anything new, but merely to present some of the more common errors for discussion. He agreed with Dr. Peck that many fractures would be better treated without any splints than with the ordinary splints. He further thought that the condyloid fractures of the humerus are best treated in the extended position instead of the flexed, either with or without splints. This he then demonstrated on the board with reference to fractures of the condyles of the humerus, where he showed that the ulna is forced back so as to bear an improper relation to the humerus. In fractures of the upper end of the humerus, he believed it better in most instances to let the arm hang vertically. Sometimes, however, it is better to let the arm fall forward. In many cases we need no splint at all. If we reduce the fracture, the interlocking of the fragments will ordinarily keep the fracture in place. If the fracture is comminuted, however, it should be treated by splints.

Dr. W. P. Verity, of Chicago, next read a paper on

THE TREATMENT OF FRACTURE BY WIRING OF BONES AND FREE DRAINAGE.

He claimed nothing strictly original for his paper, but thought that the combination was worthy of consideration. The wiring of fragments must be done in a thoroughly antiseptic method. The disinfection of the wire and its thorough flexibility can be secured by heating it to a white heat. A drainage-tube is used and thorough irrigation accomplished. Eight cases were reported, in which he had employed his method with the most unvarying success. In some the protruding fragments of bone were sawn off, the fragments adjusted, wired together, drainage-tubes inserted, and the wound dressed antiseptically. Even where the periosteum had been removed, this method prevented the destruction of the bone, which seemed to retain its vitality and remain vascular. Adjourned.

Wednesday, April 29th.—Second Day.

The Secretary, Dr. C. B. King, of Allegheny, Pa., being absent, Dr. P. E. Archinard, of New Orleans, was appointed to act as Secretary.

Dr. H. O. Marcy, of Boston, presented a paper entitled

"DO WE FIND A HITHERTO UNSUSPECTED DANGER TO SURGICAL LESIONS FROM MICROÖRGANISMS IN ENCLOSED CAVITIES?"

He reported three interesting cases in which microorganisms were found in the abdominal cavity.

The first case was one of rupture of a cyst of the ovary following a fall; death was caused by general peritonitis forty hours after the accident. The abdominal effusion consisted of about three quarts of milky fluid, contained micrococci and large bacilli, resembling the anthrax bacillus, and were reproduced by culture.

The second case was one of a large compound ovarian cyst of rapid growth with thin walls, operated on in his private hospital. During the operation, one of the cysts ruptured, and its contents escaped into the abdominal cavity. The peritoneal cavity was washed with a 1 : 1000 solution of bichloride. Death, however, occurred in seventy-six hours, from septicæmia. The autopsy revealed no evidence of peritonitis; there were about two ounces of reddish serum in Douglas's cul-de-sac. This fluid was swimming with micrococci, and in one of the unruptured cysts the same micrococci were found, which were reproduced upon cultivation.

The third case was one of peritonitis in a child aged 4½ years. The abdomen being aspirated, a pint of creamy fluid containing an abundance of micrococci, which, when cultivated, reproduced in pairs—was withdrawn. Later, an exploratory incision was made, and two quarts of fluid removed. The abdomen was washed with a mercuric chloride solution, and closed without drainage. On the twelfth day after, a spontaneous opening occurred, and a considerable quantity of purulent fluid escaped. From that time, the patient made an uninterrupted recovery.

Dr. Marcy asked the following questions suggested by his cases: Are ovarian cysts to be considered no longer closed sacs? How can bacteria enter the unopened abdominal cavity? Have we in cystic fluid a hitherto unsuspected danger?

Most observers have failed to discover micrococci in cystic or abdominal fluid. Experiments show that micrococci may be introduced in the circulation and eliminated by the kidneys without injury; but when there is a blood stasis, as after contusion or local injury, then in certain lowered conditions of the economy we have both the seed and soil for the development of these organisms. This might explain the reason why bacilli were found in the first case, but it would not meet the second case, which was one of an old ovarian cyst.

Dr. W. A. Byrd, of Illinois, stated that these cases reminded him of an interesting case he had in 1882, and which he saw with Dr. Beck, of Illinois. The patient was a negro woman with a cystic abdominal tumor on right side; he diagnosed cyst of right ovary and aspirated three pints of fluid from it. A few days after she had what resembled malarial fever; thinking that it might be best to remove the tumor, he subjected her to the operation after she had rallied from the attack. He opened the abdominal cavity, but found no trace of tumor. The whole peritoneum was studded with millet-seed growths looking like tuberculosis; after making a thorough examination he closed the cavity and in doing

this had a good deal of trouble in bringing the edges of the incision together. The woman made a perfect recovery. The only diagnosis he can suggest for the case, is that it was a hydatid cyst of right ovary which was afterwards absorbed.

Dr. Beck, of Illinois, said that some time ago a lady consulted him with what he diagnosed as a large simple cyst of the ovary; there were no complications, the uterus was of normal size. He advised operation, and she had returned home to make preparations for it. One week after he was telegraphed that his patient was dying. He immediately went to the case, and upon examination found that the tumor was gone; there was general swelling of the abdomen. The history he obtained was as follows: On the preceding night the husband had attempted to have intercourse with his wife, and his weight coming down suddenly on the tumor had caused it immediately to disappear, the lady complained of great pain, and was almost collapsed, in which condition Dr. Beck found her. She however recovered.

Dr. N. Senn, of Milwaukee, Wis., then read a lengthy and highly interesting paper on

THE SURGICAL TREATMENT OF CYSTS OF THE PANCREAS.

After relating a well-observed and studied case which he had treated by five incisions and which resulted in cure, he gave a minute history of the literature on the subject and referred to a number of published cases, and offered the following conclusions:

1. Cysts of the pancreas are true retention cysts.

2. Cicatricial contraction or obliteration of the common duct or its branches and impacted calculi, are the most frequent causes of cysts of the pancreas.

3. A positive diagnosis of a cyst of the pancreas is impossible, a probable diagnosis between it and some other kind of cysts, amenable to the same surgical treatment, is adequate for all practical purposes.

4. The formation of a pancreatic fistula under antiseptic precautions, recommends itself as the safest and most expedient operation in the treatment of cysts of the pancreas.

Dr. Joseph Ransohoff, of Cincinnati, then reported the history of

TWO OVARIOTOMIES ON THE SAME PATIENT,

which will appear in full in an early issue of The Medical News.

Dr. Reed, of Ohio, said that assisted by Dr. Craig, he had removed an ovarian tumor of twenty-five pounds, together with the right ovary, from a woman, and that two years later he had, for the same woman, removed the left ovary with a tumor weighing twenty-eight pounds. He had found the abdominal walls much thinner at the second than at the first operation. The patient recovered, and six months after the second operation married; she has never had a child.

Dr. Warren, of New York, stated that his preceptor had always been in favor of removal of the ovaries in two operations rather than to take them out both at one time. It was pleasant to him to see that modern surgery, as shown by the statistics of Dr. Ransohoff, had come to the same conclusion. He thought himself that it was much better not to remove both glands in one operation, unless they were both found extensively diseased and enlarged.

Dr. Charles Graefe, of Sandusky, Ohio, reported a case of

GIANT GROWTH OF BOTH LOWER EXTREMITIES.

The patient is a young woman of 25 years, of English parentage, who presents an enlargement of the two lower extremities. This enlargement, which is congenital, seems to consist of hypertrophy of all the soft tissues of the parts, together with the bones, as far as it can be ascertained by palpation. The right extremity is larger than the left. The case has been pronounced one of Elephantiasis Arabum, but it differs from that disease in being congenital.

Dr. R. H. Jenkins, of Hogansville, Ga., reported a case of *Chronic Necrosis of the Tibia and Fibula of Ten Years' Duration*, cured by amputation at the thigh. Accompanying the report were the bones, which were very good specimens of the condition referred to, and form valuable specimens.

Thursday, April 30th.—Third Day.

Dr. A. Y. P. Garnett, of Washington, read a paper on

COLO-PROCTITIS TREATED BY THE HOT WATER DOUCHE, AND STRETCHING OR DIVISION OF THE SPHINCTER ANI.

He stated in introduction that he fully recognized the importance of confining himself to the single class of cases indicated by the title and described in the cases reported. Whilst the disease under consideration is usually of long standing, or chronic in its character, it is a pure non-malignant inflammation confining itself entirely to the mucous or submucous tissues, and resulting in some cases in small superficial necrobiotic ulcerations found just within the external sphincters; that such cases are often mistaken for simple dysentery and unwisely treated by injudicious medication as such. Five cases were then reported. The first was of a man previously healthy until two years before coming under observation. During that time he suffered severe pain in the rectum. Examination showed chronic catarrh of rectum, not extending to the colon. An enema of four ounces of a decoction of ipecac with twenty drops of tincture of opium to be used as hot as possible every eight hours, except from midnight to morning. Improvement followed, but the mucous membrane was found thickened and covered by long villosities, vascular and soft. The sphincter was dilated, the villosities removed by scraping, and hot water injections continued. Recovery was complete in fifteen days. In the second case the rectum was too sensitive to permit examination. The sphincter was divided by the knife, the rectum stretched. The patient was greatly relieved almost instantly. At the end of eight days she was discharged cured. The third case had been operated upon for hemorrhoids. A firm constricting band was found just above external sphincter. There was no sign of malignant disease. The hot water douche was used, the sphincters dilated under chloroform, douches were continued, the diet of hot milk ordered, and recovery followed. The two other cases were similar in character, and treated by the methods illustrated in the cases narrated with the same excellent result.

Dr. W. W. Dawson, of Cincinnati, inquired how the author gave hot milk as a diet in the cases which he had reported.

Dr. Garnett replied that he gave it in the quantity of four ounces every four hours and as hot as possible. He stated further that the English surgeons of late leave their patients almost entirely to hot milk.

Dr. Dawson then continued that these are indeed instructive cases. He had had some experience in this affection. He had had the best successes, however, from the use of the knife, liberally dividing all the transverse fibres up as far as the internal sphincter. He then narrated a case that came under his observation after having been under the care of Dr. Van Buren, of New York. He expressed the opinion that the reflex trouble would never be overcome without a division of the circular fibres. The patient, who was a physician, thought that he could stand the operation without ether. As soon as the knife was introduced the patient jumped, and only half the fibres were divided. He thought he was better and notwithstanding his protest, he went home. In a short time he returned and submitted to a complete division of both internal and external sphincters from within outward, under ether. In twenty-four hours that man was entirely changed. He had for years been unable to attend to business on account of the painful affection, but he was already somewhat relieved. In a short time he was back to business and is now robust and healthy. He had succeeded also with the method of Dr. Garnett, but he thought there were cases in which nothing short of a radical operation would relieve the patient.

Dr. Joseph Ransohoff, of Cincinnati, considered the most important feature of the paper the fact that the author had recognized at once the character of the case—that he had located the trouble at once in the rectum. It is a strange fact, that in most of these cases of rectal disease, the pain is not limited to the rectum, but extends also to the transverse, and even the ascending colon. The conditions in the cases reported are not analogous. He thought that, from the description, the first case was one of rectal papillomata. It is not an uncommon, but one of the most incurable affections of the rectum. The condition is analogous to some conditions of the bladder. Everyone has seen cases in which malignant disease, or the presence of stone, enlargement of the prostate, can all be excluded from the etiology of vesical irritation, and yet division of the bladder is the only cure. In similar conditions of the rectum, as we have been shown, division causes absolute rest. Why is it that we have this intense pain when there is little or nothing in the rectum?

Dr. W. F. Peck, of Iowa, remarked that there is very little in the text-books about the size of the rectum or the amount that it should hold. We are directed by good authority that in every matter of doubt as to conditions within the rectum, or even higher up, it is proper to introduce the hand and explore. This direction was carried out by three young physicians of his State. The smallest hand in the party was selected and introduced. Above the third sphincter—which, by the way, very seldom exists—there was found an obstruction. This was removed and the patient relieved, but he recovered with a paralysis of the sphincter. On this account suit was brought for $20,000 against the man who had had the privilege of making the exploration. In preparing to testify on the case, he had been surprised to find so little concerning the capacity of the rectum.

Dr. Dawson remarked that immediately after Simon had published the possibility of this method of exploration and had urged its trial, recommending it for safety and accuracy, it was hoped that it would open up a new and valuable field for diagnosis, especially of obscure tumors in the abdomen. It had not, however, resulted in so great advance as was hoped. He did not think that paralysis of the sphincter should be looked for as a result of the procedure. He then narrated a case that came under his observation about the time of the introduction of the method. It was an obscure case, and it was decided to explore the abdominal cavity in this manner. Several gentlemen present introduced their hands, and all thought they could feel the concave surface of the liver and nearly all the abdominal organs with great distinctness. But, on the following morning, like Asa of old, the patient "slept with his fathers."

Dr. Byrd, of Illinois, thought that the paralysis of the sphincter may depend upon an ulceration of the mucous membrane about the sigmoid flexure. The rupture of one of these strictures, or the presence of an ulcer would leave a point of irritation which, he thought, might cause the paralysis of the external sphincter.

Dr. Ransohoff agreed with Dr. Peck, that the third sphincter is rarely present, if he spoke of it anatomically; but, physiologically, this is incorrect. It is the third sphincter that keeps the bowel constantly empty. He further thought that if the examination were properly conducted in the dissecting-room, the third sphincter would be found. The rectum, when distended, is limited in capacity only by the capacity of the pelvis. How often, in the female, do we have to search, even for the uterus, when the rectum is impacted?

Dr. Owen, of New Orleans, presented a case of

A PATHOLOGICAL GROWTH

in the skin of the left temporal region. He stated that, as it had been removed eight times, the last two operations having been performed by himself, and still the tumor returned, he desired the opinion of the Section as to the character of the growth and the proper treatment to be now adopted in the case.

Drs. Kinloch, Dawson, and Warren, were appointed a committee to examine the case and report to the Section the result.

A paper was then read on

AUTOPLASTY

by Dr. F. Formento, of New Orleans. He referred to the great advancements that have been made in the numerous branches of surgery within the last half century, and more especially the advance that has been made in this peculiar branch within a few years. So great indeed have been the improvements that it has been made a special department. Autoplasty proper is the restoration of tissues taken from the region of the face by disease or injury. In some instances it implies the taking of tissues from other parts of the same individual or from another. Two cases were then reported in which the cheek and a greater portion of the upper lip had been torn away from the face of a young lady, rendering her not only unsightly, but unable to eat or talk on account of the enormous growth of cicatricial

tissue that had resulted. The jaws could be separated only wide enough to admit the end of the little finger. Eight teeth remained in the jaws, but were forced into an almost horizontal position. The dangers of so extensive an operation as that which would be required for the relief of the case were explained as well as the great possibility of the measure failing. The procedure was, however, urged. The first step was to dissect up all the cicatricial tissue in all directions as freely as possible. The large bands were then removed. A flap large enough to cover the denuded surface was then dissected from the neck, a good amount of adipose tissue being taken with it. This was secured to the denuded surface. Several others had to be taken from the neighboring parts before the surface was covered, for so great was the tension that after the cheeks had been as freely dissected from the bones as possible, they could be drawn so as to cover only about a third of the surface. Sixty sutures were required to retain these flaps. These were removed at different intervals, and on the fifteenth day the patient was able to be out of bed.

The second case was that of a woman in this city who consulted a quack cancer doctor for an insignificant wart upon her nose. Caustics were applied, and when the small wart was removed there was left a large hole in the nose many times as large as the original. This did not heal, but gave her so much pain that the sense of smell was destroyed and the Schneiderian membrane was constantly irritated. In the operation for its relief, he dissected up flaps from either cheek large enough to cover the ulcer, after the edges of the latter had been vivified by scraping with the knife and a spoon. The flaps were closely united, and union took place by first intention. The result was perfect.

DR. KINLOCH, as Chairman of the Committee appointed to examine the case of Dr. Owen, reported that the Committee had coincided in their opinion with Dr. Owen, that the case was one of "recurrent fibroid" tumor, or, as it would be called under the modern pathological nomenclature,

A SARCOMA,

involving the periosteum. It was of slow growth, and in the opinion of the Committee, nothing more should be done in the way of extirpation, and only palliative remedies employed.

Adjourned.

SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

TUESDAY, APRIL 28TH.—FIRST DAY.

The Section was called to order by DR. J. A. WHITE, of Virginia, Chairman.

DR. FLAVEL B. TIFFANY, of Kansas City, read a paper on

OSSIFICATION OF THE CHOROID, WITH SYMPATHETIC OPHTHALMIA.

The enucleated eyeball preserved in alcohol was shown to the members.

DR. R. E. MURREL, of Arkansas, read a paper on

DETERMINING ERRORS OF REFRACTION BY DOUBLE IMAGES AND PARALLAX.

His methods are very similar to those made use of by Prof. William Thomson, of Philadelphia, in the construction of his ophthalmometer and perforated disks.

DR. HERBERT HARLAN, of Baltimore, reported a

A CASE OF HEREDITARY GLAUCOMA.

The mother of the patient had been attacked by glaucoma at the age of nineteen, and was blind from that disease. The grandfather, great-grandfather, and great-great-grandfather had gone blind at an early age, presumably from the same cause. A maternal uncle and an aunt and two cousins had been affected in a similar manner. Dr. Harlan operated and preserved fair vision. There was some little debate. It seemed to be the sense of the Section that perceptible tension was the exception rather than the rule in simple chronic glaucoma.

WEDNESDAY APRIL 29TH.—SECOND DAY.

DR. G. F. FULTON, of St. Paul, Minn., read a paper on

THE RELATIONSHIP OF ERRORS OF REFRACTION TO HEADACHE,

which was a good presentation of the subject. The prevailing tone of the discussion was that though headaches were often caused by errors of refraction, the correction of which gives relief, very many headaches own other causes which the oculist must not overlook.

DR. ST. CLAIR reported a case of

GLIOMA OF BOTH EYES IN AN INFANT.

Although the growth had become extraocular in both eyes, he enucleated one globe and eviscerated the other orbit. Sixteen months after, the child is perfectly well.

Adjourned.

SOUTH CAROLINA MEDICAL ASSOCIATION.

Thirty-fifth Annual Session, held at Charleston, April 21, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE Thirty-fifth Annual Session of the South Carolina Medical Association was held at Charleston, April 21, 1885.

The meeting was called to order by the PRESIDENT, DR. A. A. MOORE, of Camden, S. C., and addresses of welcome were delivered by Dr. J. Somers Buist, President of the Medical Society of South Carolina, and by the Hon. William A. Courtney, Mayor of Charleston.

DR. MOORE then read his annual address, entitled

THE COUNTRY PHYSICIAN: SOME OF HIS DIFFICULTIES AND CAPABILITIES.

After thanking the Association in graceful terms for the honor conferred upon him in his election and expressing his high appreciation of the same, he explained that he embraced in the expression "country physician," practitioners in towns and villages as well as those in rural districts. He then alluded to most of the difficulties that beset a physician both in and out of the profession. He said it is difficulties such as these that fetter the zeal and energy of the struggling physician. Is there no remedy for these evils? he asked. Can no relief be afforded the hard-worked and half-paid physician by legislative enactment?

The landlord is secured for his rent, the merchant for his advances, the lawyer for his fees, and the common laborer for his wages. Why, then, should not some protection be guaranteed to the physician?

In this connection he called attention to a hardship which the law imposed on the physician, and which bears especially hard on the country physician. We are not unfrequently summoned ten or fifteen miles to attend a coroner's inquest. The circumstances surrounding the murder or sudden death, as the case may be, are such as to make a careful dissection absolutely essential. We are thus called away from our regular duties at the sacrifice of time and labor, and probably more pleasant and lucrative employment, besides incurring the personal risks of septic poisoning, and for all this, exclusive of mileage, we are allowed the large fee of ten dollars. But the trouble does not terminate here, for of course we are subpœnaed to attend court as expert witnesses, where we may possibly be detained a whole week for our testimony and we receive no higher compensation than ordinary witnesses. It appears to him, then, neither inconsistent with his calling nor with the dignity of the Association to demand a proper pecuniary recognition for such services.

There is another difficulty to which I would briefly allude before leaving this part of my subject. We all know that druggists, and especially those of our country towns, often transcend their province and assume the role of physicians by counter-prescribing. This is not only a usurpation fraught with danger to the lives of their patrons, but is a palpable infringement of the rights of the physician which merits our unqualified condemnation.

Dr. A. A. Moore, of the Committee on

PRELIMINARY EDUCATION

for the study of medicine, presented a report of that Committee, which was adopted after amendment, so as to read, "That this Association recommend to its members the necessity of due caution in regard to the receiving of illiterate students into their offices for the purpose of studying the profession, and that, as far as possible, they shall endeavor to have the preliminary education of such students brought up to the standard of a thorough knowledge of English, a respectable acquaintance with history and literature; arithmetic, embracing rules of fractions; geometry, at least three books of Legendre; elements of physics and chemistry, familiarity with Greek and Latin, including their grammars and translations of sentences, as selected from the Commentaries of Cæsar and the Anabasis of Xenophon."

A further amendment was then offered, "That one of the modern languages could be substituted for one of the ancient languages," and the report was then unanimously adopted as amended.

Dr. T. L. Ogier, of Charleston, read an interesting article on

THE TREATMENT OF EPITHELIOMA,

giving the history of three cases which were successfully treated by what is known as Collins's cure for epithelial cancer, modified according to the circumstances of the case. The prescription was the following:

℞.—Acid. carbolic. . . . . ℥ss.
Acid. sulphuric. dil. . . . . ℥ij.
Glycerine . . . . . ℥ss.
Aqua destil. . . . . ℥ij.—M.

S.—Ft. lot.

Very finely powdered fresh ergot, ℥j.

Directions: With the lotion paint the tumor freely with a camel's-hair pencil, and just before it is dry dust freely with the powdered ergot. This to be repeated night and morning. Every second night apply a bread and milk poultice, to keep the surface of the tumor soft. The modification of this is to make the poultice contain equal quantities of bread and powdered ergot, and paint the tumor once during the day with the fl. extr. ergot.

Dr. Charles W. Kollock, of Cheraw, reported the successful

REMOVAL OF A FOREIGN BODY FROM THE VITREOUS

humor of the eye by means of the electro-magnet, without the loss of sight.

Dr. Cornelius Kollock reported

TWO CASES OF OVARIOTOMY

with one recovery. In neither operation was carbolic acid used, except the sutures, which were carbolized.

Dr. Francis L. Parker, of Charleston, read a paper on

TRANSPLANTATION OF THE CONJUNCTIVA OF THE RABBIT TO THE HUMAN EYE, IN A CASE OF SYMBLEPHARON ASSOCIATED WITH CONVERGENT SQUINT.

After which he reported

A CASE OF ANOSMIA, ASSOCIATED WITH CONGENITAL BONY STENOSIS OF THE VOMER WITH NEARLY IMPERVIOUS INFERIOR MEATUS OF THE NOSE; OPERATION BY DRILLING, FOLLOWED BY RAPID IMPROVEMENT IN SMELL.

(Both of these papers will appear in full in future issues of The Medical News.)

Dr. Middleton Michel, of Charleston, read a paper on

EXENTERATION, A SUBSTITUTE FOR ENUCLEATION OF THE EYE,

illustrated by a case of gunshot injury of the eye, in which he had resorted to this procedure to avert sympathetic ophthalmia. (The paper will appear in full in an early issue of The News.)

During a temporary business recess occurring the next day, Dr. Michel operated, before the Association, upon another patient, who three weeks previously had sustained an injury of the eye that had developed serious symptoms of sympathesia, thereby practically exhibiting the character of the new method which he had described.

PARACENTESIS.

Dr. F. Peyre Porcher, of Charleston, reported nine cases (new series) of pleuritic effusion with removal of 709 ounces of fluid; also one of paracentesis in an abscess of the liver. These cases were all seen in the course of four or five months, and were intended to show the unusual frequency of this condition. In the case of the abscess of the liver, twenty-four ounces of pus were withdrawn with recovery.

Dr. E. Miller, of Florence, reported

A CASE OF CÆSAREAN SECTION

in a deformed primipara, who had not sat up or walked since she was six years old and being in her twentieth year, she had spent fourteen years in bed. She weighed about sixty pounds.

DR. A. MEMMINGER, of Charleston, read a paper entitled *Hyperinosis the Cause of Death in a Case of Chronic Parenchymatous Nephritis.*

DR. T. LEGARE, of Charleston, reported the successful treatment of

CHYLURIA

by means of the following tonic:

R.—Tr. ferri chlor. . . . . ℥j.
Syrup hypophosphites . . . ℥ij.
Aquæ . . . . . ad. ft. ℥vj.—M.
Sig.—A dessertspoonful in a wineglass of water.

DR. J. F. MACKEY, of Lancaster, reported

A RARE FORM OF DISEASE

which appeared over a portion of that county, and resembled very much an epidemic of dysentery much increased in malignancy and characterized by a tendency to sudden collapse. The straining and tenesmus were not near so great and distressing as in an ordinary case of dysentery. The distinguishing feature of this disease, however, was the powerful impression made upon the nervous system, producing general congestion, but more especially that of the kidneys with a strong tendency to collapse, as shown by a partial and sometimes total suppression of urine, low temperature, pulse feeble and frequent. Quinine and opium proved to be the only drugs which at all controlled it.

The following were then elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. O. B. Mayer, Jr., of Newberry.

Vice-Presidents.—Drs Thomas J. McKie, of Edgefield; H. D. Fraser, of Charleston; T. Munro, of Union.

Recording Secretary.—Dr. W. P. Porcher, of Charleston.

Corresponding Secretary.—Dr. J. L. Dawson, Jr., of Charleston.

Treasurer.—Dr. H. W. DeSaussure, Jr., of Charleston.

MISSISSIPPI STATE MEDICAL ASSOCIATION.

Eighteenth Annual Session, held at Greenville, April 15 and 16, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE Mississippi State Medical Association held its Eighteenth Annual Session in the city of Greenville, April 15 and 16. The Association was called to order by Vice-President Gresham, as the President, Dr. D. L. Phares, was prevented from attending the meeting by illness. Rev. Stephen Archer, of Greenville, delivered the address of welcome, which was replied to by Dr. Hyer. The attendance on the meeting was very small, in fact the smallest ever had. But few reports were received on special medical topics.

DR. PHARES sent on his report on the *Medical Flora of Mississippi*, which was referred, without reading, to the Committee on Contributions.

DR. WIRT JOHNSTON presented a report on *Aspiration*, together with several cases of hepatic abscess and empyema. The relative value of the aspirator and free incision was discussed, and many seemed to favor incision as a possible curative procedure.

DR. ROBBINS, of Vicksburg, reported a case of *Traumatic Tetanus* occurring twenty-four days after operation, with the wound almost completely healed.

Among other valuable contributions offered, were Dr. Brownrigg's on *Fractures*, and exhibition of his apparatus for extension and counter-extension in fracture of the bones of the arm and forearm.

The Association elected for nomination the following for members of the

STATE BOARD OF HEALTH:

First Judicial District.—E. P. Sale, M.D.
Second Judicial District.—John Wright, M.D.
Third Judicial District.—S. V. D. Hill, M.D.
Fourth Judicial District.—J. H. Blanks, M.D.
Sixth Judicial District.—R. T. Edwards, M.D.

All the above were reëlected, with the exception of Dr. Edwards, who was elected to fill the unexpired term of Dr. C. A. Rice, resigned.

The Association, deeming it necessary to have a *State Hospital*, appointed a committee, consisting of Drs. Robbins, Stillwell, Sale, and Todd, to prepare a memorial and present it to the Legislature on the subject.

ELECTION OF OFFICERS

for the ensuing year resulted as follows:

President.—J. B. Gresham, M.D., of West Point.

First Vice-President.—I. B. Pease, M.D., of Concordia.

Second Vice-President.—S. R. Dunn, M.D., of Greenville.

Corresponding Secretary.—M. S. Craft, M.D., of Jackson.

Recording Secretary.—W. E. Todd, M.D., of Clinton

Assistant Recording Secretary.—Geo. K. Harrington, M.D., of Jackson.

Treasurer.—John F. Hunter, M.D., of Jackson.

The Association selected Jackson as its next place of meeting.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Eighty-seventh Annual Meeting, held at Baltimore, May 12, 13, and 14, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, MAY 12TH.—FIRST DAY.

THE 87th annual meeting of the Medical and Chirurgical Faculty of Maryland was held in the hall of the Historical Society of Maryland, on Tuesday, May 12th, at 12.30 P.M. The PRESIDENT, DR. T. S. LATIMER, of Baltimore, was in the Chair.

After preliminary business the Faculty listened to

THE PRESIDENT'S ADDRESS.

THE PRESIDENT, after a few preliminaries, introduced his subject which was,

THE ORIGIN AND DIFFUSION OF CHOLERA.

He began by stating that this disease is indigenous to Asia and to Asia only. Although it is said that ancient Greek and Roman physicians, as well as Arabian writers, mentioned cholera, an examination into these claims shows that they rest upon an erroneous diagnosis between two similar but distinct diseases. The one, cholera Indica, is communicable and fatal in at least fifty per cent. of the cases, the other, cholera nostra is non-communicable and rarely fatal. In Hindoo writ-

ings we have descriptions of cholera in the 16th and 17th centuries, but they are unreliable because they confuse dysentery, diarrhœa, and colic with it.

The earliest reliable account is that by Gonerat, in 1768–'69, of an epidemic that swept off 60,000 persons in one year. Dr. Latimer referred to other early accounts of cholera, and said that it was almost certain that it had been epidemic in extra-Indian countries before 1817. In this year the disease, which had heretofore been for the most part confined to India, overran the whole peninsula and penetrated almost to the whole habitable globe, numbering its victims by millions. There have been, in all, five pandemics: 1817–1823; 1826–1837; 1845–1853; 1865–1875. The fifth is now in progress. The speaker then proceeded to describe the course of the first two cholera pandemics, going less extensively into the others. The result of a careful investigation of the history of these pandemics shows that each time cholera has left its native home it has occupied more territory, and certainly has not abated its violence. Certain sections have enjoyed notable immunity, as, *e. g.*, Switzerland, several mountainous districts of Scotland, large parts of Greece, and there are examples of smaller localities that have been encircled by severe epidemics of cholera and yet have remained free from the disease, notwithstanding frequent communication with the infected districts.

The fifth and present pandemic commenced in 1883 by an outbreak in Egypt. What this outbreak was has been the cause of much dispute, some claiming that the disease was not cholera, but was only caused by the extremely bad hygienic conditions that prevailed. These unhygienic conditions are allowed on all hands, but, as direct communication can be traced, it seems most natural to believe that this was true Asiatic cholera, especially as the restraints on commerce with infected ports were removed shortly before its appearance.

The question of the contagiousness of cholera is still an unsettled one. The fact that nurses and attendants upon cholera patients are not attacked any more frequently than others, cannot be explained on the theory of contagion. The contrary fact that those who wash the clothes of the sick are very frequently attacked, can hardly be explained on any other theory than that of contagion.

Koch and his followers, who believe that cholera is due to the presence of the comma-bacillus, of course believe also in its contagiousness. But Koch has not yet succeeded in establishing his theory. Similar bacilli have been found in the saliva of healthy persons. Injections of solutions containing dejections of cholera patients into the stomach of dogs have produced no results. Other experiments, in regard to the action of the bacillus on the organism, have yielded negative results. Klein, in India, found a bacillus, exactly similar to Koch's, in drinking water which was being used in large quantities, while the people remained healthy. Koch has an answer to these objections, but yet they throw great doubt upon his theory, which must still be held *sub judice*. It may be that, as Klein thinks, the poison is a chemical one.

Still, even if the comma-bacillus be proven to have no direct influence, there may, nevertheless, be a germ, and the disease may be communicable. It seems very clear that drinking water, whether Pasteur's view be correct or not, has a very direct effect in the causation of the disease, since improvements in the water supply have been followed by most satisfactory results in the diminution of the disease.

There is no doubt that soil-saturation favors the development of cholera, that is, where the saturation, be it of water or of more directly poisonous fluids, is not so great as to prevent permeation of the air. Lowlands are first attacked, also low parts of the cities. Sections resting upon compact stone are apt to escape, whereas, if the subsoil be near enough to the surface to keep the ground continually damp, it renders the locality peculiarly liable to the disease. Soils unfavorable to the retention of moisture, or if completely submerged, do not predispose to cholera.

A very striking illustration of the immunity enjoyed by localities resting on the solid rock, occurred in a small town within walking distance of Toulon. Although cholera was raging in Toulon, and many refugees fled to the neighboring town, which was in a very unhygienic condition, the disease did not break out there, for it had the solid rock underneath.

There are grounds for fearing that cholera may soon visit our shores and come amongst us in this city. Are there any measures to combat the spread of the disease? Quarantine will be tried, but it is a very inefficient protection. The sanitary condition of the city is the most important thing to be attended to. Much of this can be done by the Board of Health, but not all. To be effective, the citizens themselves must be willing to help the authorities. All cellars should be cleaned and ventilated; dirt in and about houses, and in back yards, should be removed. Streets should be well swept, but not swept till after they have been sprinkled. Koch, indeed, says that moisture should be avoided as favoring the growth of the bacilli; but Pasteur says that when dry the particles are more likely to float in the atmosphere. At all events, before the visit of cholera, when it is most important for these precautions to be taken, Koch's objection does not hold good. All these precautions should be taken, especially in low-lying parts of the city. Spoiled vegetables should not lie about the markets. Hucksters should be required to remove the débris from their stalls themselves, and not leave them to be cleaned up afterward. The practice some of them have of emptying their refuse into the gutters during a heavy rain, which is at all times reprehensible, is, during the prevalence of cholera, or even when it is feared, positively criminal. All privies should be emptied and disinfected.

In case the disease should really come, prompt disinfection of the premises where it has made its appearance is of the utmost importance. There is reason to believe that sulphur fires have a controlling influence, though it has not yet been proved. In regard to personal hygiene, the important things to be observed are, cleanliness, moderation in eating, the avoidance of stale vegetables and fruits, not the avoidance of all fruit, since taken moderately they are beneficial. Let the drinking water be boiled before it is drunk. This last is important.

In regard to leaving the city, we must remember that the attendants on the sick are not specially liable to take the disease; flight is expensive, apt to prove unavailing, and, for the physician, is not very honorable.

On motion it was decided to appoint a committee of three to take into consideration the practical suggestions contained in the President's Address, and to recommend the best course to be pursued in anticipation of the cholera, and report at a future session of the present meeting of the Faculty.

TREASURER'S REPORT.

DR. W. F. A. KEMP reported a more satisfactory condition of the treasury than was the case last year. The membership had been increased during the year by nine.

THE EXECUTIVE COMMITTEE,

DR. P. C. WILLIAMS, Chairman, reported that Prof. H. Newell Martin, of the Johns Hopkins University, had consented to deliver the annual oration this year; also that owing to the pressure of lectures, etc., the Trustees of the University had been unable to grant them the use of Hopkins Hall this year. The Executive Committee had, therefore engaged the Hall of the Maryland Historical Society. They were the more satisfied with this arrangement, as they hoped that the Faculty would be willing to make this Hall their permanent home.

THE LIBRARY COMMITTEE,

DR. I. E. ATKINSON, Chairman, reported that they had had much difficulty from insufficient funds. They called attention to the constitution, which provided that one-half the money received by the Treasurer for dues from members should be paid to the Library Committee. They pointed out that this rule was mandatory, and left no option in the matter with the Treasurer. If a deficit resulted from this, it would have to be met by special assessment. They complained that this amount, which belonged by the constitution to the Committee, had not been paid to them in full, and they gave notice that they would at a suitable time in the meeting offer a resolution to the effect that the Treasurer should be required to pay over to the Library Committee, month by month, one-half of the money he has received during the month for dues.

THE COMMITTEE ON MEMOIRS,

DR, JNO. R. QUINAN, Chairman, reported the death of four of the Fellows during the past year, as follows, viz.:

Dr. Riggin Buckler, born 1834, M.D. 1853, died Aug. 30, 1884.

Dr. Daniel Hartmann, born 1818, M.D. 1839, died Dec. 15, 1884.

Dr. Geo. S. Kinnemon, born 1848, M.D. 1874, died Dec. 12, 1884.

Dr. J. Robt. Ward (President State Board of Health), born 1807, M.D. 1828, died April 29, 1884.

A short sketch of each of these was given, and suitable eulogies.

THE COMMITTEE ON ETHICS.

DR. P. C. WILLIAMS, Chairman, reported that, as they had made a full report to the Faculty at a special meeting concerning certain members who had given their public endorsements to a quack medicine, and as the Faculty had acted upon that report in suspending or reprimanding the delinquents, the Committee had deemed it unnecessary to make any further report, as nothing fresh had been brought to their notice.

WEDNESDAY, MAY 13TH.—SECOND DAY.

THE ANNUAL ORATION

was given by PROF. H. NEWELL MARTIN, of the Johns Hopkins University, who chose for his subject

THE PHYSIOLOGICAL ACTION OF DRUGS.

As the object of all the education of a soldier is to enable him to destroy his enemy, so the object, from first to last, of all medical education is to enable him to destroy his enemy—disease. As the science of modern warfare differs from the ancient, so the science of medicine differs from that of the Greeks and the Egyptians; and, as a consequence upon the advance that has been made, we have the establishment of physiological and pathological laboratories, whose object is to enable the physician to fight disease more successfully.

Pharmacology can hardly be said to have existed till the present century. The meaning of the Greek word from which it is derived contains the idea, not only of the use of drugs, but also of the use of spells, poisoning, witchcraft, and sorcery; so that one who practised this art might be a physician, a sorcerer, or poisoner. Even to-day among the laity this idea has not altogether passed away, as is seen in the lingering belief in the seventh son of a seventh son.

Prof. Martin proceeded to outline the progress of the use of drugs from the time when persons seriously ill were exposed in the streets of Egyptian cities in the hope that some passer-by, having seen some similar case recover, might be able to suggest a remedy. But medicine gradually advanced through a long course of empirical research. This method was, as far as it went, sound. But in the middle ages this was replaced by false and absurd sciences and fanciful ideas concerning drugs. He particularly instanced the doctrine of "signatures," which resulted in giving as medicines for various diseases of the body such plants as possessed some fanciful likeness to the parts affected. Hence, we have the names "liverwort," etc. These and other fancies held their sway over the minds of physicians as long as they practised on mere *à priori* grounds without careful investigation. All this time pharmacology as a science was impossible. Even after the time of Sydenham, it had to wait for chemistry to come to its aid. Bichât, early in the present century, pointed out that all organs were composed of several tissues, of which some might be healthy and others diseased, and seems to have noted that the action of drugs on the various organs needed to be investigated. Magendie, his pupil, made the first pharmacological research.

Prof. Martin went on to describe in detail Magendie's experiments with strychnia (upas). He went through the various experiments by which Magendie arrived at the conclusion that strychnia is carried by the blood to the spinal cord, and that it exerts its influence there. From strychnia he passed on to the consideration of chloral, which the Professor said "we owe entirely to scientific research." It is a substance discovered by Liebig, in 1830, when engaged in a purely chemical investigation. It and choloral hydrate remained for years a chemical curiosity, chiefly useful in the light it threw upon the chemical architecture of ethylic alcohol, etc. It was found that, when heated with alkalies, it broke up into formic acid and chloroform. Liebreich, taking

the fact that the blood is feebly alkaline, thought that it might prove of therapeutic value by slowly giving off chloroform in the blood, thus proving a safe anæsthetic, and productive of sleep. This having been tested on lower animals, it was tried on human subjects with success, although the theory on which it was tried is not correct. This is a drug, then, for which physicians have to thank experimental research.

Amyl nitrite is a good example of how many sciences coöperate in adding to the physician's armament. A chemist was employed to extract from a certain make of wine, in the south of France, an oily bitter substance, known as oil of marc, which interfered with its sale. In the course of his experiments on this he discovered nitrite of amyl. For years it was unknown as a therapeutic agent. But other investigators were preparing the way. Prof. Martin then described the discovery by physiological research of vaso-motor nerves, the localization of their centre in the medulla oblongata, and the explanation that these discoveries gave of flushing and pallor. Guthrie (1859) observed that amyl nitrite, when inhaled, caused flushing of the face, and suggested that it might be useful in asphyxia from drowning and strangling. Benj. Richardson (1865), from physiological study, found that it caused dilatation of the smaller arteries and capillaries. It was afterwards found, in a similar way, that the drug lowered arterial tension. Then pathology came in. Brunton lived with a patient who was a victim to angina pectoris. He found from the syhygmograph that arterial pressure was great in this disease. He remembered Richardson's experiments, and let the patient inhale the drug—result, relief in thirty seconds. Other physiologists have verified this action of the drug. Wood says: "It seems useless to speculate how the nitrite acts, but there is now abundant evidence of its value in relieving almost instantly agony which has resisted all other treatment." This has not been discovered by chance, but by scientific reasoning.

Dr. Martin then spoke of the importance of laboratories for the study of the action of drugs on the living body. There is no such institution used *exclusively* for this purpose in the United States. He gave it as his opinion that pharmacology depends upon experiments on living animals. He thought such observations should be tried on the lower animals first, the Bishop of Oxford to the contrary notwithstanding. Prof. Martin went on to explain that it is a great fallacy to think that the chief thing to be considered in vivisection is pain. It is to save life as well as to relieve pain in man. Men and women subject themselves and their children to pain in order to cure deformity or to enhance beauty, which shows that, in their judgment, physical pain is not the worst thing in the world. We wish to increase our effectiveness as physicians, and is not a practice which offers reasonable hope for this, though a hundred—nay, a thousand—animals be sacrificed, and some of them suffer pain, justifiable and right? When we consider the great activity of chemistry in discovering new compounds every year, of their probable value therapeutically, of the diseases that now baffle us, we can see the importance of not hindering scientific research.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 20, 1885.

THE PRESIDENT, CHARLES A. LEALE, M.D., IN THE CHAIR.

ON calling the meeting to order, the President stated that since the last meeting the members had received the first volume of the Transactions of the New York State Medical Association, containing more than fifty contributions from those who are daily working in the field of scientific medicine. In referring to the list of membership, we see that before the close of the first annual gathering there were more than five hundred Fellows, representing nearly every county in the State. An incorporated organization developing such vitality during the first year of its existence, demonstrates its necessity, and the great power it has for future usefulness.

The New York County Medical Association is the eldest of the now numerous children of the New York State Medical Association, and as such heartily tenders its congratulations to the parent association on having been able, in so brief a time, to present to each of its Fellows a volume containing so many living thoughts of a living present.

DR. J. LEWIS SMITH then read a paper on

INCONTINENCE OF URINE IN CHILDREN,

in which he stated that the condition is more common in boys than in girls. The enuresis may be both diurnal and nocturnal, but is more frequently nocturnal. At the outset he gave a description of the anatomy of the bladder, dwelling particularly upon the muscular coat with its two layers of unstriped muscular fibres, and their physiological action. He also described the nerves of the bladder, stating that the sympathetic innervation greatly predominated over that derived through the sacral nerves for the spinal cord.

Etiology. Having mentioned that two or more are often present in combination, he proceeded to give eight causes for incontinence, as follows:

1. Too great acidity of the urine, causing undue contraction of the bladder. The acidity is commonly due to uric acid, but in certain instances depends on the presence of lactic and hippuric acids.

2. Increased quantity of urine. Sometimes, when there is no disease present, like diabetes, this is due merely to the too free use of liquids.

3. The presence of a vesical calculus. When there is stone in the bladder, the incontinence is both diurnal and nocturnal.

4. Abnormal contractile power of the muscular coat of the bladder. It was from this increased functional activity, due to too great irritability, that Trousseau was led to classify incontinence of urine in children as a neurosis, and the importance of this cause is shown by the fact that belladonna is useful in so many of the cases of enuresis.

5. Weakness of the muscular fibres constituting the sphincter of the bladder. Incontinence from this cause is rare in those in good health, and is usually seen in the poorly nourished and children suffering from impairment of innervation as the result of disease. It is associated in some instances with incontinence of feces, the loss of power in the sphincter of the anus being no

doubt due to the same cause as that of the sphincter of the bladder. In this connection, he gave the report of a case in which this failure of the sphincters was associated with the presence of spina bifida.

6. Reflex action, through the agency of the nerves supplying other organs in addition to the bladder. There are certain cases of incontinence which depend on structural disease of the spine, the presence of ascarides in the rectum, phimosis, preputial adhesions, etc. In many cases of the latter it is not necessary to perform circumcision, or even to slit up the prepuce, relief being afforded by simply dividing the adhesions, clearing away hardened smegma, and stretching the preputial orifice with a probe. In the out-door department of Bellevue Hospital, large numbers of young children suffering from incontinence of urine are cured in this way every year.

7. Dr. Roberts Bartholow had directed attention to a psychical cause, viz., the child dreaming that it was in a convenient place for urinating, and so yielding to the inclination. That the enuresis is to a considerable extent under the control of the will is shown in cases in which the habit was broken up by the sending of the child among strangers or to boarding-school, where the sense of shame constituted an influence sufficient for the purpose. Numerous instances are on record in which a flogging has permanently broken up the habit.

8. Malformation of the bladder or its appendages. These are sometimes of such a nature as to render the incontinence incurable. Thus, Dr. Thomas W. Madden had reported the case of a young lady who suffered from a constant dribbling of urine, both by day and night, in which he found, on examination, that there was undoubtedly a malformation of the right ureter, which discharged the urine from the kidney on that side directly into the vulva, instead of into the bladder.

Prognosis. This depends naturally on the cause or causes giving rise to the enuresis, but in the majority of instances it can be cured by the adoption of measures appropriate to each individual case. Where the affection is not controlled before, the influence of puberty or of marriage and pregnancy in checking it seems to be well founded, but of course treatment is not to be delayed with any such idea in view.

Treatment. The all-important point is to discover the cause, when the management of the case can be conducted in an intelligent and effective manner. If the trouble seems to depend on the character of the urine, this is to be rendered as bland and unirritating as possible, and Dr. Smith said that since he had recognized the acid character of the urine as a frequent cause of incontinence, he has been able to treat very satisfactorily quite a large class of cases which had formerly proved troublesome. It is his practice to endeavor to render the urine as bland as tepid water. If there is acidity, he gives from three to five drops of liquor potassæ, well diluted, three, four, five, or six times a day, until the urine becomes neutral in reaction, and then continues the alkali in just sufficient quantities to maintain the neutral condition.

When there is increased functional activity the great reliance is to be placed in belladonna, which has the direct effect of diminishing the muscular irritability. The tincture is the preparation commonly used in this country, and of this five drops may be given every night and morning, the dose being increased by one drop each day until the desired effect is obtained or the physiological action of the drug has become apparent. When belladonna is found efficient, it is to be kept up for some weeks in full doses, and the quantity then gradually diminished. This agent has been highly lauded by Trousseau, who used it very freely. Dr. Smith related a case in his own practice in which a girl eleven years old, who suffered from both diurnal and nocturnal enuresis, and who had previously taken belladonna and other remedies, was cured. The urine was highly acid, and the treatment which he prescribed was five drops of liquor potassæ three times a day (or more if this was necessary to keep the urine neutral in reaction), and tincture of belladonna in nine drop doses, the dose gradually to be increased to fourteen or fifteen drops.

If the enuresis is due simply to the large quantity of urine secreted, the liquid food is to be restricted, especially towards evening; and, if diabetes is present, of course the treatment appropriate to that disease is to be adopted. In diabetes insipidus, ergot is found to be of great service. Suspicion of the presence of a stone in the bladder should be excited by painful micturition, increased quantity of mucus in the urine, and the sudden stoppage of the full stream. The use of the sound will render the diagnosis positive, and the stone can then readily be crushed. In many cases of incontinence, it is important to make a careful examination of the parts contiguous to the bladder, such as the rectum and the genital organs, for the existence of ascarides, phimosis, preputial adhesions, hardened smegma, etc.

If the enuresis is due to paresis of the sphincter, a treatment very different from that by belladonna is required, and here ergot, either alone or combined with nux vomica, or its active principle strychnia, is found very useful in restoring the impaired innervation and stimulating muscular contractility. Two years ago Dr. George B. Fowler, of New York, reported two very interesting cases, in which there was fecal incontinence also, treated with ergot in combination with strychnia. In one there was a relapse, which was successfully treated with ergot alone, in the form of the extract, administered in five grain doses by the rectum. Here there was a markedly relaxed condition of the sphincter ani, indicating also relaxation of the sphincter vesicæ.

A considerable number of remedies which had been formerly employed to a large extent for incontinence of urine are now seldom used; but some of them are still deserving of confidence in certain special cases. Among them is strychnia. In children under four years of age, there was some danger in giving this agent, and it is better to employ nux vomica under the circumstances; but above that age it is perfectly safe to administer it. Tincture of cantharides, although as a rule an unpleasant remedy, can sometimes be employed with advantage, if given in small doses. Cubebs and vegetable tonics and astringents are also sometimes called for. Dr. Smith then related a case reported by Eustace Smith, in which he successfully employed drachm doses of tincture of belladonna in combination with bromide of potassium and infusion of digitalis. It is to be remembered, however, that the English tincture of belladonna has only half the strength of the American preparation.

Local treatment is often attended with a satisfactory degree of success, and the best agent for the purpose is nitrate of silver, applied for the cauterization of the neck of the bladder. Having referred to the use of baths and douches, Dr. Smith closed by speaking of the suggestion of Trousseau, that the patient should be required to urinate as frequently as possible during the daytime.

Dr. Wm. Detmold expressed the opinion that in the majority of instances nocturnal enuresis is simply a vicious habit, He thought it advisable to avoid the expression, incontinence of urine, in this connection. The condition is one of enuresis, and not properly incontinence. The habit, however, is an almost irresistible one, and the only remedy which he had found at all reliable for it is to have a nurse sit by the bedside and take the child up every hour or half hour, compelling it to sit upon the pot until it had evacuated the bladder. When the habit is once broken, the cure is generally complete. Trousseau was right, he thought, designating the condition as a neurosis, and if not cured before puberty, it is very apt to be so at that time. There are some instances, however, in which the difficulty is not overcome until marriage. The enuresis is accompanied by a certain sense of voluptuousness, and he had frequently observed the condition in young soldiers, and in unmarried female adults.

There is only true incontinence when the urine dribbles constantly, both by day and night, and this is observed in patients where there was some organic defect, as in the case of Dr. Madden's reported by Dr. Smith, in which the right ureter discharged into the vulva. Ordinary enuresis, therefore, he looked upon as a neurosis or a vicious habit. Whatever produces local irritation tends to give rise to the habit. The irritation of the glans penis, however, might be a result, and not the cause, of the habit, this being excited by the contact of the wet bedclothes. Where medicine has an effect, he is inclined to believe it is simply a moral effect, produced by the fear of the doctor or the nauseousness of the dose. The more unpleasant the remedy, therefore, the more efficacious it is likely to be.

Dr. J. W. S. Gouley said that he thought Dr. Smith's anatomy and physiology needed a little revision. There was no sphincter vesicæ in the same sense anatomically as physiologically; the so-called sphincter of the bladder not being at all comparable to that of the rectum. It had been demonstrated, beyond question, forty years ago that there is no such thing as an anatomical sphincter to the bladder; though there is a distinct physiological one. It is not the circular muscular fibres, but the longitudinal and oblique ones which exert this sphincter-like action. In regard to the compressores urethræ having any power to control the stream of urine after it had emerged from the bladder, as mentioned by Dr. Smith, this is an entire mistake; the physiological sphincter alone having any such control. He agreed fully with Dr. Detmold, that the word incontinence when applied to children who wet their beds is incorrect, nocturnal enuresis being the proper term for this condition. The urine is passed, not because the bladder cannot contain it, but because it has to hold too much. There is rather retention, with an overflow of urine.

Dr. Smith had attributed to Dr. Bartholow something which did not belong to him, as it was Jean Louis Petit, who lived more than a hundred and fifty years ago, who first called attention to the cause of nocturnal enuresis mentioned in connection with Dr. Bartholow's name. Petit stated there were three classes of children who wet the bed: *First*, those who are too lazy to rise and urinate; *second*, those who sleep so soundly that the sensation of desire which precedes the act of urination is not sufficiently strong to awaken them; and, *third*, those who dreamed that they were urinating. Trousseau had added a fourth class, viz., those who through fear would not arise to urinate; but this class of Trousseau's, as well as the first class mentioned by Petit, he thought ought to be excluded, so that there would remain simply the second and third classes just stated.

It will be found that there is usually a considerable accumulation of urine in the bladder, and the most frequent causes of the enuresis are lithuria and polyuria; the latter being often met with in nervous children. Children after they become two or three years old do not wet their clothing through the day, but only at night. In some instances such children retain the habit until they are grown, and he had seen men twenty-five, thirty, and forty years of age, who were still subject to it. No amount of whipping will cure a child of wetting the bed; on the contrary, corporal punishment does harm, and only makes the condition worse. Lithuria is much more common in young subjects than is generally supposed. When this is present, there is not an accumulation of urine, but a constant enuresis, both diurnal as well as nocturnal. Dr. Gouley here related a case in a boy four years of age, who was an epileptic. In all such cases, he said, the trouble will continue indefinitely unless a decided course of treatment is adopted.

He did not agree, therefore, with Dr. Detmold in the idea that treatment is of no service. On the contrary, he believed that there should be both local and general treatment. He thought, however, that it is a mistake to attempt to make the urine as "bland as tepid water," as Dr. Smith spoke of doing. This would only increase the enuresis, as very bland urine, like pure water itself, is known to be irritating to the bladder. Dr. Smith had spoken approvingly of lithotrity in cases of stone; but in children, under the age of ten, this operation had been tried and found wanting, lithotomy being in reality much more safe. As to cauterization, he trusted that Dr. Smith did not mean that this should be done with Lallemand's *porte-caustique*, as he regarded this as excessively dangerous. But in connection with the internal administration of iron, more particularly the old-fashioned tincture of muriate of iron, he had often afforded great relief by the introduction of the sound or catheter every two or three days. As a rule, the steel sound, if skilfully used, was preferable to the gum catheter. In both boys and girls (although the number of the latter that he had seen suffering from enuresis was quite small), he had observed excellent results from this practice, and he did not think Dr. Smith had mentioned the simple passing of the sound. He believed that Trousseau, Vulpian, and Nélaton, had all employed it. Dr. Gouley also spoke of the influence of heredity in the etiology of nocturnal enuresis.

Dr. P. Brynberg Porter called attention to the much greater tolerance of belladonna, proportionally, in chil-

dren than in adults. In the *British Medical Journal* of February 7, 1885, Dr. E. Paget Thurston had reported a case of nocturnal enuresis in a girl seven years old. At first she was given ten minims of tincture of belladonna three times a day; but this had no appreciable effect upon the condition. He then ordered the belladonna in drachm doses, one dose to be taken in the afternoon, and another four hours later, just before going to bed. The second night there was no enuresis; after which only one dose a day was taken, at bedtime, and this was continued for four more nights. The cure was then complete and permanent. He had himself also often noticed, in giving belladonna in whooping-cough and other affections, what large doses children would bear without showing the constitutional effects of the drug. He would like to ask Dr. Smith whether he had had any experience with chloral hydrate in nocturnal enuresis. During the last four years this agent had been highly lauded in this condition, and he had personally tried it in a number of cases in which the affection did not seem to be dependent on any removable local cause. While, however, in certain instances it had seemed to afford partial relief, as a rule, he had been disappointed in regard to its action.

DR. JANEWAY said that from his own experience he could undoubtedly confirm the truth of Dr. Porter's assertion in regard to the very marked tolerance of belladonna in children. He was frequently in the habit of using atropia, rather than belladonna itself, for the sake of accuracy, and sometimes gave no less than one-seventieth of a grain three times a day, while in other cases he gave as much as one-fiftieth of a grain. It was well to remember that we ought not to depend on any set of rules in regulating the dose, but in each particular case to increase the quantity gradually until the desired effect was produced. Trousseau used to give belladonna in exceedingly large doses for epilepsy, as he did strychnia for chorea. Where the enuresis seemed to be dependent on the spinal cord, there being too easy reflex, he had found a combination of iodide of iron, ergot, and belladonna of more service than anything else which he had tried.

DR. C. S. WARD said he regretted that he had not heard a considerable portion of the paper, but it seemed to him that the children who suffered from enuresis could be divided into two great classes. The first consists of those who are poorly nourished, surrounded by bad hygienic conditions, and apt to be scrofulous; and in this class of cases he had found that syrup of the iodide of iron and cod-liver oil, in addition to good food and fresh air, generally prove of much service; so that he could not agree with Dr. Detmold that treatment does no good. The other class of children consists of those who are healthy, well-fed, and active, and in this class belladonna, in connection with chloral, is often the most useful. It is the best plan, however, to attend first to any local trouble that may give rise to the enuresis, and sometimes the use of moral influences is sufficient to break up the habit. In this connection he related the case of a boy with phimosis, who was accustomed to wet the bed at night, in whom the threat to perform circumcision had the effect of working a cure.

DR. F. V. WHITE said that, like Dr. Gouley, he believed that heredity had some effect in causing enuresis.

DR. JANEWAY said that he had neglected to mention that some of the cases were in reality cases of latent epilepsy, in which urination took place during nocturnal attacks.

DR. T. R. VARICK, of Jersey City, remarked that it is very evident that the condition does not depend on any one cause, and it is necessary to investigate every individual case for itself. Many of the cases seem to be due to what used to be called "contiguous sympathy." In one instance, in a child of two years, with a very narrow preputial orifice, he had cured the enuresis by performing circumcision, and he had seen another case, in a boy ten years of age, in which the trouble was dependent on a preputial calculus as large as a bean. Ascarides in the rectum are a not infrequent cause, and he is in the habit of treating this condition by a formula which he learned many years ago from his old preceptor, Dr. John H. Whittaker. Two drachms of aloes are rubbed up with a mint of milk, and given in divided doses by enemata. There is another cure of nocturnal enuresis which is a sort of "old woman's idea," but which he thought may, after all, have some effect, and that is, slapping on the back. It seemed probable that this excites a certain amount of irritability in the trigonum vesica, and the ordinary remedy for it among the common people is to fasten a spool at the small of the back by means of a string passing around the body. As to medicinal measures, he had tried about everything that had been mentioned this evening. When there is a strumous diathesis, in addition to iron, he is in the habit of employing tincture of cantharides, pushed until a slight degree of strangury is produced.

DR. SMITH, in closing the discussion, said that, in his account of the anatomy and physiology of the bladder, he had quoted the views of many of the highest authorities, and for the statement in regard to the action of the compressor urethra, Belfield is responsible. In regard to the rendering of the urine bland and neutral in reaction, the good results which he had obtained since he had adopted this practice were sufficient, he thought, to justify him in continuing its use. He fully agreed with the gentleman who had spoken in reference to the greater tolerance of belladonna in children; as was also the case with arsenic. Fowler's solution can generally be given in as large doses to young children as to adults. In regard to chloral, he said that he had not tried it in this connection; but it seemed to him that, if it were given in nocturnal eneuresis, it would only render the trouble more aggravated by procuring more profound sleep. He agreed with Dr. Varick, that it was very important that a careful study of the probable cause should be made in every case presented for treatment, and on this point he said he could not speak too strongly. In paresis of the sphincter vesicæ, he spoke favorably of the action of large doses of syrup of the iodide of iron.

DR. JANEWAY presented these interesting pathological specimens. The first was one of

DILATATION AND RETENTION CYST OF THE VERMIFORM APPENDIX.

The dilatation of the appendix vermiformis, which was due to occlusion of its orifice, did not extend throughout its entire length, the distal portion of appendix being atrophied. The distended portion was

about three-quarters of an inch in diameter, and it no doubt contained mucus with white flakes of cast-off epithelium floating in it, though it had not as yet been opened. This was the third case of the kind which had come under Dr. Janeway's observation. In the first case which he had seen, the cyst of the vermiform appendix was as large as a fœtal head at term, constituting a tumor which would have given rise to considerable difficulty in the way of diagnosis during life. In the second case the cyst was about six inches long and twice as large in diameter as the present one. From this same patient, who died of cerebellar apoplexy, Dr. Janeway also exhibited the uterus, which showed *Cystic Degeneration of the Endometrium* from atresia of the cervical canal.

Finally he exhibited a specimen of

COLLOID CANCER INVOLVING NEARLY THE ENTIRE STOMACH,

from the pylorus to the cardiac orifice, and affecting all four of the coats of the organ. It had been two and a half years since the first symptom manifested itself, and the patient was a lady of 50, whose father had also died of cancer of the stomach. Pain had been quite a constant feature of the case, and Dr. Janeway had washed out the stomach a number of times with good effect. A portion of the omentum was found to be also affected with colloid cancer.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 7, 1885.

The President, A. Jacobi, M.D., in the Chair.

Dr. E. Darwin Hudson read a paper on

THE PHYSICAL EXAMINATION OF WEAK CHESTS AND DIFFERENTIAL DIAGRAMS OF THE SEVERAL FORMS OF EARLY PHTHISIS.

While the profession, he said, had come to regard physical diagnosis in the hands of experts as affording exact knowledge of the conditions of the intrathoracic organs, the interpretation of physical signs can never be dissociated from some theory of the nature of the existing disease, a conception of its pathogenesis and a knowledge of its gross and minute pathology, as well as the pathological processes which determine its consecutive steps or stages, and its periods of transition from one to another form. The views of Bayle and Louis as to the specific nature of all phthisis and its transmission solely by heredity, had not been questioned for fifty years, but the last twenty years have witnessed almost a complete revolution of opinion as to the prominence or causative relation of miliary tubercle in phthisis, and a majority of all investigators and of the profession have come to acknowledge the three forms of phthisis, the catarrhal, the fibroid, and tubercular. In very many cases the disease exists in a mixed form. Our physical exploration is incomplete if we discover only the presence of cavities and softening, or the evidences of local consolidation, and a thorough diagnosis should include, *in extenso*, an exact knowledge of the condition of each portion of the respiratory apparatus, including the air-passages, vesicles, interstitial tissue, and pleura.

The views presented related to the methods of examination most useful in studying weak chests with tendencies to phthisis, in detecting the times of transition from danger to disease, and in differentiating the early forms of phthisis. While recognizing the correctness of the views of Simon, of London, and of Niemeyer and Rindfleisch, observation has also made Dr. Hudson a firm believer in the agency of inflammation as the chief factor in developing pulmonary phthisis, whether in those predisposed by heredity or in those free from such predisposition. He then proceeded to review the essential evidences of the three definite types. Having given an epitomized statement of the main physical signs of early phthisis, as generally held, under two heads (in speaking upon the second of which, he said, that an area of notable dulness or flatness on percussion, and of different conduction of sounds, pointed to fibroid phthisis), he expressed the opinion that many careful students of chest acoustics have come to a recognition of the differentiation of the forms of fibroid consolidation, whether starting from the bronchi, as centric and diffuse, or again, distinctly of pleural origin, and pointed out the signs by which they are enabled to do this.

The first point which he said he desired to discuss with reference to efficient and correct chest exploration was the importance of examining all parts of the chest, from apex to base of lungs—front, side, and back. Two areas, almost wholly passed over by most examiners, often afford most valuable information, viz., the high axillary region and the interscapular spaces. In cases of irregular pleuro-pneumonia, and in certain low and indefinite forms of pneumonia, the initial area of pneumonic consolidation, as evidenced by bronchial breathing, has been found only in the axilla. Dr. Hudson dwelt for some time on the importance of the interscapular exploration. It is here that we have the larger bronchial trunks and the hilus of each lung, close to the posterior wall of the thorax, but in order that this area may be examined with advantage it is necessary that the arms should be crossed in front, each upward at an angle of 45°, and the hand on either side made to grasp the convexity of the shoulder, thus increasing the space more than twofold by rotating and drawing outward the scapulæ, while at the same time the ordinarily thick and flaccid muscles are rendered tense and thin.

In regard to *inspection*, he said that he was convinced that in a large proportion of chest cases, and in a large number of phthisical ones, an approximate diagnosis can be made by inspection alone; the second point of the paper being the diagnostic importance of this method of exploration, and the desirability of extending it, in detail, to all the structures of the thoracic wall. In this connection he called attention to the direction of the clavicle. When the latter is deflected upward and backward at an angle of 30, 35, or 45 degrees, the chest development has manifestly been most defective during a long term of years, and the presumption is in favor of the existence of lungs, undeveloped at their apices, which have never fully occupied the supraclavicular and clavicular areas. With reference to the relation which slight lateral curvatures of the spine have to the condition of the respiratory organs, he said that an inquiry into the history of a considerable number of cases of lateral curvature will elicit the fact that its appearance has been subsequent to the occurrence of a pronounced

attack of pleuritis or pleuro-pneumonia, or a period of long-continued unilateral thoracic pain associated with cough. It is further found, in many of these cases, that the deflection is toward the side of the chest possessing most respiratory expansion, and that the concavity of the primary curve is toward the side presenting slight or notable diminution of respirator motion; while further exploration, by means of percussion and auscultation, establishes the fact that the curved section of the spine lies within a zone of the chest, affording evidences of thickened pleura, fibroid phthisis, or peribronchial consolidation. The third consideration, which he presented under inspection as pertaining to early phthisis, was the importance of closely observing and interpreting, with their full significance, the changes in the individual intercostal spaces, and also in the supraclavicular space, suprasternal notch, and epigastrium. The special significance of the information thus elicited was in regard to fibroid areas and bronchial distortions, which could not be dissociated from the study of phthisis, since they form a part of it, determining, as they do, the recurring hyperæmia and catarrhal processes which terminate in inflammatory infiltration and ultimate caseation.

Before dismissing the subject of chest inspection, Dr. Hudson stated his views as to the causative relation of the non-development of the chest-wall and its movements to phthisis. He believes that the disease attacks the apices preferably, because, 1st, the apices are so frequently enfeebled by contraction of the upper part of the bony thorax—whether by want of muscular activity and development, or by rounded shoulders, through carelessness and indolence, or through confining work at desk or trade. 2d. That the apex region in this enfeebled condition is soonest reached and most easily invaded by the frequent recurring catarrhal inflammations, descending from the larynx and trachea, 3d. Because the apices, when invaded by hyperæmia or catarrhal processes, are unfavorably affected by the energetic forces of cough. Dr. Hudson did not dwell on *mensuration* or *palpation*; though, in regard to the latter, he said the method was particularly valuable as relates to the subject of fremitus, and fremitus was especially instructive for negative diagnosis, often indicating the normal chest by a characteristic vibration communicated to the hands which could not be misinterpreted.

In speaking of percussion, he said that the exclusively pulmonary origin of percussion sound was readily disproved; this being most easily accomplished by referring to the percussion note of emphysema, when the overlying bony thorax is in a state of inspiratory fixation, and so tense or rigid that it does not vibrate; so that the contact of the percussing finger-tips elicits a sound relatively high in pitch and devoid of vibration or duration. When the chest-wall is poorly expanded, or when fibroid phthisis or bronchial rigidity have transferred respiratory action to the diaphragm, the motion of the ribs lessens, and the disused ribs become more or less fixed. Under these conditions, percussion of the entire chest frequently elicits only an unsatisfactory and negative sound, devoid of diagnostic features; but, on the other hand, in many cases thickening of the pleura may cause such absolute percussion-flatness as to warrant the inference of a solidified, phthisical lung. The conclusion is, therefore, that in contracted chests, and in the mixed forms of early phthisis, percussion leads to no positive diagnosis until supplemented by auscultation.

Dr. Hudson then dealt for some time on the significance of the special cutaneous reflex often found in phthisis, first described by Stokes in 1830, and designated by Lawson Tait, in 1871, as *myoidema*, or muscle tremor. The result of his personal observations is (1) that it is usually present in established phthisis, when the long-standing and progressive intrathoracic disease has wasted the body; (2) that it frequently exists in incipient phthisis; and (3) that it is exceptionally present in any other disease, and its presence in such a case justifies a suspicion of phthisis.

In treating, finally, of *auscultation*, he said that the absence or modification of the vesicular murmur has always, and properly, been regarded as a first warning of phthisis; but the presence or absence, fulness of development or enfeeblement of the vesicular murmur is not of so great value in differentiating the three forms of phthisis, and especially the relative properties of each in mixed phthisis. The crippling lesions, in many cases, have so contracted the chest, diminished its expansion, and lessened the velocity and force of the incoming inspiratory currents, that but little respiratory sound is developed to be conducted. Under such circumstances, the phonated voice supplies us with a sound produced quite independent of chest rigidity, diminished expansion, and enfeebled air-currents. But the vibration of the bronchi, the lung parenchyma, and the chest wall, by the full voice often gives no indication of the presence of the lesser lesions of early phthisis; and it is necessary to employ the whisper instead. For a long time he has come to regard the study and application of the conducted whisper as of equal or greater value than the study of changed vesicular murmur and conducted voice, and of far wider application in determining and differentiating the early steps of the three definite forms, and the many mixed cases of phthisis. Thus, at the apex the low-pitched whisper, changed by transmission through the pulmonary media to a high-pitched sound, is diagnostic of incipient infiltration; but the non-conduction of such a low-pitched whisper—silence only, or the distant transmission of a high-pitched whisper—when associated with transmission of the voice unchanged in quality and pitch, point to peribronchial thickening or centric fibroid of limited extent; while the non-conduction of both the low- and high-pitched whispers, and a distant full conduction of the voice, point to a fibroid nearer the surface, or progressing inwards from a thickened pleura. When the smaller tube of the stethoscope is used in connection with the high-pitched whisper, close comparison of adjacent limited areas can be made to great advantage, and the whisper tests are especially of value in distinguishing a healthy lung from one but slightly diseased. The conclusion of the paper was devoted to the subject of hæmoptysis, and to the interpretation of local areas of crepitus.

Dr. Alfred L. Loomis said that while he might not agree with the author in every particular, in the main he could heartily endorse all the positions taken. In speaking of inspection, he stated that in 1200 or 1500 chests which he had examined, but 10 per cent. were perfectly symmetrical; but, at the same time, he thought

that by a careful inspection of the whole chest certain information could be obtained which could not be derived from any other source. For a long time after he commenced the study of diseases of the chest, he had regarded, as he had been taught, the infraclavicular region as of special value for inspection; but later he had come to understand that the scapular spaces are of much more importance in this connection, and many and many a time he has found here the early signs of phthisis which could not be detected elsewhere. The axillary spaces are also invaluable to the diagnostician. He spoke also of the various other methods of physical exploration, and said that he would be inclined to lay more stress on the value of percussion than Dr. Hudson had done. Percussion, however, is to be rightly practised, and a single light, though firm tap, will often give more knowledge of the exact amount of infiltration present than can be gained by auscultation, especially in the scapular space. Like Dr. Hudson, he believes that the whispered voice is of far more importance than the spoken. The vesicular inspiratory murmur he also thought of significance; and there are three modifications of it which may throw light on cases of early phthisis, viz., softness, harshness, and interruption. If the murmur is full as well as harsh, it indicates pleuritic changes, probably tubercular in character. By the peculiar harshness observed in the vesicular murmur, he has detected the presence of acute phthisis in many cases, before the easily recognized signs of the disease had appeared.

Dr. Page fully concurred with Dr. Hudson as to the importance of the diagnostic value of myoidema, and he said that he has now a case under observation, the future course of which he will watch with great interest. This is a lad, fifteen years old, in whom this sign is well-marked, though there is as yet no positive sign of phthisis. He has, however, a hacking cough, and both his temperature and pulse constantly remain considerably higher than normal.

Dr. E. G. Janeway said in reference to myoidema, that he had studied the matter sufficiently to be convinced of the unreliability of the sign from a diagnostic point of view. There are various muscles all over the body which when tapped will exhibit this phenomena in emaciated patients, and it is especially well marked over the biceps and deltoid. It is not often observed in other diseases than phthisis, because in them the physician is not likely to tap the chest. He believes that it is purely muscular, and that it can be developed in many other localities than the chest, and in many other affections besides phthisis. As to the ordinary physical signs in the early stages of the disease, the most that we can make out by them are condensation, thickening, consolidation, and local bronchitis. The special significance of these conditions it is not always easy to determine, and the chances of error have always to be taken into consideration. While all the signs have their value—palpation perhaps the least of any—they are all liable to mislead at times. There are, however, some others of importance to which allusion has not been made. In cases of doubt it is sometimes very useful to employ percussion during inspiration, during expiration, and in the interval. He is inclined to lay more stress on irritation of the bronchi than Dr. Hudson had done. Râles in the smaller bronchi, limited to supra- and infraclavicular spaces, are of great significance. When there is evidence of consolidation, it will not do to trust to one examination, since not infrequently pneumonias occur at the apex of the lung. Such pneumonias run a characteristic course, and are apt to leave untouched the anterior portion, involving the posterior and middle part of the upper lobe. At the present time he said he is not willing to make a positive diagnosis without resorting to the microscope. The character and number of bacilli present in any given case are of great importance in establishing the kind of phthisis from which the patient is suffering. Such microscopic examinations should always be conducted with great deliberation and care, and by the best methods, as there are a number of sources of error which are liable to mislead. Dr. Janeway also spoke of the great importance of careful inquiry into the past history of the patient. The signs of early phthisis may be present, and yet a thorough investigation of the case show that they are simply evidences of a bygone disease which had existed several years before in the lungs.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, April 23, 1885.

The President, E. O. Shakespeare, M.D., in the Chair.

NOTES ON THE MORBID ANATOMY OF PNEUMONIA.

Dr. Osler read a paper summarizing his experience while pathologist at the Montreal General Hospital. Of 105 autopsies in cases of lobar pneumonia of which notes were available, five were discarded for various reasons. The mortality at the hospital is high on account of the large percentage of grave cases which are admitted; very many in persons debilitated and dissipated.

Of the hundred cases seventy were males and thirty females. Of ninety-four instances in which the age was given, there were eleven case under twenty years; twelve between twenty and thirty; eighteen between thirty and forty; twenty-one between forty and fifty; twelve between fifty and sixty years; and twenty cases over sixty. In fifty-one cases the right lung was affected; in thirty-two the left; in seventeen both. Other details were given of the various lobes affected. The heaviest lung weighed was 72⅓ oz., and in eight instances the affected organ weighed over 64½ oz. In about fifty per cent. of the cases there was red hepatization; in thirty per cent. mixed red and gray; and in about twenty per cent. gray hepatization. The condition of the pleural air passages, bronchial glands, and unaffected portions of the lung tissue, was described. Among the terminations there were four instances of abscess formation; three cases of gangrene; and one in which there was a process of fibroid induration beginning in the lung. This case was a man aged 55, admitted with pneumonia of the right lung five days after the initial chill. Resolution did not occur, and he died in the fifth week. *Post-mortem:* The right lung was found solid, grayish in color, and in many areas the tissue had a smooth, homogeneous, translucent aspect, and in these a fibroid change was going on; the alveolar walls were thickened, and the fibrinous

plugs in the air-cells seemed undergoing transformation into connective tissue (a slide was shown illustrating this). There were no caseous portions and no tubercles.

As to the other organs, the frequency with which large, firm clots were found in the heart was specially dwelt upon. In only 35 instances was the spleen much enlarged. In 1 it weighed 21½ oz. In 25 per cent. there were marked fibroid changes in the kidneys. Of the complications, there were 5 cases of pericarditis and 16 cases of endocarditis. In 8 instances the meninges of the brain were inflamed, in 5 of them associated with ulcerative endocarditis. In 5 instances there was acute croupous or membranous colitis, and in 1 instance croupous gastritis.

Dr. Tyson, in the discussion of Prof. Osler's paper, said that he had been rather incredulous of the termination of croupous pneumonia in fibroid induration, but the specimen exhibited by Dr. Osler demonstrates conclusively that such a condition exists. The facts presented in the paper are such as are not generally collated. Collective reports of autopsies in cases of particular forms of disease are of great value in the study of pathology.

Dr. Formad asked Dr. Osler why his was not a case of acute phthisis. Croupous pneumonia is a very common accident in acute phthisis. It is croupous pneumonia which causes death, which is well shown by recent investigations of Mercur, of the University of Pennsylvania. Dr. Formad did not believe that croupous pneumonia can last five weeks.

Dr. Shakespeare said that the remarks of Dr. Osler about the frequent existence of very firm clots in the right heart, extending into the ventricles, can be corroborated by any one who makes autopsies of cases of pneumonia at hospitals. He had seen them in cases of phthisis quite as extensive and firm, reaching into the vessel going to the affected part of the lung. It is interesting to note the systemic involvement of these cases of croupous pneumonia, and the affection of internal organs as well as lungs in the process which has been regarded as a local disease. We have to do with a general wide-reaching affection rather than local inflammation.

The opinion was advanced by Dr. Osler that the exudation in the air-cells organized, that the process in the organization of croupous exudate is similar to that in the clot in arteries after ligation, and that comparison was the point which Dr. Shakespeare wanted to bring out.

Dr. Shakespeare said that he did not believe that a blood-clot in a vessel ever organizes, and his opinion is based on facts detailed in an investigation, which he has published, on the healing of arteries after ligature. The vessel healed not by the agency of the white cells caught in the meshes of the reticulum, but by proliferation of the endothelium of the tunica interna and subjacent connective tissue cells. He thought there is reason to believe that there is in this process in the lungs an analogue of the processs after ligature.

We have to do with an outgrowth of the interalveolar walls. The ground which Dr. Shakespeare takes is purely that of analogy to the process in a blood-clot in a ligatured artery.

Dr. Osler, in closing the discussion, said that it is well-known that croupous pneumonia may persist five or six weeks, or even longer, before resolution takes place. It is difficult for anyone, who has not had the experience, to realize the anxiety which such a case may cause. He had reported two such cases of delayed resolution, one in the fourth week and one in the eighth, both with perfect recovery. He is quite aware of the difficulty in distinguishing certain cases of acute phthisis from pneumonia, and had seen a case with Dr. Ross, in which the diagnosis was for some time in doubt, but in the case in question the person had been under observation from the onset, and the symptoms were those of ordinary pneumonia.

Post-mortem, there were no caseous masses, no miliary tubercles, only the condition already described. The termination in fibroid induration, though rare, is perfectly well recognized. In Cornil and Ranvier's *Manual*, as well as in Green's *Pathology*, is a figure which might have been taken from the slide under the microscope.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 28, 1885.

The President, Robert F. Weir, M.D., in the Chair.

COMPLETE PARALYSIS OF THE RIGHT TRIGEMINAL NERVE.

Dr. T. M. Markoe, presented a man, about fifty-five years of age, whose case was interesting principally from an anatomical and physiological point of view. The patient denied positively any syphilitic antecedents, and there was nothing at present calculated to excite suspicion except some superficial ulcers on the lower part of the leg. About eight years ago he began to have pains on the right side of the head, which, in the course of two years, took on a severe neuralgic character, the entire right side of the face being affected. The neuralgic character of the pains subsided gradually, and gave place to a feeling of numbness and insensibility on that side of the face. There is now complete anæsthesia in the region of distribution of the right trigeminal nerve. The sensation in the tongue had been carefully tested by application of chloroform and nux vomica, and complete insensibility found to exist upon the right side, while sensibility on the left side appeared normal. The right eye is also insensitive to the coarsest touch. The man can rub his finger over the cornea without feeling it. In addition to paralysis of sensation, there is also paralysis of motion in the muscles supplied by the trigeminal, the temporal and the masseter muscles being very markedly atrophied. Mastication is exclusively performed by the muscles of the left side, nutrition seems to be perfectly maintained in all the paralyzed parts, but about two years ago a little pimple formed on the margin of the right alai nasi, which ulcerated slightly and then disappeared. Following this, however, there has been a gradual disappearance of tissue about the ala, until now it is almost entirely absorbed, leaving a large and very deforming opening into the side of the nostril.

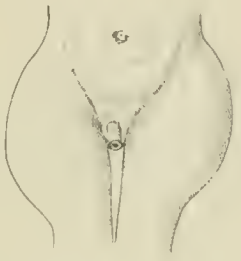
In considering the probable seat of the lesion of the trigeminal nerve, Dr. Markoe thought it must lie between the emergence of the nerve from the pons Varolii and its entrance into the Gasserian ganglion. If the

lesion were within the brain or pons, there probably would be other manifestations.

Attention was also called to the scarcity of the moustache on the right side, and to its whiter color.

UNUSUAL ABSCESSES CONNECTED WITH SPINAL DISEASE.

THE PRESIDENT presented a boy (with illustration), eight years of age, who exhibited unusually large ab-



scesses over the trochanters and upper two-thirds of both thighs resulting from spinal disease in the lumbar region, which latter began four years ago, and two years later the swellings over the anterior portion of the external iliac and trochanteric regions began to make their appearance, and increased in size until at present they are each as large as a loaf of bread. Examination per rectum showed that the matter had worked its way down on either side of the projecting surfaces of the sacrum, and had passed out through the sciatic notch.

DR. LANGE asked what was the proposed form of treatment.

THE PRESIDENT replied that, inasmuch as the abscesses were increasing in size, and the patient's condition deteriorating, he intended to open and drain them, one at a time, under full antiseptic precautions.

NEWS ITEMS.

CANADA.

(*From our Special Correspondent.*)

ONTARIO MEDICAL COUNCIL.—The election for members to the Council will be held May 26. It is expected that there will be quite a large number of new men elected to fill vacancies caused by resignations, and that many of the old members will have difficulty in securing reëlection.

ONTARIO MEDICAL ASSOCIATION.—The fifth annual meeting of this Association will be held in London, Ontario, June 3d and 4th. Many interesting papers have been promised, and discussions in the following subjects are announced: Diphtheria, plaster splints, intrauterine medication; and uses of cocaine hydrochlorate.

Dr. A. Worthington is President of the Association for this year.

PUBLIC OPINION ON THE ACTION OF THE ASSOCIATION ON THE ORGANIZATION OF THE INTERNATIONAL MEDICAL CONGRESS.—The recent action taken by the American Medical Association is no more effective than would be a pope's bull against a comet, and was an untimely and over-zealous effort to undo what had been placed in charge of a Committee previously elected to discharge, without restriction, a special duty. The resolution which created the Committee does not ask it to report, thus showing clearly that it was the intention of the Association to give it full executive power. The work which it has performed should be accepted without special dissent by all who have any interest in the forthcoming meeting of the International Medical Congress, as its success depends upon its remaining undisturbed. The grievances which were presented at New Orleans are too trivial to require serious comment. The sources from which they came, and which coaxed the Association into performing a meaningless act, give no guarantee that the work can be any more satisfactorily performed than it has already been.—*Medical Record.*

Just as it had begun to appear that the Committee had achieved something tangible in the direction of doing away with the difficulties to which we have alluded, by an unusually representative and creditable organization, comes this shameless attempt by a few soured men to throw cold water on the whole affair.

It was not that the malcontents cared a fig to oust any man on account of his ethical proclivities or the place of his residence; they simply wanted the "ins" to be made "outs" in order that they themselves might become "ins." To accomplish this purpose, they naturally seized hold of the most promising pretexts, and the event proved the depth of their cunning.—*New York Medical Journal.*

The only subject on which action was taken of doubtful propriety, was in relation to the proposed International Medical Congress of 1887.—*Journal of the American Medical Association.*

A score somewhat above the customary high-water mark was made, in consequence of a breeze stirred up by certain unhappy critics relative to the preliminary work of the Executive Committee of the coming International Medical Congress.

Whatever may be the substrata of the grounds for the vigorous protest of Dr. Shoemaker and his supporters, there would seem to be nothing at the surface in the published "Rules and Preliminary Organization" of the Committee that could warrant the accusation that it had made a bargain with the New Code men, nor does a closer scrutiny of the document bring to light aught to discount Dr. Billings's statement that, "Whether the Committee had acted erroneously or not, it had acted to the best of its ability and with pure and honest motives, the character of its members being the best guarantee of this assertion."

A glance at the "Rules and Preliminary Organization" shows that twenty-nine States, the District of Columbia, and Canada, have been honored by the appointment of one or more of their distinguished physicians as members or officers of the Councils and Sections. . . . . It is true that the territories, several of the States in the far West, and two of the Southern States are left out of the count, but so also are two Eastern units of our Union, one a Middle and the other a New England State.

When the relative importance of the great cities of the States as medical centres and conservators of medical talent is taken into account, this distribution of honors, though not above criticism, cannot be counted unjust, and we believe that the list in the main, though savor-

ing somewhat of petroleum and codfish, will be found to be fairly representative of the profession in America. —*Louisville Medical News.*

RULES GOVERNING VIVISECTION ADOPTED BY THE UNIVERSITY TRUSTEES.—The Trustees of the University of Pennsylvania have adopted the following rules in reference to vivisection :

1. Experiments may only be made on living animals for the purpose of serious inquiry, or for giving instruction of importance.

2. Experiments on animals are only permissible during lectures, so far as they are necessary for the lecturer to explain his subject matter.

3. The operative preparations for the lecture experiments are, as a rule, to be made before the commencement of the demonstration, and in the absence of those attending the lectures.

4. Experiments on animals may only be performed by the professors and lecturers or on their responsibility.

5. Experiments which can be made on the lower animals without essentially prejudicing the results required are only to be performed on those, and not on the higher animals.

6. In all cases, whether for research or instruction, in which it is not absolutely incompatible with the object of the experiment, the animal must be put under the full influence of anæsthetics, in such a manner that the effect of the anæsthetics shall last for a sufficient time.

These are substantially the rules issued by the Prussian Minister of Education and are founded on very careful inquiries made upon the practice of the German Universities. The Trustees, in adopting these rules for the control of all persons in the University who may have occasion to employ animals in research or for illustrative use in lecturing, expressed the desire that the professors concerned should see that they are strictly enforced, and gave them authority to refuse the use of laboratories to persons who do not obey the regulations.

THE PHILADELPHIA POLYCLINIC.—Dr. B. F. Baer, President of the Philadelphia Obstetrical Society, and late Demonstrator of Diseases of Women in the University of Pennsylvania, has been elected Professor of Diseases of Women and Children; and Dr. H. Augustus Wilson has been elected Professor of Fractures and Dislocations, and Secretary of the Faculty.

NOTES AND QUERIES.

HEMORRHAGIC MALARIAL FEVER.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of May 2d, is a synopsis of the proceedings of the Louisiana State Medical Society recently held in New Orleans, in which I am reported as saying in a discussion of the paper read by Dr. I. J. Newton on Hemorrhagic Malarial Fever, "that several cases in his (my) parish treated with large doses (quinine) had died. He (I) related a case of malarial hæmaturia in which there was no fever, but rather a subnormal temperature. He (I) had used diuretics, such as nitre and copaiba, and after the attack small doses of quinine."

I beg that you will allow me, through your Journal, to correct this error *in toto*, as it does me great injustice and misrepresents my views in the treatment of this disease from beginning to end. The reporter has unintentionally substituted my name for that of some other speaker. I did not participate in the discussion of the paper at all, so far as regards the treatment indicated. But the writer, in tracing the history of the disease, fixed a knowledge of its first appearance in this country about 1846 in the State of Georgia. In reference to this point, I did state that as early as 1837 and up to 1843 I encountered and treated many cases of this disease in the Wabash and White River bottoms in the States of Indiana and Illinois, and from 1843 to 1846 in the White River lowlands in the State of Arkansas, and that in each of these localities where I practised at the periods named, I found this disease more or less prevalent every year.

Yours very respectfully,
RICHARD H. DAY, M.D.

BATON ROUGE, LA.

TREATMENT OF CROUP.

To the Editor of THE MEDICAL NEWS.

SIR: An editorial in your last number has honored me by referring to my views concerning the treatment of croup. Some of the statements contained therein are rather incorrect, so that I beg the privilege of referring to it in a future issue of your Journal, and detailing, briefly and compactly, all I have to say on the subject.

Very respectfully yours,
A. JACOBI, M.D.

110 W. 34th ST., NEW YORK, May 11, 1885.

We shall be most happy to give space to Dr. Jacobi's intended article —ED.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 5 TO MAY 11, 1885.

MCKEE, JAMES C., *Major and Surgeon.*—Sick leave of absence still further extended four months on surgeon's certificate of disability.—*S. O. 105, A. G. O.*, May 8, 1885.

BILL, JOSEPH H., *Major and Surgeon.*—Ordered for duty as member of Army Medical Examining Board, New York City, N. Y.—*S. O. 100, A. G. O.*, May 2, 1885.

SPENCER, WILLIAM G., *Captain and Assistant Surgeon.*—From Department of the East to Department of Dakota.—*S. O. 100, A. G. O.*, May 2, 1885.

BRECKEMIR, LOUIS, *Captain and Assistant Surgeon.*—From Department of the East to Department of the Platte.—*S. O. 100, A. G. O.*, May 2, 1885.

DAVIS, WILLIAM B., *Captain and Assistant Surgeon.*—From Department of Dakota to Department of the East.—*S. O. 100, A. G. O.*, May 2, 1885.

STERNBERG, GEORGE M., *Major and Surgeon.*—Detailed to attend, as a delegate on the part of the Government of the United States, the Sanitary Conference to be held at Rome, Italy, on May 15, 1885.—*S. O. 103, A. G. O.*, May 6, 1885.

BROWN, JUSTUS M., *Major and Surgeon.*—From Department of the East to Department of the Platte.—*S. O. 105, A. G. O.*, May 8, 1885.

DEWITT, CALVIN, *Captain and Assistant Surgeon.*—Ordered to Department of the East.—*S. O. 105, A. G. O.*, May 8, 1885.

COWDRAY, STEVENS G., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon, Fort Bliss, Texas.—*S. O. 65, Department of Missouri*, May 2, 1885.

DELOFFRE, A. A., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Sisseton, Dakota Territory.—*S. O. 46, Department of Dakota*, May 4, 1885.

WYETH, M. C., *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty at Fort Wadsworth, N. Y. H.—*S. O. 95, Department of the East*, May 6, 1885.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

VOL. XLVI. SATURDAY, MAY 23, 1885. NO. 21.

ORIGINAL ARTICLES.

NEPHROLITHOTOMY.[1]

BY L. McLANE TIFFANY, M.D.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF MARYLAND.

I was asked, in February of this year, by Dr. Frank Donaldson, Jr., of Baltimore, to see with him a patient in the pelvis of whose right kidney Dr. Donaldson had diagnosticated trouble, for the relief of which surgical treatment was judged necessary. The patient was a male, aged twenty-six years, married, the father of one child, pale, emaciated, and gave the following history: at the age of seventeen years he began to experience pain in the right loin, paroxysmal in character and not very intense. The attacks of pain gradually increased in severity and at shorter intervals; he was, however, able to finish his apprenticeship, that of tinner. About six years ago he noticed that his urine was lightish in color and deposited a white sediment, as he expressed it. At that time exercise did not bring on an attack of suffering, neither did he observe blood in his urine. On July 4, 1884, he was seized with an attack of pain extremely severe on the right side just below the ribs, pain has continued almost constantly ever since, remissions being rare; during the night pain has been more severe than during the day. Since last July, the patient under consideration has taken much morphine—without it, he says he could not live.

Physical examination showed tenderness on percussion and on pressure acute pain, over the front of the belly about the region of the kidney; no tumor was detected, although searched for.

The outer portion of the right external oblique was rigid, and the lumbar muscles were more rigid than natural; percussion gave a sound somewhat more dull than over the corresponding region of the left side. The patient moves slowly, holding the trunk stiffly, for quick motion and any exertion cause much pain.

Urine was passed in normal amount, and contained much pus; casts were not observed, although searched for; there was no history of blood or gravel having been passed at any time. Micturition not unduly frequent or painful and in full stream.

These symptoms justified exploration of the kidney, so on February 21st, H. J., being anæsthetized with ether, I exposed the kidney by an incision carried half an inch below and parallel to the last rib. The quadratus lumborum muscle was divided, as also the outer edge of the erector spinæ. The perirenal and subperitoneal fat being divided, the kidney was watched and seen to rise and fall regularly with respiration, thus excluding perirenal inflammation to any marked degree. To the touch the gland seemed more hard than normal and a needle passed into the kidney did not touch stone; on passing the needle again in, it was directed more forwards than the first time; I at once struck a stone. The kidney was then freely opened lengthwise with the hot blade of Paquelin's cautery and the finger passed in to explore. The kidney pelvis was filled by stone so closely that without undue force I was not able to pass any forceps so as to grasp the calculus. In attempting so to do, I broke off a piece of stone and saw that I had to do with a phosphatic concretion.

I then directed an assistant to press with the flat of his hand upon the patient's belly so as to force the kidney towards my incision, while with a Volkmann's sharp spoon and forceps I broke up and removed the stone. The spoon acted charmingly, cutting a hole in the centre of the mass with rapidity. The débris was washed away by means of a syringe. The fragments which were collected weighed 556 grains, phosphate of lime. Hemorrhage was insignificant and ceased under hot water irrigation. A large drainage-tube was passed into the pelvis of the kidney and an oakum and iodoform dressing applied. At the (12 M.) conclusion of the operation the pulse was 156, respiration 18, temperature 101.4°; at 11 P.M., the pulse 132, temperature 101°, respiration 18. Forty minutes after the operation the patient passed water and complained of its burning him.

Convalescence calls for no special comment. All went well; the patient sat up out of bed and had a full diet in a week and left the hospital three weeks and four days after operation; the wound being reduced to a healthy granulating surface, level with the skin, through which no urine came; it has since healed perfectly, and gives no discomfort.

Two noticeable facts became apparent as healing went on: 1st. That during the early days after operation when the urine from the wounded kidney came through the back, the urine from the bladder was clear and almost quite free from pus, as however the incision closed, pus again appeared in the urine, indicating that the kidney not opened was probably healthy.

In the second place, it was found possible to inject water into the drainage-tube and so through the ureter into the bladder. Pus was still to be found in the patient's urine when he left the hospital, but of course in greatly diminished quantity.

While the term nephrolithotomy is not a new one, yet it has been revived, defined, put upon a good surgical basis, and appended to a successful case by Henry Morris (vol. xiv. *Clinical Soc. Trans.*), to whom is due much credit. It is used to indicate the removal of a stone or stones from an otherwise healthy kidney, as distinguished from such operation as may be necessary to remove a stone or stones from a kidney dilated by pus or urine, or where the stone

[1] Read before the American Surgical Association, April 22, 1885.

may have escaped by ulceration into the perinephritic tissues, or where a sinus opening externally conducts the operator to the stone, or indeed where the kidney may present evidence of much disease.

A lumbar swelling which fluctuates, is opened, discharges pus and permits the operator's finger passed through the incision to touch a stone free in the abscess cavity, is a very different procedure from that for removal of a small stone from the kidney cortex which has not set up suppuration, yet I venture to hope that at no distant period the one will be operated for as certainly as the other. The matter is an affair of diagnosis, to obtain which it is most fitting to question the experience of others.

Four-fifths probably of individuals hitherto subjected to nephrolithotomy have been young, between 19 and 30 years inclusive, but it is fair to suppose that this experience will be changed somewhat as the necessity for the operation becomes more widely recognized, since all the patients suffered for years before the stone was removed; a calculus is removed from the urinary bladder when discovered, and I would apply to the kidney pelvis a similar treatment. The male sex largely predominates, in this respect differing not at all from that which one would expect, since calculus of the bladder in the male is so much more often met with than in the female.

I find no occupation apparently particularly liable; statistics, however, are not full enough to warrant any conclusion. From a limited number of observations it would appear as though the left kidney was the more often affected, although the excess is small. The theory of hereditary predisposition is not supported. The symptom which is most prominent throughout, and the one for which the physician is consulted is pain. Pain was complained of for a long time, thus a male aged 50 suffered during 24 years; a male aged 24 suffered since schoolboy days; a female aged 19 since 8 years of age; a male of 19 since 7 years of age; a man of 19 for 8 or 10 years; a female of 23 during the past seven years, and this is the history with all. With all, the pain for a long time, if not always, is paroxysmal, recurring at first rarely; subsequently, however, the intervals become shorter and shorter, until finally constant suffering may be experienced. The acuteness of the attack is apt to be in direct ratio with its frequent recurrence. This is not an unvarying rule and the intermissions are occasionally long, in one case four and in another ten years of rest being enjoyed. Sooner or later there may occur, however, a marked exacerbation in all symptoms, which I am inclined to attribute to a dislodgement of the stone from its fixed position, thus permitting movement in the kidney pelvis, with injury to the mucous membrane.

Pain is described as follows by different reporters:

At varying intervals from a day to a week; during the past four years pain has nearly left him, now he has a dull pain on exertion.

Pain in loin shooting to testicle, which is retracted; pain and tenderness on deep pressure in loin.

Shooting pain in right lumbar region, in groin and loin. No tenderness or resistance; this appeared by the time of operation.

Neuralgia of testicle daily and for several hours; during an attack the patient writhed with agony, the testicle was drawn into the canal and could not be touched. An attack was usually preceded by pain deep in the belly, also by lumbar pain.

Hidden pain in loin, side of belly, testicle, inside of thigh. During four years, attacks occurred every six months, then constant pain for two years, and finally during ten months the patient has remained in bed.

Great pain in the loin down the ureter to testis and thigh, followed by hæmaturia. Pain has been observed to shoot down the thigh as far as the knee. Atrophy of the testicle succeeded the pain in one instance. Exertion, in all cases that I have noted, has given rise to pain, and especially such motion as throws the muscles of the loin into action. Sudden active movement induces much suffering in an advanced stage of the malady. The lumbar muscles are occasionally quite strongly contracted and rigid over the affected kidney, and the outer portion of the external oblique may be likewise contracted; under anæsthesia this symptom will disappear. A lumbar swelling and dulness have been in one instance observed to disappear under anæsthesia, doubtless muscular rigidity had much to do with their presence. Frequency of micturition has been noticed several times, particularly after a paroxysm. Symptoms referable to the urine are not very clearly defined, since during the years of suffering the urine will probably have indulged itself with various changes at different times; the urine is thus described in various cases:

Sp. gr. 1010, neutral, contains blood and triple phosphates; later, urine from the same patient contains albumen and pus, with sp. gr. 1024.

Sp. gr. 1020, acid, trace of pus.

Sp. gr. 1020, in copious quantity during the twenty-four hours, never any pus or blood.

Sp. gr. 1020, alkaline, pus, no blood or casts; a few days later blood appeared and the urine became acid.

Probably a noticeable fact from a diagnostic standpoint is rapid change of urine from alkaline to acid, or the reverse, without apparent cause, dietary or what not. The constituents of the urine may be thought of from a similar standpoint. Blood will probably be found in the urine according as much or little exercise has been indulged in, in one instance it is thus described: The urine is dark with blood after exercise, rest cleared it up; in another instance: blood in quantity has been passed lately after exercise, enough to obstruct the urethra by coagula; after a paroxysm, blood is apt to be present in the urine. Sand and gravel have both been exceptionally met with. Casts of the urinary tubules are observed very rarely, probably because they are hidden by other constituents of the urine. But the indications of stone already noted do not suffice for a diagnosis any more certainly than calculus of the bladder is accepted as present without being touched, so the kidney must be exposed and sounded. It goes without saying that the incision to expose the kidney is to be utilized for extraction if a calculus be found. The incision which is as convenient as any other, is one parallel to the last rib, and about half

an inch below it; or the usual colotomy incision will do, and the kidney sought for posterior to the colon. The quadratus lumborum is to be divided and erector spinæ if necessary, since an empty colon moves towards the spine, carrying the peritoneum, and both should be avoided. A thin fascia has been recognized in the perirenal fat, but this may be disregarded, for as soon as this fat is exposed the finger can feel the gland, and it may at once be cut down upon. The length of the various cuts will depend upon the exigencies in each case. The rise and fall of the kidney with the respiratory movements have been observed in more than one instance. Examination of the exposed kidney by touch, is to be made from in front, as strongly urged by Howse, the gland is thus pressed against the psoas muscle, which offers resistance, and enables the investigating finger to appreciate changes in density, etc. I think it inexpedient to explore widely in the perirenal tsssue, for the kidney will probably be opened, and a split kidney will cicatrize more comfortably with its connection to surrounding parts undisturbed, than not. Failing to recognize a stone by touch, a needle may be passed into the kidney and the pelvis explored. This is the usual method. I am rather of the opinion, however, that it is needless, and that the kidney which justifies exposure also justifies cutting open and exploration of its pelvis. Acupuncture holes are apt to bleed somewhat for a moment or two. The kidney is to be opened by a longitudinal cut, which bleeds very sharply, but yields to pressure promptly, and probably also to hot-water irrigation. If Paquelin's cautery is used, there is no bleeding. It is interesting to learn that in one case, that reported by Anderson, the stone had two projections like the fangs of a tooth, between which was engaged a piece of renal substance; in extracting, this piece was torn away bodily, yet no harm resulted and the wound healed promptly. It may be inferred from the foregoing that the kidney is to be treated as other glandular organs of the body, and will heal as promptly. The finger is the best instrument with which to explore the kidney pelvis, as well as the secreting substance from within.

The smallest stone that I have noted is that of Howse, oxalate of lime 26 grains; the largest is the one now reported and shown; the next largest is that of May, crystalline phosphate of lime with nuclei of oxalate, 473 grains. Calculi hitherto extracted are largely made up of lime oxalate and phosphate. The mortality following this operation is small, probably five per cent. or ten per cent. at most, even now in its very infancy, a mortality which may confidently be expected to decrease as we gain experience. It will probably take its place among the most successful of major operations.

Will the kidney, the subject of nephrolithotomy, return to a healthy condition? Time must reply to this query; at present no answer can be given; a sufficient period has not elapsed since Morris's first operation, 1880. On general principles we should expect a return to health after removal of a foreign body, but we know that the age of the patient has much to do with permanent and complete recovery after removal of stone from the bladder, so I am inclined to think that the same may hold good in regard to the kidney pelvis. May's patient, three months after operation, passed urine sp. gr. 1020, alkaline, containing mucus, pus, and triple phosphates. The possibility of a recurrent attack suggests itself, but we are without data on the subject.

I have mentioned that I was able to inject my patient's bladder with water through the ureter. This has been to me a fruitful theme.

Exploration and catheterization of the ureter from the bladder in the female has been attempted not over successfully, but it could be done from the kidney extremity in either sex. The injection of colored water through the ureter, a catheter having been passed into the bladder through the urethra, would demonstrate its patency in case of pressure by a tumor or calculus; or the latter might be touched by a slender flexible bougie, metal tipped, and extracted. There is still another way in which this suggestion might be utilized, when a nephrotomy has been done and the question of removing the diseased kidney arises, by washing out the ureter, and then plugging it, the urine from the other kiney could be collected and its healthiness investigated, for wherever a nephrectomy is under consideration the fitness of the remaining kidney for the extra work to be thrown upon it will come up for discussion. I am inclined to institute a comparison between the reservoirs at either end of the ureter, when, in addition to the normal fluid contents, a stone is present. In both, certain symptoms occur which we should recognize; in both, we should sound, find the stone, and extract, and I am strongly inclined to believe that in nephrolithotomy, as in lithotomy, the age of the patient, as already stated, has much to do with the outcome. How important then is it to diagnosticate and operate early.

There remain for consideration a certain set of cases, in number not a few, which cases have been diagnosticated as fit subjects for nephrolithotomy by not only competent, but by eminent surgeons, and yet no stone has been found after the kidney was exposed, and also, after the kidney was cut open and explored by the finger; for instance (*Lancet*, June 2, 1883, p. 948):

C. S., aged 29 years, married, female, dated her illness from an attack ten years ago, characterized by sudden and excruciating pain in right loin, accompanied by vomiting.

Shortly after this her urine smelt badly, and contained a yellow deposit. She came under the surgeon's care February, 1881; chief symptoms were lumbar pain, increased by exertion, fetid urine, and frequent micturition. Under ether, nothing was found wrong with the bladder, uterus, or rectum. There was no lumbar swelling. Urine acid, and contained pus. January, 1882, on examining the right loin something was felt to slip under the fingers, she at the same time complaining of a sharp, stabbing pain.

On admission she complained of severe pains in right loin, which extended from groin into the labium and down back of thigh; they were increased by exertion, and prevented her from walking any considerable distance. Unine alkaline faintly; sp. gr. 1014; gave reaction to guaiacum blood test. Microscope showed triple phosphates, mucus, pus, shrivelled blood corpuscles. She got thinner, and became slowly worse.

December 25, 1882, kidney exposed; it was observed to rise and fall in respiration. No resistance could be felt in it. It was punctured in three places with an acupressure needle, a gritty sensation attending the last puncture. The kidney was cut open and the pelvis explored with the finger, but nothing was found. Hemorrhage small, and ceased spontaneously very soon.

The wound was closed, and recovery followed. March 8, 1883, patient was going about her work without pain, but urine continues rather unpleasant. The operator (Lloyd) says: "Whatever her disease is, I feel sure it is situated somewhere between the bladder and the kidney substance, and is out of reach of surgical investigation."

I cannot avoid thinking that the territory between the kidney and bladder is not out of reach of surgical investigation, and that if the methods of exploration already noted in this paper had been employed, something might have been learned concerning the "dark continent." I do not accept the diagnosis of the reporter.

Here is another case (*Bull. de Thérap.*, 1881, 101, p. 343):

M. X., aged 55 years, suffered from several attacks of left nephritic colic, especially during the past three years, which were followed by the passage of uric acid sand, extremely fine; no piece of gravel had ever been passed. For more than six months continuous pain, with a sense of impending colic, rendered it impossible for him to continue his occupation. Finally the patient was obliged to remain in bed, or else to occupy an extension chair; walking induced much suffering. The left loin appeared more large and rounded than usual. Percussion here awakened suffering, as did also pressure. No febrile phenomena existed.

The kidney was exposed by incision; digital examination revealed nothing; acupuncture practised four or five times; a grating sensation, attributed to small sand; later a stone was believed to be struck. With Paquelin's cautery an incision, six or seven centimetres long, was made into the kidney, but no stone finally found. The wound healed, and complete cure resulted.

The incision through the fibrous capsule, dislodgement of small sand from kidney substance, and revulsive action of cautery are believed to have contributed to a cure; but the operator gives the most credit to free division of the kidney capsule, and with this opinion I concur. The irritation set up by the presence of sand in the kidney substance, or by adjacent inflammation in the pelvis of the kidney, is sufficient to determine a congestion and swelling of the gland, which will, of course, be resisted by the fibrous capsule, hence pain results, and if the pelvis is inflamed, pus, etc., will be in the urine. A similar train of symptoms is seen when the testicle becomes painful and tense from inflammation in an adjacent epididymis. In both cases similar treatment brings relief, namely, division of the fibrous capsule.

With our present knowledge, then, it is apparent that the symptoms of kidney stone may be so closely imitated as to deceive any one, but while the diagnosis is in doubt the treatment is not: a free incision is demanded.

To the comparison already made between bladder and kidney pelvis, I would add another, that both may require free incision, drainage, and rest, to bring about a cure of chronic inflammation, thus still further applying a common rule to different parts of the urinary apparatus, and so simplifying surgery.

THE INFLUENCE OF THE BROMIDES IN THE PREVENTION OF IODISM. REPORT OF A CASE.

BY HENRY SELDEN NORRIS, M.D.,
VISITING PHYSICIAN TO CHARITY HOSPITAL, NEW YORK.

DURING the past four months there has been under my care, a case of bone syphilis and periostitis, in a man thirty-six years of age, in whom the obstacles to treatment were, to me, rather unusual. In the beginning he informed me that the iodides acted very badly with him, producing such severe coryza that it was impossible for him to take them except in insignificant doses. Still, he expressed his willingness to try them in whatever form or amount I might think necessary, and to persevere in their use if such a course should seem desirable.

Disregarding, to a certain extent, this statement concerning his idiosyncrasy, I began by ordering five grains of the iodide of potassium three times a day, in water, intending to increase the dose gradually. The first dose produced a metallic taste in the mouth, a feeling of tension about the forehead, and slight sneezing; the second increased all these symptoms and caused, in addition, a profuse watery discharge from the nose, lachrymation, swelling of the nose and eyes, and great general discomfort. Notwithstanding this condition, the third dose was taken, which still further aggravated the coryza and produced headache, restlessness, and real suffering, which lasted throughout the night. The next day his eyes and nose were red and swollen to disfigurement, both discharging water freely, and he felt ill and scarcely able to go to his business.

I waited until all the catarrhal symptoms had subsided and then tried the iodides of sodium, ammonium, and lithium, in turn, with the same results. The syrup of the iodide of iron, in teaspoonful doses, resulted similarly. Gardner's syrup of hydriodic acid in drachm doses, was well borne, and I thought I had at last found a form in which iodine could be taken, but as soon as the dose was increased to two drachms coryza appeared, and it was abandoned. I then went back to the iodide of potassium, which I gave in one grain doses to begin with. This produced a salty taste in the mouth, and was increased to two grains without any further manifestations, but could not be increased to three grains without unpleasantly severe symptoms.

These experiments occupied some two months. I gave the salt in water, in syrups, and dry in capsules. I used the latter thinking that perhaps the contact of the solution with the mucous membrane of the pharynx had something to do with the extreme susceptibility, and noticed that a larger dose could be taken in this way than in any other, but the difference was not important.

No improvement taking place after these prolonged and varied efforts, I thought that my perseverance with the iodides had possibly increased my patient's susceptibility to their unpleasant effects, and I de-

cided to abandon them entirely for a time, hoping that by so doing I could return to them with a better prospect of success. For the following three or four weeks I gave McDade's "succus alterans," of which he took about twenty-four fluidounces. I would say here, that mercury, either as the protiodide or bichloride, was given from the beginning and maintained throughout. In the meanwhile, the disease was slowly but certainly advancing, and the necessity of iodine becoming daily more apparent, I began again with small doses of the potash salt, but did not find my patient any more tolerant than before. At this juncture it occurred to me that by virtue of their action on the vasomotor system, the bromides might antagonize this action on the upper air-passages. I decided at once to try the experiment, and having in mind the combination of bromine with quinia for the prevention of cinchonism, I combined the iodide and bromide of potassium in the proportion of one grain of the former to two of the latter. I began with five grains of the iodide thus guarded, in water, three times a day, and to my delight no coryza followed its use. After a few days I slowly increased the dose to six, seven, and at last ten grains, always preserving the same relation between the two salts. My patient was then taking thirty grains of the iodide and sixty grains of the bromide a day, and I soon began to see an improvement. Wishing to satisfy myself as to just what part the bromide was playing in the absence of coryza, I one morning directed that ten grains of the iodide should be taken alone. This one dose was followed by such severe coryza that all treatment was suspended for thirty-six hours. I then returned to the mixture as before, beginning again with a five grain dose, increasing slowly and carrying it up to fifteen grains. On forty-five grains a day improvement was pronounced and rapid. Sometimes he would take three doses of fifteen grains each, sometimes the whole quantity in two doses, just as it was convenient, but with the same freedom from coryza.

After the disease was thoroughly arrested and improvement had well begun, I slowly diminished the quantity of bromide, maintaining the iodide at fifteen grains, until in two or three weeks he was taking it alone, and continued to do so until he was entirely well.

My object in reporting this case is not to report a case of syphilitic necrosis and periostitis, so I have said very little about that part of it, but to call attention to the undoubted service rendered by the bromide of potassium in establishing a tolerance of the iodide in a case which was prominently intolerant. Whether it will always thus protect I do not know, having never heard or read of its being used for this purpose before, but where there is this susceptibility to the disagreeable effects of iodine, I would look to the bromides with a good deal of confidence.

MURIATE OF COCAINE IN EXTERNAL HEMORRHOIDS.

By H. A. SMITH, M.D.,
of Philadelphia.

The uses to which the muriate of cocaine has been put led me to try it as a local anæsthetic in the excision of external hemorrhoids.

The patient was a man about fifty years of age, of nervous temperament, with a timidity of pain amounting to fear, dyspeptic, and general health considerably below par. After having exhausted the materia medica of "remedies" and obtaining no relief, he finally consented to an operation. On examination I found the skin and mucous membrane around the anus a mass of corrugations with slight patches of ulceration between the folds; five piles protruded from the anal fissure, four of moderate size and one with a base about one and a half inches in its long diameter.

I considered this an excellent case for operation. After the usual preliminary preparation, I began by injecting about one-third of a grain of muriate of cocaine into each of three of the piles, and in about two minutes, with scissors, I excised them close to the base, the patient experiencing hardly more than slight discomfort. His timidity preventing any further operation that day, a week later I excised the remaining small pile, in the same manner, and then began on the large tumor by inserting the needle of a hypodermic syringe, containing about two-thirds of a grain of the salt into the base of the tumor, injecting a few drops just under the skin, then traversing the pile in its entire length, depositing the solution in the track of the needle to a point just within the skin on the opposite side. I withdrew the needle, inserted a tenaculum, put the pile upon the stretch, and excised it without inflicting the slightest sensation of discomfort except that caused by the entrance of the needle into the skin, much to the surprise and delight of the patient.

This operation suggests to me the probability of the usefulness of this drug in the painful clamp and cautery operation for the removal of internal piles.

After the operation there was an unusual amount of mental excitation, slightly flushed face and contracted pupils. This may have been due to the reaction from his profound depression previous to the operation, as I have not heard of any such effects having been attributed to the drug in the amount used.

MEDICAL PROGRESS.

Pathogenesis of Small Cysts of the Epididymis. —Dr. Ch. Monod, in a paper read at the recent French Congress of Surgery, considers that the origin of small cysts in the epididymis is in relation:

1. With the extent of the sclerosis of which the testicle is the location in men of ages ranging from fifty to sixty, and beyond.

2. This sclerosis, which is principally peritubular, in some regions results in complete obliteration of the tubules of the epididymis, as a result of which there is varicose dilatation behind the constricted portion of the tubule.

3. The formation of the cystic cavity results from the development of these ampullar dilatations.

4. Cystic dilatations are either multiple or disseminated throughout the whole thickness of the head of the epididymis, or less numerous, forming isolated tumors and easily detached from the subjacent tissue of the epididymis.

5. The process by which they are formed is analogous to that by which cysts are developed in the kidney during the course of interstitial nephritis, or in the parotid gland subsequent to the ligation of Steno's duct.

Vice of Conformation in the Penis.—M. Grias reported, at a recent meeting of the Anatomical Society of Nantes, a singular anomaly in the conformation of the penis, in which the organ appeared to have undergone a complete rotation, whereby the inferior surface had become superior, and vice versa. The following is a full description of the anatomical disposition of the component parts of the organ.

The corpora cavernosa were normal in respect to volume and length. The canal of the urethra was situated upon the superior groove formed by their apposition. Their inferior face was occupied along their whole length by a vein one-half inch in diameter. The glans was of normal form. The meatus urinarius occupied its summit, and a sound could easily be introduced into the bladder. The frænum was situated upon the superior surface of the glans; prepuce normal. On cutting the urethra longitudinally along its superior wall, it was found:

1. That neither the corpora cavernosa nor the corona of the glans were reached by the incision.

2. That the frænum was divided, and that the glans, whose direction in the normal penis in its flaccid state is from above downward and from behind forward, was here directed from above downward and from before backward.

3. That the bulb of the urethra is found not below the canal, but on the upper portion of that wall, and was embraced in the incision, which being extended to the neck of the bladder, the veru montanum was seen upon the opposite surface of the urethra. The vesiculæ seminales and the prostate gland were in their normal position.

Similar cases were reported in 1859 by MM. Verneuil and Guerlain.—*Gazette Medical de Nantes*, April 9, 1885.

Researches upon the Respective Rôles of Ptomaines and Microbes in the Pathogenesis of Septicæmia.—Drs. Jeannel and Laulanié, at the late meeting of the French Surgical Congress, expressed their views as to the etiological relation of microbes and the ptomaines to septicæmia as follows:

1. The respective rôles of microbes and ptomaines may perhaps be determined by a comparative study of the absorption of saline solutions and putrid solutions from the surface of granulating wounds.

2. Any substance capable of being absorbed is immediately taken up from the surface of a granulating wound by the process of endosmosis. Therefore, the ptomaines which are in a state of solution are absorbed as soon as they are produced upon the surface of such a wound.

3. The granulating membrane is a filter which permits the passage only of such substances as are in solution, and not of those held in suspension, such as microbes and other albuminoid bodies.

4. Septicæmic fever is never observed in those having granulating wounds the surfaces of which are covered with putrid pus, for the reason above stated.

5. When the granulating surface of a wound secreting pus is broken or unhealthy, fever becomes a prominent symptom: because the filter (granulating surface) being broken the passage of the microbes contained in the pus is permitted.

6. If the intact granular membrane absorbs the ptomaines by endosmosis when they exist upon the surface of the wound and nevertheless the injury is not complicated with fever, and if, on the other hand, septicæmic fever in one or the other of its recognized forms is only manifested when by breaking of the granulating membrane the microbes are enabled to enter the economy, it is evident that the ptomaines are only a secondary element, while the microbes exercise the principal influence in the production of septicæmia.

The Transmissibility of Tuberculosis by Means of the Sputa of Phthisical Patients.—Prof. S. Sirena and Dr. B. Pernice have lately made a series of investigations upon the transmissibility of tuberculosis by means of the sputa of phthisical patients. Their experiments were performed with great care as to details, and lead to the following conclusions:

1. The liquid obtained from the evaporation of tubercular expectoration is constantly free from the bacilli of Koch, and, when injected into the cornea, subcutaneous cellular tissue, or into the peritoneal cavity, as a general result, produced neither local nor general tuberculosis.

2. That phthisis-producing bacilli are not found in the surrounding atmosphere, as a result of evaporation of tubercular sputa, though such organisms may be very abundant therein.

3. Respiration for several hours, or for a protracted period of several days, in a close atmosphere in which are contained the exhalations from phthisical sputa, does not produce tuberculosis in animals.

4. Animals confined in close quarters and compelled to breathe an atmosphere laden with the dust of dry tubercular sputa, do not contract tuberculosis.

5. The subcutaneous injection of tubercular matter produces for the most part a local specific manifestation, as is shown by the presence of tubercular bacilli in the pus of the lesion, and after a variable time produces tuberculosis of the abdominal or thoracic organs.

6. The injection of tubercular sputa into the peritoneum, produces first a local, and secondarily general tuberculosis in animals.

7. Tracheal injection of a solution of tubercular sputum, even in animals affected with broncho-pulmonitis, is not the cause of a specific infection, but for the most part of septic croupous pneumonitis characterized by the presence of micrococci on the exudation.—*Gazzetta degli Ospitali*, March 29, 1885.

Hypodermatic Injection of Sodium Iodide.—M. Arcari, in the *Gazzetta med. Ital.*, Lombardia, 1885, No. 11, recommends the hypodermatic injection of sodium iodide in syphilis, when irritability of the stomach renders its administration by the mouth impossible. According to M. Arcari, the same result obtained by ninety grains of the drug administered by the stomach, may be procured by thirty grains by the mouth, and two hypodermatic injections of two and a half grains each, daily.—*L'Abeille Médicale*, April 30, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 23, 1885.

THE PLYMOUTH EPIDEMIC.

THE weight of evidence thus far collected tends to the conclusion that the disease which has prevailed in the town of Plymouth since early spring, is true typhoid fever caused by the specific contamination of a mountain stream, partly supplying the town with drinking water, by the excretions from a case of fever which were deposited on the surface of the ground close to the stream, and washed into the current by the melting of snow and by rains. It had not occurred to the physician and attendants of this case to destroy the specific character of the dejections; otherwise the record of this dire calamity probably would not have passed into history.

The sequel affords a most impressive lesson, by no means new, as similar and equally conclusive cases have every now and then been brought to public notice. Among these may be mentioned, for the sake of comparison, the outbreak of typhoid fever in the village of Nunney, recorded by Ballard. Here the inhabitants had been in the habit of using the water of a stream more or less polluted for years without causing fever; but when a case had come into the village, and the discharges from this person were washed into the stream, a virulent outbreak of fever occurred. Between June and October, 1872, no less than seventy-six cases occurred in a population of 832 persons. All those attacked drank the stream water habitually, or occasionally. All who used filtered rain water or well water escaped, except one family who used the water of a well only four or five yards from the brook.

The remarkable outbreak of fever which occurred in North Boston, N. Y., in 1843, described by Dr. Flint, is equally instructive. No cases of typhoid fever had ever been reported in the village until the year named, when a traveller, who had been several days sick, arrived at the inn. The evacuations from the fever-stricken patient were thrown into a cesspit in close proximity to a well which supplied most of the village with water. Over half the community were attacked with fever, and all these persons had used water from the tavern well, daily. These cases show conclusively that the water produced the disease, and though polluted even with excrement, no enteric fever appeared until the specific agent of the disease was present.

The practical lessons of prevention relate to the treatment of the passages of patients sick with infectious disease, and the preservation of the water supply from impurities. It is unquestionably the bounden duty of those having charge of cases suffering from diseases transmitted by means of the alvine discharges, such as typhoid fever, cholera, dysentery, scarlet fever, etc., to see that the dejections are wholly disinfected at their very issue from the body. For this purpose chloride of lime, dissolved in soft water, in the proportion of four ounces to the gallon, or corrosive sublimate dissolved in soft water, in the proportion of two drachms to the gallon, are most efficient agents.

The protection of the water supply from impurities involves an exact knowledge and vigilant supervision of the source, collection, storage, and distribution of the supply. Sewage and all foul matter, especially of the excremental sort, should never be permitted to flow into a stream used for drinking water. In the town of Plymouth the small volume of water and the nearness of the points of infection and of distribution, were conditions favorable to a violent eruption of disease. The water supply of large cities is often similarly polluted, but the great bulk of water, by its dilution and other natural means of purification, has doubtless prevented an occurrence similar to that which has overtaken unhappy Plymouth. Nevertheless, the apparent self-purification of running streams which have been certainly polluted in some part of their course, cannot be depended on as a guarantee that the water is fit for domestic use. Disease germs are very difficult to deprive of their vitality; they may be even frozen and yet preserve their activity. Admitting the presence of disease germs in water, it may be diluted until the chance of taking even a single germ into the system is so small that it may be disregarded; and yet, if the prevailing theory be true, a single germ, if taken, may produce disastrous results.

The whole subject reverts to the one essential condition of cleanliness as the most certain preventive of disease. The complete and inoffensive removal of all refuse matters as fast as produced, and the

rendering innocuous of such matters as are unavoidably detained, are cardinal rules of sanitation. Had the authorities of Plymouth applied these rules, the people of that quiet town would have been spared the harrowing incidents of the past few weeks.

This local outbreak of typhoid fever above alluded to furnishes a fresh illustration of the serious consequences which sooner or later follow after a reckless disregard of the laws of health. What has happened at Plymouth has happened before and will happen again. People become accustomed to these occurrences, and pay little heed to the lessons they teach until the pestilence is at their own doors. Then wisdom is purchased at a terrible cost.

It needs no argument to show that the scourge from which the people of Plymouth are suffering might have been prevented; or that, with proper sanitary administration, either local or general, its progress might have been stayed long before this. For the want of such administration, weeks have elapsed before the true cause of the disease has been satisfactorily determined, and then only by voluntary investigations, prompted by a desire to extend aid to fellow-beings in distress.

No stronger argument need be required for the prompt organization of a State Board of Health than that furnished by the circumstances connected with this outbreak of disease. Had such an organization been in existence, it would have demonstrated its usefulness, by promptly determining the cause of the sickness, and by instituting measures for its speedy removal. It is time that our legislators realized the serious responsibility they incur by ignoring the true wants of the people. The bill for the creation of a State Board of Health should be passed without any further delay, and the people relieved from the reproach which has been cast upon the good name of the Commonwealth by continued inaction.

NITRO-GLYCERINE IN CONTRACTED KIDNEY.

It is well known that hypertrophy of the left ventricle is sooner or later an almost constant symptom of contracted kidney, and in the later stages, at least, of the disease, it becomes, through its powerful impulse, one of the most annoying of symptoms. It is generally conceded that this cardiac complication is the result of the renal affection, although all are not agreed as to the precise method by which it is brought about. It is, also, thought by some that the hypertrophy is compensating in character; that the increased amount of blood forced through the kidney gives rise to increased secretion of urine; and that in this way is made up the required excretion, otherwise impossible by reason of the diminished secreting surface in the contracted organ.

Recently, however, Rossbach, of Jena, in the *Berliner klin. Wochenschr.*, for January 19, has ventured to oppose some objections to the view that the polyuria of interstitial nephritis is due to increased blood pressure and an accelerated circulation through the healthy parts of the kidneys. He bases these objections upon the fact that by means of nitro-glycerine we can reduce the blood pressure to the normal degree, or even below it, notwithstanding which the secretion of urine not only continues increased, but a very annoying set of symptoms, including the uncomfortable palpitation and eye symptoms, and even uræmia, are decidedly relieved. He shows further, by the reports of three cases, that the effect of nitro-glycerine is not only to increase the amount of the twenty-four hours' urine, but also to diminish the percentage and amount of albumen contained therein.

These facts certainly go to show that the polyuria of contracted kidney must be due to some other cause than the cardiac hypertrophy and increased blood pressure. Possibly, as suggested by Rossbach, they may result from an increased permeability of the still sound capillary walls to the blood fluid. That such permeability exists in chronic interstitial nephritis, not only for crystalloid and colloid substances, but also to solid particles, has been shown by Thoma in *Virchow's Archiv*, Bd. 7, 1877.

Be this explained as it may, we look upon the therapeutic value of nitro-glycerine with increased favor under the circumstances. Rossbach recommends that it be prepared for administration in the following way: A given quantity is weighed, dissolved in ether, and this solution well mixed with two parts of chocolate powder, and one of gum-arabic, so that 3086 grains of the mixture will contain 1.5 grain of nitro-glycerine. After the ether has completely evaporated, the resulting powder is mixed with sufficient water to produce a thick paste, which, after hardening completely in suitable forms, is divided into parts containing from 0.0077 to 0.015 grain of the nitro-glycerine, of which the dose is one, ten to fifteen times a day, in hourly doses until the effect is obtained.

Comparative observations by Rossbach upon the use of nitrite of amyl, nitrite of sodium, and nitro-glycerine, all of which have a depressing effect upon blood pressure, have shown that the last is altogether to be preferred. Nitrite of amyl is objectionable, on account of its powerful and uncontrollable action and the short duration of its effect, and the vertigo, headache, tendency to nausea, perspiration, and sense of weakness it induces. In like manner, the nitrite of sodium and potassium produce general discomfort, headache, and nausea. On the other hand, the headache produced by nitro-glycerine rapidly disappears, and after a few days the patient

not only becomes accustomed to it, but is so much relieved that he loses consciousness of the fact that his disease is still present and even progressing, for Rossbach has no facts to show that it is in any way able to arrest the disease, although further observations by careful observers are required before the possibility of such effect can be denied.

A NEW PROCEEDING IN PERINEORRHAPHY.

The January number of the *Revue Medico-Chirurgicale des Maladies des Femmes*, states that Koeberle has recently made known a new method of restoring the perineum completely torn in labor. As the obstacle to reunion proceeds from the distention of the intestine by fecal matter resulting from contraction of the anus, Koeberle obviates the difficulty thus: He freely divides the anus posteriorly, the incision extending beyond the circular fibres, and involving the connective tissue situated behind the rectum. There is thus made a large funnel-shaped opening through which fecal matter can pass freely until cicatrization of the recto-vaginal wall is complete.

By referring to the *American Journal of the Medical Sciences*, for November, 1837, it will be seen that the late Dr. William E. Horner then first proposed division of the anal sphincter on each side, and that, in 1848, he put this proposition in practice in a case of complete laceration of the perineum upon which he operated. This operation is reported in the same journal for October, 1850. It seems to us that Horner's method would attain the object sought by Koeberle's quite as well as that of the latter. At least we see no "new method" in Koeberle's practice, as essentially the same thing was done so many years ago by Horner.

Furthermore, the late Baker Brown, who, notwithstanding his clitoridian craze, which led to his ignominious expulsion from the London Obstetrical Society a few years before his death, will long be remembered as one of the most brilliant operators in the surgical diseases of women, was accustomed to divide the anal sphincter posteriorly subcutaneously. More recently Hegar has strongly advocated two lateral incisions upon the posterior border of the anus.

All these methods, though used in the secondary operation for ruptured perineum, or perineoplasty, as it ought to be called in distinction from perineorrhaphy, which strictly signifies only the use of stitches, had the same object as that now credited to Koeberle.

INOCULATION AGAINST CHOLERA.

From Spain we have accounts of experiments by Dr. Ferrán upon the vaccination of human beings against cholera with a mitigated virus. Without full details, it is difficult to judge of their value. He appears to have followed a further stage of development of the bacillus—a spirillum form which is also referred to by Watson Cheyne in his recent report. In what way the mitigation of the virus is produced is not clearly stated, though time and the action of oxygen are mentioned.

About twenty minims of a culture are injected subcutaneously, and within a few hours the person has a rigor or fever, with constitutional symptoms, which persist for twenty-four hours, and then begin to subside. Subsequent larger injections have no effect.

A Committee of the Royal Academy of Medicine of Barcelona have reported favorably on the experiments; but, whether it will prove a complete safeguard, cannot, in the words of the Committee, be definitely affirmed, without the proof afforded by an epidemic. The British Government has sent a Commission to Spain to examine the results, and its report will be awaited with interest.

GENERAL GRANT.

During the last few weeks General Grant has enjoyed a gratifying relief from most of the distressing symptoms which were so prominent in March and the early part of April. But, unfortunately, it cannot be said that the local affection has shown a corresponding improvement. On the contrary, the area involved by the infiltration and ulceration has increased in size. Part of the uvula is now destroyed, and the remaining portion is greatly thickened. The difficulty in opening the mouth, which has always been a serious obstacle to a thorough examination of the pharynx, is also greater, and there are indications that the overgrowth of tissue in the mouth is enough to create an increasing mechanical obstruction there. The lump in the neck is larger, either by its own growth or by the implication of adjoining glands, and the periglandular swelling is also larger.

The special treatment which has been employed for the last month, and which was undertaken solely on the general principle that it should always be tried in such cases as an aid to diagnosis, was pushed to the point of tolerance, and has now been given up. It has served its purpose in eliminating a possible doubt, and, that end having been attained, and its powerlessness to arrest the progress of the disease having been demonstrated, there no longer exists any reason to continue its use.

Meanwhile, the General has been able to resume work upon his memoirs and practically to complete them. He is comparatively free from pain, sleeps fairly well, and is able to walk abroad almost daily.

SOCIETY PROCEEDINGS.

THE AMERICAN MEDICAL ASSOCIATION.

Thirty-sixth Annual Meeting, held at New Orleans, April 28, 29, 30, and May 1, 1885.

(Specially reported for THE MEDICAL NEWS.)

SECTION ON STATE MEDICINE.

TUESDAY, APRIL 28TH.—FIRST DAY.

THE session was called to order at 3.30 P.M. by DR. E. W. SCHAUFFER, of Kansas City, Mo., Chairman.

In the absence of Dr. J. N. McCormack, of Bowling Green, Ky., Secretary, Dr. F. W. Parham, of New Orleans, was requested to act.

DR. JOHN AVERY, of Greenville, Michigan, read a paper on

STATE AND LOCAL BOARDS OF HEALTH.

The protection of the health and lives of its citizens is the highest duty of the State. The poor man's health is his capital, and the wages of each day's labor is the interest that capital pays to its owner. It is as much the duty of the State to protect that capital and make its owner secure in its possession and enjoyment, as it is for it to protect a railroad corporation in its franchise. All just governments have enacted laws by which they hold a man responsible for an injury done to another man through carelessness or malice, and which disables him from labor. And, also, laws to prevent the unnecessary spread of diseases which endanger the health and the lives of the citizens of the State. The latter are known as the public health laws of the State.

In the twelve years since its organization, the Michigan Board of Health, besides performing the duties required of it by the law, such as publishing and distributing its reports and a large number of monographs on subjects relating to public health; recording the deaths; investigating epidemic diseases, their origin, causation, and prevention; analyzing articles of food and water; visiting various places in the State where nuisances were complained of, and also the various correction and charity houses; examining plans of public buildings, and giving proper advice as to the best methods for their proper heating, lighting, and ventilation; it has also endeavored to awaken a more general interest among the people in sanitary matters.

This it has done by inaugurating and conducting a series of sanitary conventions in the principal cities, towns, and villages of the State. These conventions are aided by a committee of the citizens in the localities in which they are held. Persons interested in sanitary work are invited to read papers; and these, together with the synopsis of the discussions, are published in pamphlet form and distributed gratuitously. These conventions are always fairly attended, and the people are gradually being educated.

The State Board is in direct and frequent communication with every city, village, and township in the State, and acts as a sort of central signal station.

The Local Boards of Health are charged with the duty of administering and enforcing the laws relating to the public health, and they must immediately notify the State Board of the appearance of communicable disease in their localities.

The law confers upon Local Boards of Health authority to make and enforce any regulations necessary to protect the citizens of their respective municipalities against the spread of communicable diseases.

Under the beneficial action of these Local Boards of Health, the people are gradually being educated to the necessity of protecting themselves against communicable diseases, and to demand their complete isolation for the protection of the community. But the people are forgetful and neglectful; and need to be constantly reminded of the sources of danger which threaten health and life. And in no way can these reminders be so generally, authoritatively, and effectively given as through a well-organized and well-conducted State Board of Health.

THE CHAIR asked Dr. Avery if the State Board of Michigan made any provision regarding the practice of medicine in that State.

DR. AVERY replied that the law gave no such authority to the State Board. A bill had been recommended to the Legislature giving the right to the Board to regulate the practice of medicine in the State, but it had failed to pass. There was a law requiring every practitioner in the State to register; but that law gave the privilege to any one who had practised, or who swore he had practised for five years prior to it, to register on the same footing with an educated physician. It was expected that this law would be amended, so as to require all coming into the State after its passage to go before a Board of Examiners before being allowed to register; but the law failed to provide for the Board of Examiners.

DR. RAUCH, of Illinois, said he had found great opposition in his State to any law regulating the practice of medicine. To pass such a law, it is not sufficient to get it before the Legislature: the people must be in accord with the spirit of the law. The legislators would not pass any law that would make them unpopular with the people. The people must first be educated: they must be taught that the provisions of the law are for their benefit, and not for that of physicians.

WEDNESDAY, APRIL 29TH.—SECOND DAY.

Dr. Nelson read an abstract of the paper of DR. FRANK S. BILLINGS, of Boston, on

STATE MEDICINE.

Practical experience has taught monarchial governments that "public health is public wealth," and that there must be a Department of State Medicine. No government is true to its duties that does not support State Medicine. Owing to the geographical relations of the United States, public health is not here to the same extent as in Germany and other European States, a national necessity. But, to gain public wealth, public health is with us a national necessity. As no organ or region of our body may become diseased without causing the whole to suffer, so no part of a country may be ravaged by an epidemic without causing injury to the whole nation. It is the duty of every government to study the needs of the people,—to encourage and support research,—so that the resources of the country may

be fully developed, and that the people may be so protected that they may pursue their daily avocations in safety. They should not wait until public excitement makes them act.

All true governments must be parental, whatever their constitutional form may be. In our own country, the first difficulty is to know what we shall do with our medical school system. There are too many medical schools. We should, in the future, try to improve the quality and not the quantity of graduates. The profession is not united enough to admit of examining boards, elected by the profession and authorized by the government. There must be concerted action on the part of every true physician in the United States. The medical schools should be made to conform as far as possible to a uniform plan of instruction. A legal stop should be put to the endowing or incorporating of any more schools in States where one endowed school already exists. The aim should be to have in each State only one endowed school, which should be made scientific by State force. We should do our best to strengthen our best endowed school in our respective States. It is better policy to reform such a school than to weaken it by starting a weaker opposition school.

Where the schools are State schools the Faculty should be the examiners. Under existing circumstances it would better rest in the State Boards of Health, which should consist of specialists upon hygiene, a hygienic engineer, and a competent jurist. The board of health should then be the examining, diploma-granting, and licensing-to-practise body of the State, and the schools must govern themselves accordingly. No man should practise without the diploma or license of this board.

The medical service of the country should form one comprehensive public health organization. It should begin with a national board of health in Washington city, and a State board in each State. There should be a local board in each city and large town. Each county should have its chief health officer, and each district in each county an official representing preventive medicine. All should be appointed and paid by the State.

Dr. Hibberd, of Indiana, said that boards of health are of political creation, and are not competent to judge of the qualifications of medical men. A competent board, composed of men selected for their fitness, should constitute the board of examiners, who should examine into the qualifications of every individual desiring to practise medicine. He thought the investigation should determine competency in the elementary branches of medicine only.

Dr. Dabney, of Virginia, thought that boards of examiners should confine themselves to an investigation concerning the elementary branches of medicine only.

Dr. Hamilton, of the Marine-Hospital Service, said that the influence and aid of paternal governments in encouraging original investigation had been much exaggerated. Pasteur, Claude Bernard, Koch, and others, famous now as original investigators, were only taken up and assisted by governments after they had accomplished valuable original work. Our Government has itself done much to foster and encourage original research, as witness the National Museum, the Navy Museum, and the Army Medical Museum, in all of which the labors of numbers of men, enthusiastic in pursuit of original investigation, are represented.

Dr. J. B. Roberts, of Philadelphia, thought the duties of examining boards should properly include two considerations: 1st, inspection of the diploma; and 2d, the examination of the candidate before granting a license to practise. He offered the following resolutions:

Resolved, That the Section on State Medicine earnestly advocates the establishment in every State and Territory of boards of medical examiners and licensers, whose certificate shall be the only license permitting practice of medicine in said commonwealths, though an applicant for license shall previously be obliged to obtain a medical diploma from a recognized medical school.

Resolved, That the Section on State Medicine requests the American Medical Association to direct its permanent Secretary to transmit a copy of the annexed draft of a bill to the secretary of each and every State medical society, requesting that each State society discuss said bill, and report at the next meeting of this Association its views on the desirability of advocating such a bill.

Dr. N. S. Davis said that in 1844 he had endeavored to have established a preliminary qualification and to require that three full years should be devoted to the study of medicine. He thought the main thing to do was to get the diploma out of the way. This out of the way, the question would be one of competency, and students would not seek a medical college as a place where the right to practise could be acquired at an insignificant cost and in the shortest possible time, but because there they could make themselves *competent* to practise medicine. He thought there were certain fundamental principles belonging to our institutions, and we could not model our plans after those of foreign countries. The only interference of governments in educational matters should be the establishment of schools where children should be taught to read, write, and spell. Any taxation to accomplish more than this would be unjust. As to boards of health, the same principle should apply. A board might ordain that no man should maintain any nuisance to the detriment of his neighbor, but more than this it could not justly do with a due regard for private rights. When you say that the government should support schools for the pursuit of laboratory investigation, you have gone too far. This would be taxing one man for the benefit of another, and would be wrong. It was all well, and very laudable for schools like Harvard and rich individuals to do these things, for thereby no man would be taxed. He had come long ago to the conclusion that the first thing to do was to get rid of the diploma. Medical colleges would then attempt to get students not by underbidding other schools and reducing its requirements to the capacity of the greatest number, but would depend for its patronage upon its reputation as a place of instruction and its instructors would be selected by reason of their ascertained fitness as instructors.

As to boards of examiners, he heartily approved of them, but thought that their investigation into the qualifications of applicants should concern only the elementary branches of medicine as referred to by previous speakers. Moreover, he thought legislation for or against any system or school of medicine entirely wrong, and he had always been opposed to it. The aim of such a board should be simply to ascertain the

existence of a thorough education in the fundamental branches of medicine.

Dr. Armstrong, of the Marine-Hospital Service, moved as an amendment to Dr. Roberts's resolution that the clause requiring a diploma be stricken out.

The amendment was accepted, and the resolutions as amended were adopted.

The Secretary was instructed to present the resolutions in general session, and they were adopted by the Association on May 1st.

Section on Diseases of Children.

Tuesday, April 28th.—First Day.

The Section was called to order by Dr. J. N. Pope, of Texas, Chairman.

Dr. H. R. Kelly, of Galion, Ohio, read a paper on

the treatment of diphtheria in children.

He said there had occurred five or six epidemics in his community in the last thirty years, and cases every year for the last seven. He recognizes two principal types, the "anæmic," and the "inflammatory."

In the anæmic we find a weak thready pulse, low fever, a feeling of lassitude, little headache, little or no swelling of the glands, the throat looks anæmic, the membranes seem depressed, the edges lower than the surrounding tissues.

In favorable cases the disease lasts from two to three weeks. Croup is more frequent in this variety. When epidemic it causes more or less paralysis. When fatal, patients die generally from heart failure.

In the inflammatory variety the attack begins with a chill, high fever, anorexia, and full and strong pulse. The patient complains of severe headache and earache, the throat glands become enlarged and painful, the face and eyes are congested, and there is more or less delirium. The throat has almost an erysipelatous appearance. The membrane is bright yellow with edges elevated above the surrounding parts. The course is rapid. The nose is generally implicated, and alarming epistaxis may occur. Croup is not likely to appear. The sloughing in these cases is sometimes extensive.

Out of over one hundred cases, paralysis was present in twenty-two, outside of the muscles of deglutition, which were paralyzed in nearly every instance. Only two deaths occurred. The treatment in the two forms is different. In the anæmic, alcohol from the start, quinia if necessary, tincture of iron in full doses frequently repeated. Locally he used, either as a spray or gargle, the following, which has proved most satisfactory:

R.—Acid. carbolic. . . . . ℥ss.
Acid. salicylic. . . . āā℥ss.
Borax . . . . . ℥iss.
Glycerine and water . āā q.s. ad. ℥iv.—M.

Sig.—Every two hours alternating with a drachm of a solution of chlorate of potash.

In the inflammatory variety, arterial sedatives at first, then alcohol freely administered, quinia if necessary. Locally, a spray of:

R.—Tincture of iron . . . . ℥ij.
Chlorate of potash . . . . ℥j.
Glycerine . . . . . ℥ij.
Water . . . . . ℥j.—M.

Sig.—Use every hour. If the membrane becomes fetid, add a few drops of carbolic acid.

Especial attention should be paid to diet. Children should be made to drink as much milk as possible; three quarts a day are not too much.

The treatment of the paralysis is strychnia, quinine, iron, electricity, and good, rich food.

Dr. Ulrich, of Pennsylvania, said that his experience would lead him to condemn the treatment. In his own practice he had abandoned the use of local applications. He had seen death produced by an attempt to make an application to the throat. Had first met with the disease in 1860; after a number of disastrous cases, he had scored a number of successes, with the use of large quantities of chlorate of potash. He has not materially changed his treatment since, though he has had an extensive experience. He gives now as much chlorate of potash as the patient will bear, also tincture of iron and plenty of nourishment. He lets the paralysis alone, as it gets well of its own accord. When children in the same family have the slightest sore throat, he puts them immediately on the chlorate of potash treatment.

Dr. Williams, of Michigan, said that he had met with a large number of cases of diphtheria during the four years previous to 1882 as city physician in his city. The variety he has encountered most frequently begins with high temperatures. He gives large doses of quinine, tincture of iron (one drop for every year) every hour, and uses chlorate of potash as a gargle, with instruction to swallow a portion at each gargling. Gives as much nourishment as possible, and stimulants in large quantities. Applies locally tincture of iron after first wiping off the adhering mucus. He has seen the pain in swallowing much relieved by these applications. He does not consider the use of the spray practicable. In four years he lost only one of the city cases.

Dr. White, of Texas, stated that he had seen a child with well-marked exudation get well by giving it Epsom salts, and applying locally flowers of sulphur.

Dr. Ulrich, in addition to his former remarks, said that the worst cases commence with swelling of the muscles of the neck; generally no membrane can be seen from the mouth, but the nose is always involved; they do not commence with very high temperature.

Dr. Pope, of Texas, had seen patches in the throat, with fever, from errors in digestion. He would consider paralysis as proving the disease to have been diphtheria. He mentioned the fact as a matter of curiosity, that diphtheria did not appear in Mexico prior to the coming of the Emperor Maximilian.

Dr. Kelly, in closing the discussion, said that a great deal depends on how the local application is made. He did not believe in swabbing out the fauces with a sponge attached to a probang. He had found no trouble in using the spray. He had never had as great success in treatment as during the last year, and had never used the spray before. He had seen patients choke to death with the diphtheritic membrane. It has not been his experience that paralysis gets well without treatment.

Wednesday, April 29th.—Second Day.

Dr. R. J. Nunn, of Savannah, Ga., reported some

successful results of a new treatment of diphtheria.

He first referred to an article he had written on the efficiency of peroxide of hydrogen in removing diph-

theritic deposits, and then reported a case which died seventeen days after the successful removal of the membranes by that drug. From this he became convinced that the antiseptic treatment was necessary to combat successfully the destruction of the diphtheritic poison. From the table of Dr. S. Miguel, biniodide of mercury is found to be the most powerful germicide, being three times as powerful as the bichloride. A large quantity of the drug is not necessary. In the cultivation of the "aspergillus niger" 1 part in 1,600,000 of nitrate of silver added to the nutrient fluid stops the growth of the plant. Following these indications, a solution of 1 grain of biniodide of mercury to 4 ounces of a solution containing iodide of potassium is made, and 5 or 6 drops of this given every ten or fifteen minutes. If the membrane is thick, it is first acted upon by papayotin, to prepare it for the action of the peroxide of hydrogen, which is then faciltated very much. Papayotin is used in preference to pepsin, pancreatin, etc., because it acts equally well in acids as in alkaline solutions. To sum up the treatment, we have first, the frequent application, by spray or brush, of the peroxide of hydrogen. Then the parts are cleaned and papayotin blown on them, if they seem to need it; and thirdly, the binoxide is given in the doses above mentioned. A very small quantity of the drug is given, and it can be kept up for long periods without injury to the patient. He said nothing of stimulants and nourishment, but he gives them in large quantities. He also gives syrup of the iodide of iron when there is evident depravity of the blood. The iodide of potassium being highly diffusible, and possessing some antiseptic properties, as was evidenced by his having kept the urine of patients taking this remedy for months without the occurrence of decomposition, acts both as a germicide and vehicle. For this reason the strength of the solution of iodide should be as great as the comfort of the patient will permit.

The use of small doses frequently repeated is to insure a constant flow of the germicide through the system. Out of 14 cases treated last winter, there were 3 deaths, and these 3 cases were the only ones treated without the biniodide of mercury. In the first case the peroxide of hydrogen was used alone; in the second the treatment, as advanced in this paper, was used, except that the bichloride was prescribed instead of the biniodide; and in the third, which had been treated with chlorate of potash and tincture of iron, before being called into consultation, the peroxide of hydrogen and pepsin were used locally.

Dr. Nunn then gave the history of several successful cases illustrating his treatment. In none of these cases though some were severe, were there any sequelæ. In one family he had been able to trace the origin of the disease to defective plumbing. Great stress must be laid upon the kind of mercurial treatment. The biniodide given in the manner described above, was much more efficacious than any other he had tried. This treatment was not offered as a specific, but simply as having been successful in the case mentioned, and, granting the germ theory in this disease, theoretically sound.

To summarize the treatment, it included: 1st. A blood antiseptic, which is also 2d. A local germicide. 3d. A softening agent or digester of the membrane, and 4th. A solvent of the membrane.

Dr. Walter, of Little Rock, Arkansas, said the profession in his section had tried the biniodide of mercury, but had laid it aside. He had had very poor results from his treatment at first; later, with the use of tincture of iron and chlorate of potash and vaporized water, he had been more successful. He favored the expectant treatment, the main reliance being placed on stimulants and feeding.

Dr. J. Weichselbaum, of Savannah, had used the same treatment as Dr. Nunn with great success.

Dr. Catlin, of Wisconsin, had used nearly all the remedies recommended for diphtheria except the present. Had had a great deal of experience. In one epidemic in his section of the country, there were some 500 or 600 cases in a total population of about 7000. Sometimes he never lost a case, at others he was not so successful. Epidemics varied very much in virulence. He commenced his treatment, generally, with a heavy dose of quinine, sometimes twenty grains. He followed this with a saturated solution of chlorate of potash and with tincture of iron. He depended largely upon stimulants and nourishment. He thought at one time he could always cure diphtheria. He was disabused of this, by losing 11 out of 14 cases in the same family.

In another epidemic he lost 8 cases out of about 150. His method of using chlorate of potash solution is to gargle and swallow a drachm afterwards. He had tried the bichloride without marked results.

Dr. Nance, of Illinois, had never seen a case recover after the voice had been suppressed. He asked Dr. Nunn how the peroxide of hydrogen acted.

Dr. Upham, of Vermont, had seen a great deal of diphtheria since 1860. His experience with the disease had been sad, and he has no treatment he can unhesitatingly recommend. He has seen the most violent case suddenly take a turn for the better and recover. On the other hand, he has seen mild cases, apparently convalescent, drop down dead. He does not think too much alcohol can be given. He has seen a child take a pint and a half of whiskey in a day with good results. He treats this case as he would any other case of blood poisoning.

Dr. Holliday, of New Orleans, thought the disease milder, as a rule, than formerly. Many cases lead to the belief that the disease is local; others conclusively disprove this. If the diphtheria can localize, the patient is apt to recover, with plenty of nourishment and stimulants. If it does not have that tendency, the symptoms of blood poisoning are severe and the progress to a fatal end generally rapid. He has seen cases recover after loss of voice had occurred, but this was, he thought, only when the aphonia was due to slight œdema of the larynx from its proximity to the inflamed surfaces. When the membranes invaded the larynx and trachea, he did not think there was any hope of recovery.

Dr. Nunn, in conclusion, said that the peroxide of hydrogen acted as a solvent and disinfectant to the membranes. It was a harmless remedy and could be given to the parents to use *ad libitum*. He laid special stress on his method of using the biniodide in combination with iodide of potassium.

DR. L. DUNCAN BULKLEY, of New York, then read a paper on

REPEATED DOSES OF CASTOR OIL ESPECIALLY IN CERTAIN SKIN DISEASES IN CHILDREN.

He said that, though castor oil was a very old remedy, it had only been given in large single doses from time to time, or in very small doses continuously in emulsion for the relief of diarrhœa and dysentery. He thought he was the first to give it in doses of some size, daily, for any considerable period. The cases described in illustration of the treatment, had all been treated successfully with other remedies, and showed relapses when the treatment was left off too soon or through some negligence of the patient, and it was noted also that tonics and other remedies, which before had disagreed or proved inefficacious, became useful adjuvants to the treatment. Most of the cases were accompanied by torpor of the bowels and accumulation of feces in the colon, but some were benefited even when this was not the case. The doses were regulated so as not to produce purging.

The first case, one of chronic urticaria, in a child of six years, was given castor oil in teaspoonful doses once a day for one month, and for shorter periods on three other occasions. This, together with adjuvants of quinine, tonics, and lactopeptine, accomplished a cure, the disease having been exceedingly rebellious to remedies before. In a number of cases of infantile eczema the same treatment was used with great benefit, in one of these cases an accompanying ulcer of the cornea, which had resisted treatment in the hands of oculists, yielded in a remarkable manner.

Dr. Bulkley next reported a case of acne simplex and rosacea of several years' standing, complicated with ulceration of the cornea. The treatment was suggested by the success above recorded. The patient was twenty-six years old and took continuously two to four teaspoonfuls for something over a month, with great improvement. The treatment was continued sometime longer with the addition of tonics, with the happiest results. The next case, one of tonsillitis recurring monthly, was also successfully treated in the same manner. The treatment lasted six months.

These cases, together with a number of others, prove that castor oil in suitable doses may be taken with advantage, repeatedly, for a considerable period of time. The oil acts as a stimulant to the abdominal organs, the apparently tonic action being due largely to the improved absorption and assimilation. Many cases of urticaria and tonsillitis are due to reflex irritation from the intestinal tract, and are thus benefited by the oil. As to the administration of the oil, if a good quality is obtained and a lump of ice is held in the mouth before taking a dose, then wipe the mouth thoroughly so as to remove any oil that sticks to it, and finally take a drink of ice water. Thus administered, it is not a bad dose to take. The oil should not be mixed with coffee, whiskey, or anything else. Children often become fond of it. In conclusion, castor oil is not offered as a panacea for all evils; a great deal of the success in the cases mentioned was due to the medicine given with it. On the other hand, in certain conditions no remedy has been found to equal it.

MEDICAL ASSOCIATION OF MISSOURI.

Twenty eighth Annual Meeting, held at St. Joseph, May 12, 13, and 14, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE PRESIDENT, DR. H. H. MIDDLEKAMP, not having arrived, the Association was called to order by VICE-PRESIDENT W. E. EVANS, of Booneville. An address of welcome was delivered by Mayor Hartwig, and Dr. J. W. Heddens, in behalf of the local profession, tendered to the visitors an invitation to visit the various places of interest about the city. At the request of Dr. Evans, an appropriate response was made by Dr. Trader, of Sedalia.

On motion of Dr. Trader, it was resolved that a committee be appointed to prepare a memorial of the late Dr. P. V. Schenck.

The Association then adjourned until 2 P.M. At that hour Dr. Middlekamp took the Chair.

DR. J. W. TRADER, of Sedalia, presented a paper on

CHLOERA.

Having made up his mind that hypodermic administration promised the best therapeutic results, he had prepared himself before the last cholera season with solutions of quinine, morphia, and atropia. He also had a glycerole of chloroform, and a glycerole of carbolic acid. He was called on to treat an elderly woman whose symptoms were so severe that he thought there was no hope of saving her life. He thought he would relieve her distress somewhat, and gave her a teaspoonful from one of his bottles. Soon she demanded to be told what he had given her, as she was sure that she was dying from the effects of it. On looking a second time he saw that he had given the glycerole of carbolic acid instead of the glycerole of chloroform as he intended. In a short time the woman became somewhat easier. The doctor left her, expecting nothing but death, but the next day he found her up and about, and apparently as well as ever. Since that time he had commonly made use of a mixture of the two glyceroles referred to with mint water in the treatment of cholera from diarrhœa.

In the discussion which followed, quite a number of members took part. All seemed to think well of hypodermic medication in this disease, but there was a difference of opinion to the value, prophylactic and curative, of germicide remedies.

DR. STRINGFELLOW, who saw much of the disease in 1849, then formed the opinion that large doses of calomel constituted the best treatment. Now he would favor the use of small doses of the bichloride as a prophylactic. He thought much was to be hoped for from prophylactic treatment.

DR. FISCHEL called attention to the utterly unsettled state of the views of the advocates of the germ theory so far as it related to cholera, and called attention to the successful inoculations lately made in Spain. He also referred to the use of atropia by the late Dr. John. T. Hodgen in the collapse of cholera, as a means of tiding over the period of danger and giving the patient a further chance of life.

DR. PREWITT called attention to the fact that death does not usually occur in the course of the vomiting,

but after collapse, and that any remedy which will ward off collapse will be valuable in treating this disease. Collapse he compared to the shock following serious injuries, a vaso-motor paralysis. In his opinion, the hypodermic injection of morphia at an early stage gave most promise of successful results.

Dr. Todd, of Kansas City, gave a brief exposition of his proposed treatment of cholera by the subcutaneous injections of large quantities of bland fluid which he calls artificial serum, and the administration of hot drinks in abundance, acidulated with sulphuric acid. No cold drinks are to be allowed.

Dr. Trader closed the discussion with the remark that he was disposed to attribute the successful result in his case to the anæsthetic effect of the carbolic acid rather than to any germicide action.

Dr. J. C. Mulhall, of St. Louis, then read a paper on

ATROPHIC NASAL CATARRH,

or, as he preferred to call it, atrophic rhinitis. He claims that this disease is not a sequence of hypertrophic rhinitis, and does not believe that it is the consequence of severe colds in the head. He considers it to be of neurotic origin. A coryza in a child is not likely to become fetid unless there be a strumous condition. He defines struma as a condition of impaired vitality produced by some depreciated state of health in one or both parents when the child is begotten.

A coryza in an otherwise healthy child is readily contracted and speedily recovered from. The fetid coryza of atrophic rhinitis has no tendency to spontaneous recovery, and is not susceptible of cure. The treatment is only palliative, and consists in securing scrupulous cleanliness and constitutional tonic medication. He instructs the patient as to the use of the douche anteriorly and posteriorly.

Dr. T. F. Rumbold, of St. Louis, took issue with several of Dr. Mulhall's statements. He claimed that atrophic rhinitis is *always* a sequel of the hypertrophic form of disease. He also asserted that the adjacent cavities are almost always involved, and that the crusts and discharges in the nasal passages are almost always derived from these other cavities. If these cavities can be reached with treatment, the disease can be cured.

Dr. Mulhall said that the post-mortem researches of Zuckerkandel showed that the adjacent cavities are not involved in this form of disease.

Dr. C. H. Hughes, of St. Louis, Chairman of Committee on Psychological Medicine, then read a paper on

SOME NEGLECTED PRECURSORY SYMPTOMS OF CEREBRAL DISEASE,

noting various forms of altered nervous action, including the various forms of causeless fear.

Evening Session.

Dr. J. H. Thompson, presented the

REPORT OF THE COMMITTEE ON OPHTHALMOLOGY.

The special evidences of advance which he presented were facts concerning the use of jequirity and cocaine, and the treatment of glaucoma by the stretching of the infratrochlear nerve. He also noted with growing favor a tendency to discard large probes and cutting instruments, and the use of small probes in treating stricture of the lachrymal duct.

Dr. F. J. Lutz, of St. Louis, then read a paper concerning

DISEASES AND TREATMENT OF CICATRICES.

He related two cases, one of them being a case in which epitheliomatous degeneration of the cicatrix produced by a compound fracture of the tibia, had necessitated amputation of the leg. He exhibited the bone specimen. The other case was one in which he had operated for the relief of the deformity produced by an extensive burn involving a large part of the trunk, the upper half of the arm being bound down to the side of the thorax by the contraction of the cicatricial tissue. The result of the operation, as shown by the photographs presented, was a most satisfactory one.

Dr. T. F. Prewitt, of St. Louis, stated that he had seen a number of cases in which epitheliomatous or sarcomatous degeneration had taken place in cicatricial tissues or in ulcers. He also spoke of the indebtedness of the profession to Dr. Post, of New York, for his teachings regarding the treatment of burn cicatrices, especially those causing deformity of the hands. He also related cases where he had relieved deformity of the face caused by cicatrices following wounds by means of subcutaneous incision, elevating the depressed point and bringing the cut surfaces into apposition by deep sutures.

Dr. George Halley, of Kansas City, called attention to the more favorable prognosis in cases of epitheliomatous degeneration developing in cicatricial tissue over that developed in what would appear to be normal tissue.

Several speakers advocated early removal of epitheliomatous or scirrhous growths.

Dr. J. W. Jackson, of Sedalia, stated that he has operated a number of times for scirrhous mammæ, and in every case the growth has returned. He did not state at what stage of development the operation was made.

Dr. J. P. Kingsley, of St. Louis, then read a paper on

MALARIA IN CHILDREN,

basing his account upon personal observation of several hundred cases observed in dispensary and private practice. He had seen the disease in infants of only a few days; thinks the child may be affected by the milk nursed from a mother who is suffering from malarial poisoning. The diagnosis is often difficult in children; chill is slightly pronounced, sweating stage absent, cachexia develops early, enlargement of spleen is frequent. Sometimes there are irregular nervous symptoms. Quinine in doses of two or three grains three times a day, or to a child five years old five drops of Fowler's solution of arsenic three times a day, should be given. Where these are not well tolerated, he sometimes gives with advantage tincture of iodine and carbolic acid, and in some cases uses the cold wet pack.

Dr. Nelson, of St. Louis, related the case of a child, two years old, with a spleen enlarged to such a degree as to extend from the border of the ribs to the crest of the ileum. Under the use of cinchonidia this was reduced to about normal dimensions in the course of ten days. He had used inunctions of quinine in fresh lard with good results in patients not over one year of age.

Dr. F. M. Johnson, of Kansas City, did not credit the belief that little children do not have the chill. He thinks it does exist, but the child cannot describe his sensations.

Dr. Stringfellow was doubtful whether the little ones have malaria at all. He discarded quinine in treating infantile "malaria" some time ago, and now gives only small doses of calomel with most satisfactory results.

Dr. Simmons thought that in cities and thickly settled country districts the chill is much less distinctly pronounced than in open country locations.

Dr. Fischel, of St. Louis, thought that a majority of the cases of fever in infancy which are usually regarded as malarial, and are treated with quinine, do far better under the use of small doses of calomel without any quinine.

Wednesday, May 13th.—Second Day.

After the usual routine business, a committee was appointed to nominate officers for the ensuing year.

Dr. Catlett, of St. Joseph, read a paper on

the asylum treatment of the insane.

Dr. Griffith, of Kansas City, then brought before the Society a lad of about fourteen years of age, who had suffered from

deformity as the result of morbus coxarius

since two years old. The thigh was flexed upon the abdomen and ankylosed, and the leg was flexed upon the thigh. Dr. Griffith had made a subcutaneous division of the thigh between the head and trochanter major, and after division of the hamstring tendons had straightened the limb and applied a plaster-of-Paris dressing. The result had been most satisfactory, the boy being able to walk about the room with only a cane, though generally using a crutch as well. A considerable amount of motion of the artificial joint was found.

Dr. H. H. Middlekamp, of Warrenton, then delivered

the presidential address.

He urged the importance of higher medical education, favored compulsory three-term schools, emphasized the responsibility of the general practitioner as a preceptor, recommended a State board of medical examiners, advocated the establishment of a medical library by the State Medical Association, and recommended the formation of a number of new standing committees.

A special committee of five was appointed to consider and report concerning these recommendations.

Dr. Hanna then presented a report on behalf of the Committee on *Diseases of Children*, after which the Special Committee presented a fitting tribute to the memory of Dr. P. V. Schenck, which was adopted by a standing vote.

Dr. B. F. Wilson, of Salisbury, read a paper on

typhoid fever.

He objects to direct antipyretic treatment, believing that the evolution of the increased amount of heat is a necessary part of the disease, and that attempts to prevent it are futile and tend to prolong the disease. In some cases he gives calomel in the commencement of the disease. If there is a very marked variation in the temperature, he gives quinine, but the agents on which he specially depends are opium and alcohol.

Dr. J. M. Allen, of Liberty, believed that the indications are to keep down the temperature, and "obviate the tendency to death." He thought the universally present tendency to cardiac failure should be met by the early and continued use of digitalis. He did not favor the use of large doses of quinine in these cases, but did advocate cold packing or a partial pack.

Dr. G. M. Dewey, of Keytesville, urged a milk diet and little or no medicine.

Dr. Records had tried the treatment with large doses of quinine, and thought the course of the disease had been prolonged thereby. He had come to rely almost entirely on a mlik diet.

Dr. O. D. Fitzgerald, of Lathrop, had read the article on Typhoid Fever in Ziemssen's *Encyclopædia of Medicine*. In accordance with the views there advanced he had given large doses of quinine to typhoid fever patients. He was convinced that the quinine lowered the temperature of these patients, but the trouble was that "some of them stayed cool." He was satisfied that fatal results in some cases were referable to the medication. He was a strong advocate of "the cooling bath," putting the patient into a bath at a temperature of 100° F., and allowing it to cool down of itself for twenty minutes or half an hour. He opposed the use of opium, but used milk freely, peptonizing it if necessary; and thought digitalis dangerous to continue any length of time.

Dr. Hanna advocated alcohol early in the disease.

Dr. Stringfellow urged the administration of salicylic acid.

Dr. B. F. Hart, of Brownsville, from the Committee on

collective investigation of disease,

presented a report giving the results of an investagation with regard to pneumonia. This called out a very animated discussion in which a number of members participated.

Dr. Nelson, of St. Louis, after a few remarks, offered a resolution that the Committee on State Medicine be requested to consider the urgent necessity of the establishment of an institution for the

care and education of idiotic or feeble-minded children,

and the importance of the establishment of a central institution for the reception of the chronic and incurable insane, in order to relieve the pressure of overcrowding in the other institutions, and allow more systematic classification and more effective treatment. The resolution was adopted.

Dr. A. J. Steele, of the Subcommittee on

orthopædic surgery,

then read a report in which he presented his views with regard to the treatment of clubfoot and some other deformities, and exhibited some appliances which he has found serviceable in treating such cases.

Dr. Funkhouser, of St. Louis, then read a paper on

"the determination of sex."

He related the result of a large number of experi-

ments which he has performed on dogs, rabbits, and domestic fowls, all tending to demonstrate the truth of the view which he holds, viz., that the sex is dependent chiefly upon the testicles, and is little controlled by the ovary. He holds that an ovum impregnated with sperm from the right testicle will produce a male, one impregnated with sperm from the left testicle will produce a female.

Several members took part in the discussion, and several cases were related which would seem to oppose Dr. Funkhouser's theory.

PLACE OF NEXT MEETING.

On motion of Dr. A. J. Steele, it was voted to convene in St. Louis, at 10 A. M. of the Monday preceding the first day of meeting of the American Medical Association.

Dr. Brookes, of Carthage, then read an interesting paper in which he related his own extensive experience in the *Treatment of Injuries of the Larger Joints.*

The Association then went into an

ELECTION FOR PRESIDENT,

and after several ballots, Dr. G. C. Catlett, of St. Joseph, was declared elected, and the vote was immediately "made unanimous." This election will be eminently satisfactory to the profession throughout the State.

The Society then adjourned to the Pacific House, where

A BANQUET

was prepared, the members of the Association being entertained by the local profession and prominent citizens of St. Joseph.

Thursday, May 14th.—Third Day.

At the closing session, the Governor of the State was present and made a short complimentary address.

A report on the *Progress of Surgery*, by Dr. W. F. Walker, of Mexico, a paper on *Ovariotomy*, by Dr. J. U. Heddens, and a report on *Progress in Gynecology*, were read by title.

Dr. D. H. Shields, of Hannibal, of the Committee on State Medicine, made a verbal report as to

THE STATUS OF MEDICAL LEGISLATION

in the State, reviewing the action taken in regard to the State Board of Health, and explaining that the failure of the legislature to appropriate any fund for the Board was due to strong prejudice against the personnel of the Board as then constituted. He offered a resolution endorsing the law establishing a Board of Health, and urging the Governor to appoint representative men upon the Board.

THE REPORT OF THE COMMITTEE ON NOMINATIONS

was then presented and adopted.

Vice-President.—Dr. C. A. Todd, of St. Louis.

Recording Secretaries.—Drs. J. H. Thompson, of Kansas City, and J. C. Mulhall, of St. Louis.

Corresponding Secretary.—Dr. F. J. Lutz, of St. Louis.

Treasurer.—Dr. C. A. Thompson, of Jefferson City.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Eighty-seventh Annual Meeting, held at Baltimore, May 12, 13, and 14, 1885.

(Specially reported for The Medical News.)

Wednesday, May 13th.—Second Day.

The President introduced Mrs. E. P. W. Packard, of Chicago, who, on motion, was allowed to address the meeting on the importance of the passage of

LAWS REGULATING THE TREATMENT OF THE INSANE.

Laws, similar to the one she advocated, exist in nineteen different States. The condition of the insane in our asylums is such that it becomes us, as humanitarians and philanthropists, to pay attention to it. We live in a republic; but the inmate of an insane asylum lives under an autocracy as much as if he were ruled by the Czar of Russia. The superintendent has absolute control over him; and however good the superintendents may be, the mere possession of such a power is dangerous, as it is so liable to abuse. Some persons who may be the victims of the jealousy, revenge, or of greed of others, may be incarcerated in the institutions established for the insane, and when there they are removed from the protection of the laws. This should not be so. These institutions being in a republic, should partake of the spirit of a republic and not resemble the Bastile. The inmates should be allowed, as citizens of the United States, their post office rights. At present there is a censorship over all letters written by the patients to their friends, or letters received by the patient. This is radically wrong. A sane person may be unable to communicate with the outside world, and so have no redress.

The law Mrs. Packard is urging, allows each inmate to choose one individual to whom he or she may write once a week without censorship. Mrs. Packard had visited Washington and obtained from the government assent to her proposition to allow a United States Post Office box to be placed in all asylums, public or private, in those States where this law was adopted. The patient is to choose the individual to whom these letters, that are exempt from inspection, shall be addressed; and the individual so chosen may be changed every three months. The reply of the individual is sacred from inspection. The envelope must have the name of the person sending it upon it so as to insure safety. These provisions are very simple, yet it allows just that means of communication with the outside world that is needed. Where censorship is practised over all letters, it is impossible for sane people, unjustly detained, to make their state known, or for persons who have been maltreated to complain. No letter of complaint will be allowed to go from the walls, nor will patients be discharged till their bruises have been healed. Such absolute power should not be in the hands of one man.

In Illinois, the first day after the law was in force, it was found that about one hundred persons were being wrongly imprisoned. In Maine there were between fifty and sixty in the same condition. This result was very startling, yet it showed how necessary this law is.

On motion, Mrs. Packard's suggestions were referred to a committee already appointed on the subject of

the insane, and a vote of thanks was passed for the address.

DR. ROBERT W. JOHNSON, from the Section on Surgery, read a paper on the

RECENT ADVANCES IN SURGERY.

He said that he would only treat of *some* of the advances made in this department, for the desire of the fame of new operations or procedures is so great among surgeons that the attempt to describe any considerable proportion of them would be impossible. He first referred to the local anæsthetic properties of the solution of muriate of cocaine, which is one of the most brilliant discoveries of the year. Not so much can be said of the new method of administering ether by means of the rectum. It is a method seldom required, and does not compare in ease and comfort to the inhaler. Chloroform has had its victims this year, yet in spite of this there are surgeons who still use it, though their own patients have died under its use. He expressed the opinion that any surgeon who henceforth uses chloroform, except in cases of obstetrics or where ether is not available, should be held responsible.

Passing on to the subject of surgical dressings, he spoke of the lessening popularity of the Lister spray, and of the still intense battle that is being waged between the advocates of various methods of dressing, there being but one point of unity and that being cleanliness. Hydrophobia is a disease that appears to be about to yield up its "baneful ghost" to science, owing to the experiments of Pasteur. The reporter thought that another decade might perhaps witness the bringing under control of zymotic diseases either by means of attenuated virus or by some germicide.

He then alluded to the operation of Godlee on a cerebral tumor, and spoke of the advance that had been made in our knowledge of the intracranial cavity. He concluded by reference to the operations on the thorax and abdomen. In the former, the aspirator is the most popular instrument. Resection for gangrene and drainage of tuberculous cavities has not met with promising success.

He advocated the use of disinfecting spray in all cases of laparotomy, on the ground that these were performed as a rule in general hospitals, where students and assistants have access, late from the dissecting-room or equally contagious surgical cases. Where the spray has been used, even where no restrictions have been put upon the attendants, the results have been most successful.

He passed in review Tait's operation of stone in the gall-duct, and the new operations for the permanent cure of hernia, which have yielded brilliant results, and closed with referring to the operation in this city for resection of the pylorus by Prof. R. Winslow, which ended fatally and the successful removal of a renal calculus, weighing 556 grains, by Prof. Tiffany.

DR. JNO. MORRIS, Chairman of Section on Obstetrics and Gynecology, reported on

GYNECOLOGY

under various heads.

Constitutional Treatment. There seems to be a turn in the tide in regard to this question. He referred to Drs. Albutt and Potter, who have but voiced the growing sentiment of the profession in regard to the immense amount of local surgical and medical treatment of the womb. Nervous disorders are more common in women than in men, and the practice adopted by some of specially treating every slight displacement or leucorrhœa by local treatment is not only foolish, but positively injurious to the woman. Much more can be done by general treatment than many suppose, and, in any case, the practice of confining treatment to the uterus to the neglect of constitutional treatment is becoming more and more condemned.

Pessaries. He condemned pessaries. Ten years since he read a paper, then deemed heterodox, before the American Medical Association, taking this ground. He thinks now that opinion is coming round to his side, and he referred to Dr. Bigelow's recent paper on the subject. The pessaries distend the vagina and injure its power of supporting the womb; they act as foreign bodies and set up irritation. They often cause tenesmus; they have produced much harm and little good. All the good effects produced by them can be fulfilled by cotton tampons. These adapt themselves to curves and position, and will not interfere with any of nature's laws, and are consequently scientific appliances.

Incision of the Cervix Uteri and the Use of Tents. These procedures are falling somewhat into disrepute as dangerous. As a substitute for them, Dr. Morris described Dr. Wm. Goodell's operation of rapid dilatation, which he much praised. His opinion, however, was that the plan of performing the dilatation at one sitting was too severe and harsh. He would suggest a longer time being taken and that the dilatation be carried on at successive visits. This gradual procedure would necessitate dilators of various sizes.

Emmet's Operation for Lacerated Cervix. This has met with very little acceptance and is now fallen into disfavor. Very injurious consequences have followed from it, as cellulitis, hemorrhage, sterility. Even Emmet has felt it necessary to discourage its indiscriminate use. Dr. Morris hoped that in future greater conservatism would be exercised in this as in other gynecological procedures.

Lacerations of the Urethra. Dr. Morris entirely condemned Dr. Emmet's suggestion of a "buttonhole" operation for the diagnosis of this accident. If it be suspected, much simpler measures will suffice for its detection.

Operations for Lacerated Perineum. The operations heretofore in use have been on the whole unsatisfactory. He described Emmet's and Schmidtmann's operations, both of which he approved, especially the latter.

The Alexander-Adams Operation on the Round Ligaments. After describing this operation he continued: "In the opinion of your reporter this operation is not only useless but unjustifiable. It is the outgrowth of a morbid desire for gynecological novelties which appears to be increasing every year." Some benefit may accrue if there be no adhesions, but the diseased state cannot be remedied, and it must ultimately prove a dangerous operation.

Extirpation of the Uterus for Cancer. The weight of evidence for this operation, which has occasioned so much thoughtful inquiry and discussion during the past year, has been by no means favorable to it. In 137 cases where this has been performed by abdominal sec-

tion 72 per cent. died; of the 276 cases by the vaginal method, 28.6 per cent. died. While better results for the future by the methods employed by Olshausen and Schröder may be expected, the present conclusion is that for cancer of the cervix the operation is entirely unjustifiable, while for cancer of the body its justifiability is doubtful.

Extra-uterine Pregnancy. Through Lawson Tait and Prof. Freunde and others our clinical knowledge of this condition has much increased. After discussing the various views held by the observers mentioned, he said that the general opinion of the profession is that operation should not be undertaken at the time of the rupture of the sac, but be postponed till after recovery from the shock.

For the purpose of destroying the fœtus electricity has been used with great success. It must be employed before the termination of the third month of pregnancy. It not only kills the fœtus but produces its absorption. For the first, the faradic, for the second the galvanic current should be used. One electrode in the vagina is to be applied to the uterus and the other over the hypogastrium.

Therapeutics in Gynecology. Muriate of cocaine affords relief in vaginismus, but it is only temporary. It promises to be, however, a valuable local anæsthetic in gynecological operations. The permanganate of potash has been recommended as an emmenagogue, but it has not yet been verified. Dr. Morris thinks ergot to be the only drug that acts specifically on the uterus. Iodoform is undoubtedly a valuable agent in uterine surgery. It can be used in solution, with ether or carbolic acid and glycerine, or in slender crayons made with gum, and introduced into the cervical canal. Several deaths have occurred during the year from intra-uterine injections of bichloride of mercury. This remedy is dangerous when kidney complications exist.

DR. L. E. NEALE, of the same Section, then gave a lengthy and interesting report on

OBSTETRICS.

He spoke of the advances made in this branch during the year, and began by citing Tarnier's communication on "Combined Turning in the Treatment of Placenta Prævia." Statistics of results in this condition show a high mortality when other measure are employed. The ordinary death-rate is twenty-four per cent.; while the very best are twenty-two and a half per cent. The statistics of this method, which was introduced by Braxton Hicks, in 1860, show a mortality of four and a half per cent. in the hands of a good operator, and even if we take the worst possible showing, including cases where previous measures had been undertaken, the mortality is still only ten per cent. In view of these facts it seems wonderful that it is not more generally practised. He then gave a minute and clear description of the method, and then summed up as follows the advantages of combined version:

1. It does away with the tampon, and with the dangers of infection and loss of time this involves.

2. It allows us to operate early, *i. e.*, when not much blood has been lost.

3. It arrests hemorrhage with great certainty.

4. It gives the patient time to rally, gives time for the cervix to dilate, for pain to set in. It, therefore, prevents post-partum hemorrhage, laceration of the cervix, atony of the uterus. The operation rests upon solid experience and not upon mere theory.

The use of the tampon should be restricted to cases where the os is undilatable, and then its use is only temporary. Of course, the combined method is not applicable to all cases, such as when the child is fixed in the strait and the labor pains are severe. Again there are times when the child is in the transverse position and the labor is somewhat advanced, where this method cannot be employed, and where destruction of the child is necessary. In regard to the child, clinical results show that the prognosis in the combined method is no worse—indeed, a shade better—than with other plans of treatment.

Dr. Neale reported a case of placenta prævia which had occurred in his practice during the year. The woman, a German emigrant, after having suffered a considerable hemorrhage on shipboard some twelve hours previously, entered the hospital. Examination revealed a dead fœtus *in utero*, membranes ruptured, waters escaped, placenta partially torn away, and os readily admitting the hand. Internal podalic version and extraction were performed, the intrauterine douche administered. Rapid and uninterrupted recovery followed.

The speaker then turned his attention to the obstetric forceps. After referring to the mania for "improving" them, he said that Simpson's forceps are the ones most used abroad, and that they are gaining in favor in this country. There are a certain number of cases, however, where the head is impacted in the pelvis brim, where Simpson's, or, in fact, any forceps except Tarnier's, are dangerous and impracticable. These last represent the first successful attempt to assist the efforts of nature by traction, with an instrument, with safety to the soft parts in the direction of the axis of the superior strait. The disadvantages of Tarnier's forceps are: 1, unwieldiness and complexity; 2, liability to lacerate the soft parts. Some have taught that when the head has been brought down to the inferior strait, they should be removed and Simpson's forceps substituted. Others, including Prof. William T. Howard, of this city, have urged that with care Tarnier's would complete the delivery with safety to the mothers's soft parts. Some say that Tarnier's allows too great liberty to the head to rotate unfavorably, forgetting Tarnier's direction to make pressure with the fingers of one hand in the desired direction upon one handle of the introduced blades, while steady traction was being performed by the other hand. Again the objection has been urged that it necessitates two instruments—Simpson's for simple and Tarnier's for more difficult labors.

To meet these objections, Dr. Neal presented an instrument of his own, which he said combined the excellences of both in such a way that one instrument only would be necessary in either class of cases. The points of this instrument are as follows:

1. We have Simpson's forceps practically unaltered.

2. The Tarnier axis traction rod to be used or not at the option of the operator.

3. By removing the compression screw and the handle to the traction rods, when the head is low down, without removing the forceps from the head, delivery may be completed by the unaltered Simpson, thereby subjecting the perineum to as little risk as possible.

4. By employing the fixation bar concealed in the handle to the traction rods, rotation may be governed (so far as lies in the power of the operator with any instrument), without touching the handles of the introduced blades, thus allowing them to act as an index by which we can determine the position of the head.

5. Compression by the screw may be instantaneously varied at option.

6. The instrument combines in the least complex and most practical manner the two principal forceps of the present day, viz.: The Simpson and the Tarnier, giving us either one or the other in the same forceps as desired.

Dr. Neale demonstrated the use of these forceps on a manikin and afterward the instrument, was passed around for examination. The traction rods are secured to the Simpson blades behind the fenestræ by means of a buttonhole joint. He then showed or described several instruments used abroad in obstetric practice. Among these was a glass tube for intrauterine douche upon the puerpera. It is a simple glass tube with a bulbous extremity and a constricted neck to allow free escape of the injected fluid. It has a sigmoid flexure which not only facilitates its introduction, but prevents its being inserted too far. Being glass, it is cheap and easily cleaned.

He then proceeded to explain Schultze's method of artificial respiration in the asphyxia of the newly born. He described a case in his own practice in which, after trying Marshall Hall's, Sylvester's, and other methods in vain, he succeeded in this after ten minutes.

The entire procedure is divided into two acts of inspiration and expiration, with a rest after each.

Grasp the child firmly by the shoulders—the thumbs being placed in front of them and the forefinger just behind the shoulder, and the three remaining fingers over the shoulder-blade. Stand with your legs conveniently apart, and thus hold the child. The position now will correspond to the inspiration as the chest is expanded by the child being held by his shoulders.

1. Rapidly elevate the child at arm's length as the body is correspondingly erected until the arms are about at right angles to the body or somewhat above the horizontal. Then suddenly stop the upward movement in such a manner as to cause the child to fall together upon itself, while the thumbs support the weight of its body by pressure upon the anterior thoracic walls. This corresponds to the rest or pause after complete expiration, during which time fluids, mucus, etc., may escape by gravity, from the respiratory passages.

2. Now, lessening the thumb pressure on the chest and hooking the thumbs over the front of the shoulders, the child is *rapidly slung forwards* and *downwards* into the first position. And so the regular respiratory movements should continue in systematic manner until the object is accomplished or the case prove fatal.

Dr. Neale then reported two cases of post-partum spontaneous expulsion of submucous non-pedunculated uterine fibroids. The first was discharged twelve hours after delivery; the second on the eighth day. The Doctor said he had not been able to find any mention of such cases in English text-books, and only most cursory notices by foreign authors.

He closed his report by speaking of abdominal palpation as a means of diagnosis in the physical exploration of the pregnant female, a method too much neglected in this country. He illustrated its application upon a manikin.

THURSDAY, MAY 14TH.—THIRD DAY.

DR. JOHN S. LYNCH, Chairman of the Section on Practice, reported his

EXPERIENCE WITH ANTIPYRIN IN FEVERS.

His attention had been called to this drug during the past year. He regards it as one of the most important therapeutic agents recently given to the profession, almost equal to quinine in its value. Its chief action is upon the temperature of the body, and this action is almost certain. His first trial of it was in the case of one of our colleagues, Dr. Kinnemon, whose death occurred during the latter part of last year. He was suffering from phthisis, and all the usual medicines employed to check the rise in the temperature had proving unavailing. After a great deal of difficulty he procured some antipyrin and tried it on him with the result of at once lowering the temperature and improving the condition of the patient. He has no doubt that had he been able to obtain antipyrin longer this patient's life would have been much prolonged. He said he had used it in a number of similar cases with constant effect. In rheumatism it is fully as efficacious in his hands as salicylic acid; he has used it in dysentery and in a great number of febrile affections. He regards it as a perfectly safe remedy. The only disagreeable effects which he has noticed are that it sometimes causes nausea, and that the first dose will sometimes give rise to profuse sweating. The former is readily controlled by suspending the drug and it is a curious fact in regard to the latter that the sweating is only brought on by the first dose. The subsequent doses are fully as effective in lowering the temperature but they do not cause the sweating. He was more ready to call attention to this drug, as he believed it was not in general use among the profession. The chief objection to the drug is its expense. As it is a product of coal-tar, and made from what was formerly considered to be refuse matter there is no doubt that it will come down in price after awhile. The dose of the drug is about seven and a half grains, and may be increased to fifteen grains.

DR. R. H. THOMAS said that his experience with antipyrin was very limited, but he had for about eighteen months been using kairin in cases similar to those mentioned by Dr. Lynch. Kairin acted well in much smaller doses than was recommended by European journals. He had found five to ten grains sufficient if given hourly. Kairin is a drug that must be carefully watched, as if continued too long it will cause too great depression of the system. His rule is to give it in five to ten grain doses every hour, having the temperature watched, and to stop it as soon as the temperature reaches 99°. The effect can then be continued by quinine. This can be done even when quinine has failed to produce effect before. If used in this way with care, he has learned to regard it as a valuable and reliable antipyretic.

DR. R. WINSLOW said he had used kairin in but one case. It then reduced the temperature, but brought on very alarming depression. He would certainly only use kairin where there was a nurse who could watch the temperature.

Dr. Lynch had used kairin in one case in two grain doses hourly without effect. He was surprised to hear that Dr. Thomas had success with it in such small doses.

Dr. Thomas said he had been surprised also, but the fact remained. He had once seen two grains effective in an adult, but only once. Most of the cases in which he had used five grain doses were under 20 years of age. He did not remember to have ever given over ten grains at a dose.

Dr. D. W. Cathell, read a volunteer paper on

RECTAL MEDICATION.

He spoke first on the rectum as an absorbing cavity and then said that he would confine his remarks to the use of morphia and belladonna in this way. He does not use medication per rectum in preference to the usual method by the mouth, but a number of cases arise where the stomach should be left at rest to perform its proper digestive functions, and yet where drugs are needed by the system. His favorite method of administering the drugs in question is to give them combined. The combination seems to unite all the good qualities of the two drugs and to lessen the unpleasant effects of each. He referred to a number of cases in which he had used these remedies together in this way, such as, "ulceration of the prostate gland" where after long agony the relief under this method began to be observed at once; vesical tenesmus; senile hypertrophy of the prostate gland, when the patient from being obliged to rise every hour during the night for micturition was enabled to sleep all night without disturbance; encysted renal calculus; vaginismus; subacute sciatica; dysentery and irritable rectum, etc. In order for the suppositories to have effect, they must be prepared carefully and accurately. The excipient preferred by himself is glycerine jelly. But where the suppositories are to be kept for a considerable time he used oleum theobroma. This last keeps fresh for a very long time and does not grease. It is often adulterated with wax, which renders the medicines contained in the suppository inefficacious. The fact, however, that the suppository is found in the dejections undissolved, provided it has been made of cocoa butter, does not mean that it has not yielded up its contained medicine, as, since it is a vegetable fat, it is able to do this without being dissolved. His own experience had shown him the truth of this. The size of the suppositories he uses is fifteen grains. The question arises whether medicine administered per rectum in capsules would not be better. He is rather inclined to favor them, as there are manifest advantages in favor of the capsule, such as cheapness, accuracy, and the exclusion of air from the drug. He generally gives the medicine once in six hours. He prefers morphia to opium and the watery extract of belladonna to the alcoholic, the usual dose being one-fourth to one-sixth of a grain of morphia and one-half of a grain of belladonna.

Dr. William Brinton read a paper on

THE GERM THEORY OF DISEASE,

in which he discussed the question in regard to cholera, syphilis, and other diseases. He said that there seemed some likelihood that Virchow's sarcastic remark, *Es gibt nichts als Pilsen in die Pathologie*, would soon become established as the real belief of the profession. He entered into the experiments of Koch and others, and passed in review the investigations that have been undertaken to establish or disprove the germ theories of the various diseases. The conclusion arrived at by the reporter was that though there is a great deal going to support the theories in question, and though the theory is not only a convenient but apparently a logical one, it must still be held as a matter of doubt whether it has been established.

Dr. F. Donaldson, Sr., read a paper on

THE USE OF THE MURIATE OF COCAINE IN DISEASES OF NOSE AND THROAT.

He claimed that laryngologists were the first to use cocaine as a local anæsthetic. He himself has been using it since it was first brought to the notice of the profession last autumn. He has been using it almost daily as a local anæsthetic. He has found it anæsthetizes the nasal tissue in all painful operations on them and on the throat. He has used it also in rhinitis with satisfactory results. It enables the rhinoscopist to examine the posterior nares, and its application so contracts the nasal tissue as to enable the observer to examine with ease the deeper tissues of the nose from the front, and to locate morbid growths with greater accuracy. He regards it also as a valuable hæmostatic. He employs it generally in strength varying from two to six per cent.

Dr. John N. Mackenzie and Dr. R. H. Thomas in the main expressed similar views, the former denying its hæmostatic properties.

Friday, May 15th.—Fourth Day.

Dr. W. C. Van Bibber, Chairman of the Section on Sanitary Science and Hygiene, presented a report in which he considered

THE TONIC EFFECTS OF TRAVEL.

Tone in its primary signification is tension, and tension primarily means strength, hence its application to the natural healthy state of the animal organs. It, therefore, means in medicine that strength and activity of the organs from which proceeds healthy function. Travel is supposed to benefit chiefly from change of air. Its real benefit is, in fact, from the entire change to both mind and body which the present quick mode of travel allows. This rapid change is altogether modern. In 1845 it took thirty-eight to forty days to go to New Orleans from Baltimore. Now it is made in as many hours. It is possible in the winter time to leave the snows in Baltimore and Washington and be eating oranges in Florida in twenty-six hours. The question arises, Is the sudden change as desirable as a more slow transition? For the *real* invalid the slower mode is the preferable, but there are conditions where the excitement caused by the rapid change of scene is of great benefit. The same question can be asked in regard to the transition from warm to cool atmospheres, as in the case of children in summer. Whether the change be sudden or not must depend upon the individual case. There are times when from weakness, etc., the patient cannot stand rapid travelling. The great advantages of this change are seen in numerous instances every summer.

Dr. Geo. H. Rohé read a paper entitled

THE NON-NECESSITY OF ANY RADICAL CHANGE IN THE PRESENT SYSTEM OF DISPOSAL OF THE DEAD.

Incineration has been proposed as a remedy for certain admitted evils connected with interment. Is cremation really unobjectionable? It is said that decaying bodies pollute the soil and contaminate the ground water and ground air, and that hence we have unhygienic conditions and positive disease. There is, however, very little trustworthy evidence for this; the examples brought forward are not conclusive. Smolensky found that the percentage of carbon dioxide in the ground air is less than half of that found in the soil used for deposit of offal. Note the generally observed good health of workmen in cemeteries, and note their own testimony to this. Experiments show that microörganisms are not moved by air currents if attached to a moist surface. Hence, the difficulty of conveying germs from a decaying cadaver. Water from wells near cemeteries as a rule is of equal purity to that obtained from places inhabited by human beings and where the soil is more or less polluted. Note the absence of special tendency to disease in those who constantly drink such water. There are no trustworthy observations on record to justify us in saying that infectious diseases may be communicated through the air, water, or soil, polluted by corpses of those dead with the disease. Most of the observations leading to such a conclusion lack accuracy and are, therefore, unreliable. He was prepared to maintain that the greatest violence of the yellow fever epidemic in Savannah, in 1876, in Memphis and New Orleans, in 1878 and '79, was not in the vicinity of the cemeteries. People say it would be more economical to cremate; this is absurd, the cost is what people chose to make it. The cost of reaching the cemetery is an incidental item and cannot be included in the total. A brief calculation shows the fallacy of the plea that in epidemics burning is a more rapid and effectual way of disposing of the dead than burial. The average number of deaths in Baltimore daily is less than 23; for this four cremation furnaces would be needed. Suppose an epidemic of cholera and a death rate of 100 per diem, would it be possible to reduce all these bodies to ashes in the four furnaces? Would a community sink funds to prepare for such a contingency when they might or might not be used? The supposed advantages of cremation in time of war were disproved at Sedan.

The objections to cremation are: (1) In cases of criminal poisoning cremation would destroy all evidence of crime. (2) The overwhelming majority of people cling to old customs and are shocked at cremation. There may be poetry in the funeral pyre, but not much in a furnace blast fired up like the blast in a foundry.

After summing up the above points, Dr. Rohé said he did not intend to seem to approve of violations of sanitary laws so frequently met in cemeteries. They should be kept strictly under supervision, guided by a proper code of sanitary regulations, and all infractions of these should be promptly punished. Intramural cemeteries are objectionable, but when bodies are buried in suitable soil, their decay goes on rapidly and without giving rise to offensive emanations.

Dr. John Morris said that Dr. Rohé's views were not new. The same kind of objections were urged against all new improvements. He was surprised that Dr. Rohé should have been so dogmatic, especially as Dr. Formento at the Public Health Association had so abundantly refuted Dr. Rohé's statement that there was no evidence that graveyards favored the spread of epidemics. Again, the testimony of workmen to the healthfulness of their trade is worthless. Those who work in the most disgusting trades will testify they are healthful. He spoke of a recent analysis of water in the vicinity of Greenmount Cemetery, which showed it to be loaded with nitrates. The expense is a secondary question. We want to have the hygienic needs met. Cremation is certainly the method in epidemics. He spoke of the blistering corpses he had seen, years ago, in Norfolk, Va., during a yellow-fever epidemic. Cremation was found to be a necessity in the Franco-Prussian war.

Dr. Jas. Carey Thomas read a paper on the importance of the

STUDY OF HYGIENE IN MEDICAL SCHOOLS.

Preventive medicine is now taking the place it occupied in the older civilizations—in the formost ranks of medical inquiry. A tablet of old was raised, dedicated to Æsculapius and Health. We now reverse the motto, and read, "*Sanitate et Æsculapis.*" It is of the greatest importance that physicians should be able to advise district and municipal authorities on matters of public health as well as to study the constitution, habits, and surroundings of the families and individuals committed to their care, so as to prevent such sickness as is preventable. He instanced the epidemic at Plymouth as the example of the result of neglecting sanitary precautions. A movement is on foot to introduce physiological and hygienic study in the public schools, and it is important that physicians should be able to keep in advance of the growing public intelligence on the subject. The schedule of the Illinois State Board of Health requires hygiene as among the "minimum requirements of a medical college to be held in good standing."

Dr. Joseph T. Smith, in discussing this paper, said that it and Dr. Rohé's paper on cremation went together. As soon as public opinion is educated to look at these questions from a rational point of view, the main objections to cremation will cease. The fact that the germs of disease show such wonderful vitality lends much support to the theory that one cause of the virulence of epidemics is partly, at least, caused by the custom of burial.

Dr. J. S. Conrad. Chairman of the Section on Psychology reported. He spoke of the alarming increase

IN INSANITY

in this country, and entered rather minutely into the statistics of Mr. Wines on this subject in the census for 1880. The increase appears to be going on, and everywhere there is a call for increased accommodations for the insane. What is to be done with the present rapidly accumulating number of the insane, is a question which demands our attention. Legislation in New York has provided for the separation of acute from chronic cases. Owing to the rapid accumulation of chronic cases this law has been only partly carried out. The objection to the association of the two classes is that the duties of the officers and attendants is so taxed by the chronic patients that they have not the proper amount of time

in which to attend to the acute cases. The subordinate staff of an insane asylum are taxed beyond endurance, hence neglect on their part, naturally resulting from the present system. Let the acute be separated from the chronic cases. This is the remedy. Let these receive the kind of care they need. Let cheaper accommodation be provided for the chronic cases, who need chiefly custodial supervision. Let there be one or more State hospitals for acute cases exclusively. The pressure at present upon the superintendents is such that they have to leave the treatment largely in the hands of untrained young men—the assistants. These, as well as nurses, are likewise selected largely by political preferment.

Another difficulty is the almost complete absence of any systematic study of pathology of brain diseases. Only one State hospital (at Utica) has made any provision for this study. Forty thousand patients ought to furnish a large field for observation, yet it is all lost.

Dr. Conrad then continued to consider the status of the medical profession in relation to insanity. He spoke of the fact that the subject is not taught in our schools, and that few had read systematic treatises on the subject. How could you expect such a person to be acquainted with the subject? Yet, though he knows no more than a layman, he will curl his lip at the opinion of such a one in the case of a man suspected of insanity. He does not know the difference between an hallucination in acute mania and in melancholia.

Dr. Conrad then made a supplementary report, which consisted of a reply to Mrs. Packard's remarks in the second day's session. Mrs. Packard's assertion that there were persons unlawfully detained in our asylums, is supported only on her own statement. Dr. Kirkbride, who had treated over 10,000 patients, said that no case of improper confinement had ever come under his notice. In a discussion the unanimous opinion of physicians representing 50,000 patients was the same. It is all right to have post office boxes in asylums, but letters should be inspected by Board of Managers. He adduced many instances of those whom the public and juries considered sane, whose after conduct proved the contrary. The unlimited privilege of correspondence with friends and others is most objectionable, as the patients continually expose themselves, and use obscene language, etc. The proper suppression of correspondence is a protection to the patients themselves. The charge that the sane are kept for years from their friends is made out of whole cloth. Does Mrs. Packard forget the habeas corpus act, and the government of asylums? He read a report of Dr. Earle's (Mass.) showing that in ten years in that asylum the letter box privilege had not brought out one case of unjust treatment.

DR. R. H. THOMAS reminded the Faculty that Mrs. Packard had made no charge against the asylums in Maryland, had not asked for unrestricted powers of correspondence between the insane and their friends, but only that each patient should be allowed to write one letter a week to one person only, without censorship. Dr. Earle's report only showed that good superintendents had nothing to fear. She had said that the arrangement had resulted in the liberation of a number of inmates in Illinois and Maine. The objection to the present system in Maryland is the possession of unrestricted power by the superintendents.

DR. GUNDRY remarked how readily attacks are made on medical schools and hospitals for the insane. To-day both seemed under fire. The last speaker stated that once upon a time in Illinois upon the enactment of a certain law it was discovered that 149 persons were improperly kept as sane persons in an asylum, and that the Committee on Buildings was discharged as unnecessary. His recollections did not agree with these statements. In 1866 or 1867 the law requiring jury trials in every case was enforced, and those cases that had been admitted under a former law were discharged to undergo the required formality. Also that if building asylums had been suspended, it was only for a short time. Since that date two asylums had been opened and one was now being finished at Kankakee, to accommodate 1200 patients. Dr. Gundry thought that while there were some things to criticise in Mrs. Packard's address, he did not care to notice them. It was well to have the attention of the medical profession called to the condition and wants of the insane. Mrs. Packard's proposed law would hardly meet the case, he thought. Better far have the correspondence held sacred between every patient and some designated official person. Such a person visiting the asylum would soon find out whether his correspondence was suppressed. Dr. Gundry had for twenty years been in the habit of sending all letters directed to patients unopened, but not all letters from them. He would offer three suggestions: 1. To secure some plan by which a patient could be placed in a hospital without delay, but with proper safeguards of judicial care and professional opinion. Each case should be registered. 2. Some general agency such as State Board of Charities should have the right to visit them. This general agency should have no power to order changes, but simply to inspect. 3. The medical profession should aid the work by their influence in providing for those not provided for of the insane, and especially for the separation of the idiotic from the insane. The number unprovided for is very great.

DR. J. C. THOMAS agreed in the main with Dr. Gundry. Wherever irresponsible authority exists it should be under some proper control. The common sense of the community demands this. As to Dr. Conrad's charge against the profession, his supplementary report disproved it. What higher testimony to the ability of the profession could be found than the testimony of Dr. Conrad, who had said that there had been no case shown where a person had been unjustly sent to an insane asylum.

DR. R. WINSLOW read a carefully and judicially prepared paper on the advantages and disadvantages of

LAPAROTOMY FOR GUNSHOT AND PERFORATING WOUNDS OF THE ABDOMEN.

He reported a number of cases from his own practice. In none of these had it seemed to him that abdominal section was advisable. The post-mortem appearances in the cases that had died had justified his decision, except in one case, where there was a bare possibility that the patient might have recovered had an exploratory incision been made. The most remarkable case he reported, was that of a woman who lived five days with a gunshot wound perforating the abdominal aorta. He reported cases where, under the conservative plan of treatment, the lives of several patients very seriously

injured by perforating wounds in the abdomen recovered. His conclusions were, that abdominal section is sometimes indicated, but unless it is very clearly, the conservative plan (opium, etc.) should be pursued, as, on the whole, offering the best chances for success. At the same time, he did not at all condemn the practice when it is clearly indicated.

DR. J. N. MACKENZIE made some

OBSERVATIONS ON THE ORIGIN AND CURE OF THE DISEASE CALLED "HAY ASTHMA" (CORYZA VASO-MOTORIA PERIODICA).

Ignorance of intranasal pathology on the part of those investigating the complaint, false theories, and especially the pollen theory, have by drawing attention to less essential conditions, been barriers to therapeutic progress and have contributed to the sufferings of the patient. After criticising the various theories on the subject, Dr. Mackenzie proceeded to show that the disease, hay fever, is no new affection, but has descended through the centuries under the guise of the convulsive asthma and nervous coryza of the older writers and nosologists, and that the so-called idiosyncratic influence in its production may be traced in all probability to the time of Galen. Dr. Mackenzie does not regard the disease as an affection of any particular country or confined to any condition of mankind. According to his conception, the affection commonly known as "hay fever" is simply a grouping together of certain prominent and frequent symptoms of a particular form of nasal inflammation to which he has given the name "rhinitis sympathetica," characterized by a peculiar excitability of the nasal cavernous tissue possibly linked to an exalted state of the nerve-centres (see abstract in *Md. Med. Journ.*, April 11, 1885, also on pathology of the affection, *Trans. Amer. Laryngol. Assoc.*, 1884, p. 113, *N. Y. Med. Rec.*, July 19, October 18, 1884). For the intelligent treatment of such cases, certain principles should be borne in mind which underlie the etiology and mechanism of the paroxysms. It should be borne in mind that the excitability of the turbinated tissue is a secondary phenomenon dependent, as a rule, upon a direct impression made upon the sensitive nerves of the mucous membrane and upon the terminal filaments of the olfactory; or an indirect influence conveyed or reflected through the vaso-motor centres from a distant organ, or finally from some excitation starting in the centres themselves. This stimulation of the nerve-centres from whatever cause originating is reflected outward probably through the sympathetic filaments which reach the turbinated structures with the sphenopalatine nerves. Now as these nerves are distributed over the posterior and inferior portions of the nasal fossæ (sensitive reflex area), the turgescence of the erectile tissue is most noticeable over this particular area, and it will be found that this surface represents the most sensitive spot to the reflex-producing impression. Destruction of the terminal filaments of the sensitive nerves accomplishes thus one result, it closes one door against *ab extra* irritation of the nerve-centres. In order to exclude completely the influence of the latter, it is necessary in addition to remove all sources of local irritation, from whatsoever cause originating. In this way the production of paroxysms from external agents acting directly on the mucous membranes is prevented. The above means alone are obviously insufficient to protect from paroxysms due to agencies operating within the organism, or from reflected irritation from other parts of the body. The indication here is to remove the cause and diminish or abolish the reflex excitability of the erectile tissue—mark it, not to produce artificial contraction of its muscular elements, whose inevitable result will be permanent weakening and dilatation of the intercellular walls, but so as to alter the nutrition of the nerve-centres that they may not respond so easily to impressions which awaken reflex. Failing in the above methods, the destruction of the cavernous tissue should be undertaken. In the majority of cases it is neither necessary nor advisable to destroy large portions of the cavernous bodies; the amount to be sacrificed depends upon the exigencies of the particular case. Dr. Mackenzie does not usually wait for the interregnum of immunity, but operates between the paroxysms, and by this means has succeeded in preventing their return, when the individual has been exposed to the exciting causes of the paroxysm. He makes a stellate incision with the cautery knife in the tissue to be removed, the advantage of which resides in the resulting cicatrix and the greater patency of the nostril secured therefrom.

The prognosis depends not only upon the special predisposing and exciting causes of the disease, and the facility of their removal, but also upon the amount of structural injury done to the respiratory organs, to the central nervous system, and to the parts of the body subjected to the reflex disturbances, to which the frequency of the paroxysms has led. In general it is good, relief can always be secured, and in a fair proportion of cases a cure may be effected.

Dr. Mackenzie related the case of a clergyman out of whose right sinus pyriformis he had extracted a large pedunculated fibrous growth. The growth was very difficult to reach. He had to make the patient gag, and catch it with a pair of forceps, and then pass a wire snare over the handles of the forceps, and so secure the growth. Muriate of cocaine was used, no pain and hardly any hemorrhage, though not much cocaine was used for fear of hemorrhage into the anæsthetized larynx.

SATURDAY, MAY 16TH.—FIFTH DAY.

DR. CHARLES O'DONOVAN, JR., read a paper reporting five cases of

OVARIOTOMY

that had been performed by Dr. Howard.

This paper related in full five cases of ovariotomy that occurred in the service of Prof. Wm. T. Howard at the Hospital for Women, resulting in four successes and one death; together with a minutely accurate account of Prof. Howard's method of performing ovariotomy and his treatment after the operation. Two of the cases were very interesting. The first was of a girl thirteen years old, in whom menstruation had not yet occurred, from whom were removed a teratoma of each ovary, weighing respectively 7.7 lbs. and 1 lb. 6 oz. These had developed in four months.

The second was a case of cystoma of the right ovary, complicated by cystic degeneration of the left ovary, which had fallen into Douglas's cul-de-sac, and in which had developed an adeno-carcinoma as large as an orange, with carcinomatous infiltration of the pelvic

and abdominal glands. The ureters and pelves of the kidneys were dilated from pressure on the ureters, and the kidney tissue was pale and in an advanced stage of fatty degeneration. This case resulted fatally in seventy-two hours of septic peritonitis.

In the preparation for, the performance of, and the treatment after ovariotomy, Dr. Howard follows very closely the teaching of Keith. He uses carbolic acid solution for his instruments and sponges, and has the spray running throughout the operation, though not directed into the abdomen. He dresses the wound with dry iodoform gauze and absorbent cotton. He attaches great importance to the necessity of stopping all hemorrhage before closing the abdomen. He believes that the best way to control vomiting during anæsthesia is to have the stomach empty. He uses ether exclusively in prolonged operations, though beginning with chloroform.

After ovariotomy when trouble arises he draws favorable or unfavorable conclusions from the pulse rather than from the temperature. The paper relates an instance of reduction of temperature by the India-rubber coil from 104⅕° to 100° in four hours, without retarding the fatal result.

Dr. W. T. Howard, in speaking of this paper, referred to his own experience in ovariotomies. His earlier cases were all successful. The next four all died. In looking back over these, in the light of after experience, he does not think any of them could have been saved except possibly one. The cases just reported by Dr. O'Donovan were brought up because he had heard a report that the ovariotomies at the hospital were mostly fatal. Four out of the five, as it would be seen, had recovered. The fifth was hopeless in any case. After keeping the woman under observation for two weeks, and finding that she had increased by actual measurement two inches, he had operated only as a *dernier ressort*. The carcinomatous infiltration could not have been detected before the operation. The post-mortem revealed advanced Bright's disease of the kidneys. Albuminuria, however, is not of itself a contra-indication for operating, as many recover who have albumen in the urine. The fourth case is interesting as occurring in so young a girl, and having been according to the history of such rapid growth. As dermoid cysts are generally congenital, it is probable that it had existed unnoticed for a long time.

He adopts Keith's rule—never to allow the woman any solid food for some time after the operation. Hot water and a little Scotch whiskey is all that Keith allows. It is Keith's plan never to tie an artery during the operation, he just clamps the bleeding vessels until the operation is done. Neither does he use the spray, but in all other particulars he uses Listerism.

Dr. Joseph T. Smith asked whether the urine was examined in the fatal case before operation.

Dr. W. T. Howard said that in the case in question it was omitted, but it is his custom to examine it.

Drs. John S. Lynch, Branham, and J. T. Smith spoke strongly during the discussion which followed, upon the great importance of examining the urine before any serious operation is performed, as the condition of the patient's kidneys will exercise a most important effect upon the recovery of the patient.

Dr. F. Donaldson, Jr., said that in case of applicants for life insurance, good companies would pass them even if albumen had been found in their urine, provided it was only temporary.

Dr. W. T. Howard said that Bright's disease of itself is no contraindication for ovariotomy. Marion Sims had said to him only the last time but one that he saw him, "If we exclude cases of albuminuria from operation, we exclude many that will recover." It depends something upon the variety of the disease. Contracted granular kidney may last for years. Prof. Elliott, of New York, was strongly criticised for saying that all forms of casts are found in the urine of pregnant women, which disappear after recovery. But years after, he reiterated the statement, and said he had verified it. Prof. Howard had a case of puerperal eclampsia in consultation, where the urine was loaded with albumen. Barnes's dilators were used, delivery without laceration, and the woman recovered. The physical conditions which give rise to albuminuria in pregnancy are present in ovarian tumors, and the highest authorities on the subject unite in not considering it a contraindication. The real reason for examining the urine for albuminuria is not to see whether it be safe or otherwise to perform ovariotomy, but to see whether to use chloroform or ether. If there be albuminuria use chloroform, as ether may probably give rise to suppression of urine.

Dr. Branham read an interesting paper on

THE TREATMENT OF STRICTURE OF THE URETHRA.

He reported a number of cases and showed specimens. He prefers the internal to the external operation. Some of his conclusions were: 1. The nearer the meatus the greater the reflex symptoms. 2. Natural condition may give rise to symptoms. 3. These may exist elsewhere than at the meatus.

Dr. Cristopher Johnson read a paper that had been written by Dr. David Stewart, of Fort Penn, Del., who was absent, on

CARBON AS AN ANTISEPTIC.

Animal charcoal was used and carefully purified and used as a permanent surgical dressing for wounds. This he highly extolled.

Dr. Morris said his old preceptor used a dressing of charcoal and sugar.

Dr. Tiffany said that he had seen the skin tattooed from the use of charcoal dressing.

Dr. J. E. Michael read a paper written by Dr. W. S. Maxwell, of Still Pond, Kent County, Md., on a case of

PERICOLITIS RESULTING FROM PERFORATION OF THE BOWEL

from the presence of a foreign body lodged there. The symptoms were obscure during life, at first simulating typhoid fever. The suffering became localized, and was very intense, though intermittent.

MISCELLANEOUS BUSINESS.

The Faculty then proceeded to the transaction of business, and listened to a number of reports; among the more interesting and important was a report by Dr. George Halstead Boyland on *Potent Drugs*. The Committee recommended the passage of a law forbidding the sale of potent drugs (opium, etc.) without the prescription of a legally qualified physician, under penalty

of fine, the law not to apply to wholesale dealers. The committee was continued.

Dr. George H. Rohé, chairman of a committee appointed last year, reported recommending the profession to appoint a committee to report the most feasible means for the regulation of sanitary matters with a view to urging their passage upon the Legislature, if the Faculty approved of them. The committee was appointed.

Dr. J. S. Conrad, of committee to memorialize the Legislature on the passage of a law for the protection of the insane, reported that they had interviewed the Governor and prominent men, and the prospects for the passage of such a law were good. On motion of Dr. R. Winslow, it was decided to appoint a committee to memorialize the Legislature to pass a law regulating the practice of medicine in Maryland. The amendment to the constitution offered by Dr. J. E. Michael last year, to change the word "gentleman" to "person" in the article relating to applications for membership, was passed. The object of this was explained to be to allow a female practitioner to become a member if she were otherwise suitable.

The Nurses Directory Committee were not satisfied with their showing for the year. They were continued.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. John R. Quinan.
Vice-Presidents.—Dr. A. H. Bayly, Dr. J. E. Michael.
Secretary.—Dr. G. Lane Taneyhill.
Assistant Secretary.—Dr. Robert T. Wilson.
Reporting Secretary.—Dr. R. H. Thomas.
Treasurer.—Dr. W. F. A. Kemp.

CORRESPONDENCE.

THE PLYMOUTH EPIDEMIC.

To the Editor of The Medical News.

Sir: The importance of the two subjects of the causation of extensive epidemics of typhoid fever, and of the possible contamination of drinking water, is such as to call for much care in drawing conclusions from facts of the kind presented in the interesting paper of Dr. L. H. Taylor on the fever epidemic at Plymouth, Pa., in The Medical News of May 16th.

With much reluctance to appear to be in the minority in regard to such a topic, I beg leave to offer some reasons for hesitating to accept at once the judgment of Dr. Taylor, that the sole cause of the epidemic at Plymouth must have been the entrance into the mountain stream, chiefly supplying the town with water, of excreta from a patient suffering from typhoid fever between the third and fourth reservoirs above the town.

The essential facts are, in brief, these: After a visit in December to Philadelphia, the man returned in January to his house, situated forty feet from the bank of the stream, and there was attacked with typhoid fever. After two months of illness, by March 18th and 19th he was still not well, having hemorrhage from the bowels. His excreta were, during the illness, either thrown from the house to the ground, or emptied into a privy, where they remained on the surface of the ground. There was *no drain from the house to the stream*, and the ground is described as being, at least till the beginning of April, *frozen and covered with snow.*

We are, nevertheless, asked to believe that these excreta, lying for some two or three weeks upon snow and frozen ground, and then possibly washed by April showers into the stream, had enough specific virulence to account, alone, for a sudden outbreak involving more than a thousand cases of fever, with probably more than a hundred deaths. Is not this proving rather too much?

New cases are still occurring, although it is reported that the mountain stream "hydrant" water is now free from contamination. A principal reason given in Dr. Taylor's summary for his prefaced explanation of the epidemic is, that "it is well known that excreta from *one* typhoid patient have frequently poisoned the water supply of a whole neighborhood and caused an epidemic of such fever." What is certainly well known is that foul water, whether contaminated by typhoid excreta or otherwise, is a very frequent promotive, if not alone a sufficient cause, of the prevalence of typhoid fever. But it is also patent, that typhoid fever occurs often *in the absence* of any such cause; and it appears to be straining a point very far, on behalf of the theory of specific infection, to assert such a vitality in the "germs" of typhoid as will persist on frozen ground for weeks together and then develop at a distance so terribly destructive a power.

Along with the facts thus noticed some others ought to be appreciated:

1. Water was pumped from the Susquehanna into the mains from March 20th to March 26th. Though said to be "reasonably pure," the quality of that water may be held to be, not without reason, open to grave suspicion.

2. There are "four successive reservoirs" through which, whether the stream be high or low, its water passes before it is supplied to the town. Its detention in these reservoirs must render it subject to injury in more than one way, which ought to be inquired into.

3. The town is said by Dr. Taylor to have suffered from "accumulated filth," although those living in its cleanest parts have also been among the subjects of the fever.

My purpose in mentioning these several unsanitary conditions is to suggest the view that they may *all* be factors in the causation of this unusually violent and extended epidemic. If the theory of *exclusively specific infection* or contagion be true, its evidence will withstand, and gain in the end by, the most searching examination of all that appears against it. To my view, the facts in the way of its final adoption are many and important; and it is needful for the public, as well as professional, interest, that such a case as that of the Plymouth epidemic should not be decided upon without a thorough, scientific, and what may be called judicial, investigation. With great respect,

Henry Hartshorne.

Philadelphia, May 18, 1885

NEWS ITEMS.

The Cholera Conference at Berlin.—We learn from the *British Medical Journal* that the conference on cholera, which met last August, reassembled in Berlin on Monday, May 4th, to hear the result of recent experiments with the cholera bacilli which have been

made by Dr. Koch since the last meeting. Profs. Virchow, Bergmann, Leyden, Hirsch, Bardeleben, Drs. Skrzeczka, Kersandt, Pistor, Struck, Wolffhügel, Coler, Eulenberg, Fränkel, Gaffky, Neumann, and Schubert, who were present at the last meeting again attended, and in addition Profs. Pettenkofer, of Munich, and Günther, of Dresden, took part in the present meeting. Dr. Koch began by discussing and refuting the views of Finkler, Prior, Klein, and Emmerich. He demonstrated pure cultivations of comma-bacilli from France, Italy, and Germany; all these resembled one another. Of one hundred and fifty medical men who attended Dr. Koch's courses of practical instruction, one got "cholerine," and in his dejecta comma-bacilla were found. The pure cultivations from Germany, mentioned above, were obtained from this case. Dr. Koch considered that the cholera bacilli belonged exclusively to cholera, that they were easily distinguishable from other bacteria, and hence were serviceable as a diagnostic. He then proceeded to describe the successful experiments on guinea-pigs made with pure cultivation. His method of procedure was as follows. Five cubic centimetres (about eighty-five minims) of a five per cent. solution of soda were first administered; twenty minutes later, ten cubic centimetres (nearly three drachms) of meat infusion containing pure cultivations of the cholera bacilli were injected into the stomach. Immediately afterwards tincture of opium was injected into the abdominal cavity, and the animals were thus kept under the influence of the drug for about one hour, and then recovered, for the time, completely. Next day they became ill, and in from one to three days after the operation died. On post-mortem examination, the small intestine and cæcum were seen to be filled with a colorless alkaline flaky liquid, containing almost a pure cultivation of cholera bacilli. These experiments were successfully performed on eighty-five guinea-pigs. In the discussion which followed, Prof. Pettenkofer declared himself unconvinced; cholera, he held, produced conditions favorable to the development of the "comma-bacilli." Dr. Koch, in his reply, pointed out that his experiments had been attended by positive results. He added that the experiments would be continued. The discussion has not yet concluded.

The American Climatological Association will hold its second annual session at the hall of the Academy of Medicine, New York, on May 27th and 28th, under the presidency of Dr. A. L. Loomis. The following papers are announced to be read: "The Climate of Mexico," by H. D. Didama, M.D., of Syracuse; "Antiseptic Inhalations," by Beverly Robinson, M.D., of New York; "Catarrhal Affections of the Nasal Cavities as a Cause of Pulmonary Phthisis," by W. C. Jarvis, M.D., of New York; "The Home Treatment of Consumption," by F. C. Shattuck, M.D., of Boston; "Further Consideration of Pneumatic Differentiation, with Demonstration of the Pneumatic Cabinet," by H. F. Williams, M.D., of Brooklyn; "A Rule for the Even Disposition of Climate, based upon the Average of the Combined Atmospheric Humidities in the United States," by Ch. Dennison, M.D., of Denver, Col.; "Elements of Climate and their Relations to Pulmonary Consumption," by J. H. Tyndale, M.D., of New York; "Geographical Distribution of Phthisis in Michigan, with Sketch of Topography," by E. L. Shurley, M.D., of Detroit; "The Treatment of Laryngeal Tuberculosis," by E. F. Ingalls, M.D., of Chicago; "The Problem of Acclimatization," by J. H. Platt, M.D., of Brooklyn; "Tampa Bay as a Health Resort," by J. C. Wilson, M.D., of Philadelphia; "The Results of the Home Treatment of Consumption Contrasted with those of Changed Residence and Climate," by E. D. Hudson, Jr., M.D., of New York; "Hay Fever and Allied Affections," by F. H. Bosworth, M.D., of New York; "The History of the Stethoscope, with the Presentation of a Modification of the Cammann Stethoscope," by D. M. Cammann, M.D., of New York.

Indiana State Medical Society.—At the annual meeting of this Society held last week the following officers were elected for the ensuing year:

President.—J. S. Gregg, M.D., of Fort Wayne.
Vice-President.—W. J. Hurt, M.D., of Waynetown.
Secretary.—E. S. Elder, M.D., of Indianapolis.
Assistant Secretary.—W. H. Lopp, M.D., of Columbus.
Treasurer.—G. W. H. Kemper, of Muncie.

Pennsylvania State Medical Society will hold its annual meeting this year at Scranton, on Wednesday next.

Public Opinion on the Action of the Association on the Organization of the International Medical Congress.—Instead of tendering the Committee a vote of thanks, through Dr. Billings, the Association was, we will not say led, but stampeded into taking the extraordinary action recorded in the report of the proceedings of appointing a new Committee, consisting of one member from each State, to revise the work of the first Committee, on the absurd ground that the appointment of officers had not been governed by the principle of sectional and local representation. The principle in itself is a poor one applied to this subject; and, moreover, an examination of the list of names shows that all sections of the country are very fairly and worthily represented. It is surely more important that a man should be known to be familiar with the subject he is to direct than that he should come from any particular State, county, or city.

The lists of names of officers as now made out are good ones, and cannot easily be improved. The "ins" could be made "outs" and the "outs" "ins;" but that change, with very few exceptions, would only be an improvement to the extent of gratifying some disappointed aspirations for personal notoriety. One thing, however, can certainly be accomplished by the appointment of this new Committee of thirty-eight, namely, a serious delay of the preparations for making the Congress a success, and an infusion of doubt into the minds of the profession in Europe and Great Britain as to the wisdom of coming so far with such uncertainties.

It is reported that this Committee proposes to meet next September, probably in Cincinnati. It may be by that time they will be convinced of the propriety of passing a vote of thanks to the original Committee and adjourning, but even then sufficient mischief to the scheme of the Congress will have been done by the action of the American Medical Association at New Orleans.—*Boston Medical and Surgical Journal.*

We think that the American Medical Association has by this action stultified itself, and has betrayed an inherent weakness in its present plan of organization.—*Philadelphia Medical Times.*

The brethren of the Atlantic coast are unquestionably able to acquit themselves with credit in exalted positions, but there are those in the interocean regions who deem themselves equally competent, and their right to a chance to display their competency cannot be violated with impunity. This is, practically, what the Association said, and steps were taken to redress the wrong which had been done.—*The Medical Age* (Detroit).

LUSK'S OBSTETRICS.—We are pleased to learn that the last American edition of Prof. Lusk's work on Obstetrics and Diseases of Women and Children has been translated into French by Dr. Doleris, with a preface by Prof. Pajot.

PRIZE AWARDED.—A cablegram announces that the French Academy of Medicine has awarded a prize to Dr. Murrell, of Westminster Hospital, London, for his discovery that nitro-glycerine is a remedy for angina pectoris.

DR. ROBERT KOCH has been gazetted as Professor of Hygiene in the University of Berlin, and has been appointed "Geheimer Medicinalrath."

THE DEATH OF PROFESSOR PANUM.—We regret to have to record the sudden death, on May 3d, of Dr. P. A. Panum, the eminent Professor of Physiology in the University of Copenhagen, and the President of the last International Medical Congress. Professor Panum's work was largely in the field of medical and physiological science, and in his death the profession sustains a severe loss.

DR. FERRÁN.—The Madrid correspondent of a daily paper gives the following particulars of Dr. Ferrán, whose astounding researches on cholera have been received with such enthusiasm in Spain and with so much suspicion elsewhere: "Dr. Jaime Ferrán is only 33 years of age, and after passing through the customary curriculum at the Institutes of Tortosa and Tarragona, took his M.D. degree at Barcelona. He has been in practice at Tortosa for several years, and is already well-known for his work on micro-telephony in 1878, and for his curious investigations on micro-biology and parasites, which were rewarded by the Royal Academy of Medicine in Madrid. Dr. Ferrán was sent to Toulon and Marseilles during the last epidemic of 1884, and he spent several months with German, French, and Italian surgeons, studying the epidemic, and especially Dr. Koch's comma-bacillus. Those studies impelled Dr. Ferrán to pursue his investigation, on his return to his own country, and he thus came to the conclusion that Dr. Koch had only observed one of the many stages of this microbe's successive developments. Senor Ferrán has discovered that, by submitting the comma-bacillus to certain chemical elements very similar to the bile of animals and to the gastric juice of the human stomach this microbe passes through successive and invariable stages of development, in one of which he has detected the eggs, which are, in his opinion, the real generators and propagators of cholera."

OBITUARY RECORD.—Died in Stewart, Lee Co., Ill., May 10th, of mesenteric tuberculosis, WILLIAM SLADE HERRICK, M.D. Dr. Herrick was born in West Randolph, Vt., on May 3, 1838, and graduated in Arts at Dartmouth College in 1860, and in medicine at Rush Medical College, of Chicago, in 1866. He studied medicine under Dr. E. P. Cook, of Mendota, Ill., and served as surgeon-steward on the United States Gunboat Gen. Bragg, of the Mississippi squadron for two years during the civil war. He was a brother of Dr. S. S. Herrick, of New Orleans, Secretary of the Louisiana Board of Health.

NOTES AND QUERIES.

PUMP-WELLS IN BROOKLYN.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of to-day, you say that one hundred pump-wells still exist in this city; please correct this, as all these have been filled; there remains but *one well* in Brooklyn, and that furnishes pure water. This city is supplied entirely with Ridgewood water which, as you will see by the report of July 20, 1881, of the analysis of Prof. Leeds, of Stevens Institute, stands A No. 1.

Respectfully,
J. H. RAYMOND, Commissioner,
Department of Health.

BROOKLYN, N. Y., May 16, 1885.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 12 TO MAY 18, 1885.

VOLLUM, EDWARD P., *Lieutenant-Colonel and Surgeon.*—Granted leave of absence for three months, to take effect when his services can be spared by his Department Commander.—*S. O. 110, A. G. O.*, May 14, 1885.

A Board of Medical Officers, to consist of A. K. SMITH, *Lieutenant-Colonel and Surgeon*, J. C. G. HAPPERSETT, *Major and Surgeon*, JAMES P. KIMBALL, *Captain and Assistant Surgeon*, appointed to assemble at the United States Military Academy, West Point, New York, on June 1, 1885, to examine into the physical qualifications of the members of the graduating class and the candidates for admission to the Academy.—*S. O. 106, A. G. O.*, May 9, 1885.

CORSON, JOSEPH K., *Captain and Assistant Surgeon.*—Leave of absence extended ten days.—*S. O. 109, A. G. O.*, May 13, 1885f

KANE, JOHN J., *Captain and Assistant Surgeon.*—Leave o, absence for seven days extended one month.—*S. O. 109, A. G. O.*, May 13, 1885.

CARTER, E. C., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 106, A. G. O.*, May 9, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MAY 16, 1885.

FESSENDEN, C. S. D., *Surgeon.*—Granted leave of absence for thirty days, May 12, 1885.

GOLDSBOROUGH, C. B., *Passed Assi tant Surgeon.*—To proceed to Moss Point, Miss., for special duty, May 16, 1885.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

X.

HYDROGEN PEROXIDE.

BY GEORGE M. STERNBERG, M.D.,

SURGEON U. S. A.

SINCE Angus Smith, in 1869, proclaimed his belief that peroxide of hydrogen was to be the disinfectant of the future, sanitarians have been waiting for chemists to devise some method by which this agent may be manufactured at a sufficiently low price to bring it into general use. The absence of any corrosive or poisonous properties or of any objectionable odor, and the promptness with which this agent destroys volatile putrefactive products and arrests putrefactive decomposition, seemed to make it the disinfectant *par excellence*. But we no longer accept the arrest of putrefactive decomposition or the destruction of bad odors as evidence of disinfecting power, and the question which here concerns us relates to the power of this agent to destroy germs.

The following experiments have been made by Dr. Duggan and myself, with a solution of hydrogen peroxide prepared under the direction of Prof. Albert R. Leeds, a member of the Committee on Disinfectants. When first received from Dr. Leeds, this solution contained 4.8 per cent. of H_2O_2 and 5 per cent. of sulphuric acid. At the expiration of a month the amount of hydrogen peroxide was again estimated by Dr. Duggan, and was found to be 3.98 per cent. Five weeks later the proportion was reduced to 2.4 per cent. The constant escape of oxygen at the temperature of the laboratory is shown by a continuous flow of minute bubbles from the interior of the liquid to its surface. Tested upon broken-down beef-tea, when the proportion of H_2O_2 was 3.98 per cent. (say 4 per cent.), the solution was found to be active in the proportion of 30 per cent., while it failed in the proportion of 20 per cent.; that is to say, 1.2 per cent. of H_2O_2 in two hours time destroyed all of the organisms present in the broken-down beef stock, and 0.8 per cent. failed to do so. Tested upon a pure culture of *B. anthracis* containing spores, the same solution was effective in 20 per cent. (0.8 per cent. $H_2O_2 = 1 : 125$) and failed in ten per cent. Tested upon a pure culture of a micrococcus, obtained from a drop of blood drawn from the inflamed area in a case of vaccinal erysipelas, the same solution was effective in the proportion of 10 per cent. (0.4 per cent. of $H_2O_2 = 1 : 250$), and failed at 5 per cent. In experiments made at a later date (March 28th) when the strength of the solution was reduced to 2.4 per cent. *Micrococcus tetragenus* was destroyed by 10 per cent. (0.24 per cent. $H_2O_2 = 1 : 400$), while the same amount failed to destroy the vitality of the micrococcus of pus—pure culture obtained from an acute abscess—showing a difference in the resisting power of these two organisms.

As the solution used in these experiments contained five per cent. of sulphuric acid, which in a previous series of experiments[1] has been shown by the writer to be fatal to the micrococcus of pus in the proportion of 1 : 200, it is evident that a failure to destroy the vitality of the same micrococcus in 1 : 400 does not give this solution any very notable advantage over a simple aqueous solution of sulphuric acid. The germicide power of the solution used, as tested by its action upon spores, is, however, considerably above that of sulphuric acid alone. Dr. Duggan has ascertained that to destroy all of the organisms in broken-down beef-tea requires 8 per cent. of H_2SO_4, whereas 30 per cent. of our solution of H_2O_2, containing 5 per cent. of sulphuric acid ($= 1.5$ per cent. of H_2SO_4), is effective.

These experiments indicate that unless chemists can furnish us solutions which are more concentrated and which will keep better, we are not likely to derive any great practical benefit from the use of hydrogen peroxide as a disinfectant.

As an antiseptic our solution was found, by Dr. Duggan, to be effective in the proportion of 1 : 5000 (of H_2O_2, not of the dilute solution), and to fail in the proportion of 1 : 10,000. This does not correspond with the results reported by Miquel, who places hydrogen peroxide — *eau oxygénée* — above mercuric chloride as an antiseptic. In his table of the minimum amount of different antiseptic agents which will prevent the putrefaction of one litre of neutralized beef-tea the quantity of H_2O_2 required is stated to be 0.05 gramme ($= 1 : 20,000$), while the amount of mercuric chloride required to accomplish the same results is given as 0 07 gramme ($= 1 : 14,285$.)

SIMPLE FORMS OF APPARATUS FOR ESTIMATING THE QUANTITY OF UREA IN THE URINE.[2]

BY AUSTIN FLINT, JR., M.D., LL.D.

AT the request of Dr. William H. Greene, of Philadelphia, I have the honor to exhibit to the Association his apparatus for the estimation of urea. The request is contained in the following letter from Dr. Greene, and the description of the apparatus was sent to me by Dr. Greene, with the apparatus itself:

I see that you have favorably noticed a ureometer exhibited by young Dr. Doremus to the New York

[1] American Journal of the Medical Sciences, April, 1883.

[2] Read before the New York County Medical Association, May 18, 1885.

County Medical Society on the 16th March. As you may possibly have noticed in a reclamation of priority, which I published in THE MEDICAL NEWS of the 4th inst., I consider that Dr. Doremus has acted either ignorantly or with but a slight appreciation of the ethics of scientific men in seeking to appropriate credit for an apparatus of which the only simplicity—the absence of stopcocks—is due to myself. At the same time he does not appear to comprehend the importance of corrections for temperature and pressure even in approximate measurement of gases.

I send you by express a ureometer, which please accept with my compliments, and compare with that of Dr. Doremus.

I have made no advertisement of the instrument. My deceased friend, the late Adolph Wurtz, of Paris, presented for me its description to the Académie des Sciences. Greiner and Friedrichs began manufacturing it immediately afterwards, and, at my request, sent me seven. This one, which I send you, is the third that I have presented, the other two having been given to personal friends.

I would esteem it a favor if you would either read this note or exhibit the apparatus to the New York County Medical Society.

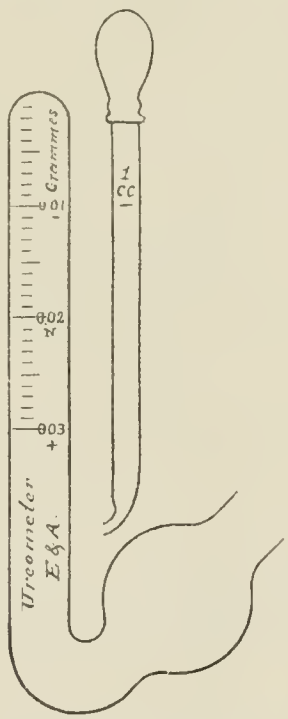
Very respectfully yours,
WM. H. GREENE.

3225 SANSOM STREET, PHILADELPHIA, April 18, 1885.

"A SIMPLE APPARATUS FOR ESTIMATING UREA. By W. H. GREENE. (Fresenius, *Zeitschrift für Analyt. Chemie*, xxiii. Heft ii. S. 275.)

"A simple apparatus for estimating urea with sodium hypobromite, which has been suggested by W. H. Greene, is intended for clinical purposes, and admits of rapid work. Its essential part is the glass vessel *a* (see Fig. 1), whose under portion, holding about 60 cc., has

FIG. 1.



a side-tube, while the upper cylindrical portion, of from 20–25 cc. capacity, is graduated.

"To make the determination, a measured quantity of urine is introduced by means of the pipette, whose end has been bent, into the glass vessel, which has been filled with hypobromite and placed in a saucer to catch the ley that escapes.

"The nitrogen produced collects in the graduated cylinder. It is advisable to choose a pipette whose fine end allows 3–4 cc. of urine to escape in a minute.

"When the decomposition is complete, a bent funnel-tube is inserted in the tubulus, and this is filled with hypobromite to the same level as that in the graduate. The reading of the volume of nitrogen is then made. If it is desired to do away with the funnel-tube, the entire apparatus may be sunk in water until the level of the hypobromite corresponds with that of the outside water.

"Quantity of urea in a litre of urine =

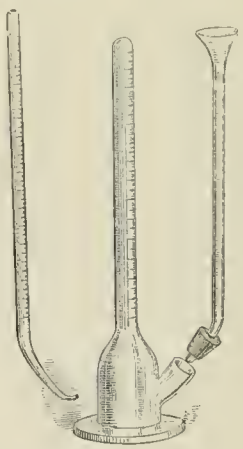
$$\frac{1000\, v\, (h - h')}{760 \times 354.3 \times a\, (1 + 0.00366\, t)}$$

"v = volume of gas.
"h = barometric pressure in millimetres.
"h' = tension of aqueous vapor in millimetres at temperature t.
"a = volume of urine employed."

To enable members of the Association who were not present when the apparatus constructed by Dr. Doremus was presented, to make a comparison between the two methods, I take the liberty of exhibiting again Dr. Doremus's process. It is proper, however, to state that Dr. Doremus makes no claim to originality, as is shown by the following extract from the *Journal of the American Chemical Society*, vol. vii., No. 3:

"The general form of the apparatus shown in the cut (Fig. 2) is not new. It was in use in Prof. Kuehne's

FIG 2.



laboratory in Heidelberg in 1871, where it was employed in the detection of fermentable sugars by introducing some yeast in the liquid, and setting the tube in a warm place. The carbon dioxide evolved collected in the long arm.

"Since then it has been given in works on animal chemistry."

The long arm of the tube is filled to a point marked = with a solution of sodium hydrate, six ounces to a pint of water, and one cc. of bromine is then added by means of the pipette. This extemporaneous mixture, for each analysis, is made in the apparatus itself, for the reason that the hypobromite is liable to deteriorate. Enough water is then added

to fill the long arm and bend of the ureometer. One cc. of urine is then passed slowly into the apparatus by means of the pipette, and the quantity of gas liberated is read from the scale, which gives the actual proportion of urea, without calculations or the use of tables. The determination can thus be made in nearly the time that has been required for its description.

Each of the two forms of apparatus is designed to present a convenient and rapid application of a well-known method for the quantitative determination of urea. There seems to be no ground for controversy as regards originality or priority; and practitioners will undoubtedly select the apparatus which is most convenient.

Dr. Doremus presented, by request, at a previous meeting of the Association, the form of apparatus which he uses in teaching, as possibly the simplest and most convenient for medical use. The graduation was made experimentally, at a temperature of 65° Fahr., with a uniform volume of liquid, so that, these simple conditions being fulfilled, the estimates are sufficiently close for all practical purposes, and "corrections for temperature and pressure" are unnecessary.

The advantages of Dr. Doremus's apparatus over the one proposed by Dr. Greene seem to me to be the following:

1. The apparatus has but two parts, which are easily filled and cleaned.

2. The mixture of the sodium hydrate with the bromine is made in the tube, and the irritating fumes of bromine are avoided.

3. The bulb receives the excess of liquid when the urine is added, and no additional receptacle is needed.

4. The pipette is more easily filled by means of the rubber nipple than by suction with the mouth.

5. The determination is made directly, by simply reading from the graduation, and no calculation is necessary.

In neither of the two forms of apparatus is there any new principle involved, and they are to be compared merely from the point of view of simplicity and convenience of application.

The strictures made by Dr. Greene, accusing Dr. Doremus of having "acted either ignorantly or with but a slight appreciation of the ethics of scientific men," seem to me to be uncalled for. The advantages of both instruments commend themselves on their simple merits to practitioners, who will, of course, select the one which seems the better adapted to their use. This question I leave to the members of the Association for their decision individually. For myself, I had seen a description of Dr. Greene's apparatus before I made my remarks at a previous meeting; and I simply commended what I conceived to be improvements on all previously described forms of apparatus, without comparing any one form with another.

A CASE OF MIXED-CELLED SARCOMA OF THE SPINE,

OCCURRING IN THE PRACTICE OF DR. WM. PIERSON, OF ORANGE, N. J.[1]

Reported by J. W. STICKLER, M.D., OF ORANGE, N. J.

W. S. H., æt. 30, American, married; no children; temperate; no suspicion of specific disease. With the exception of his last illness, was never seriously sick. Family history good.

Nine months ago the patient complained of pain in his back, especially when he walked, or in any way used his lumbar muscles. It was thought at that time that he had lumbago and was treated accordingly. He absented himself from business for a few weeks to secure rest, and then resumed work, but daily, after returning from the city, he experienced pain in the lumbar region, and found it necessary to give his back as much rest as possible.

On October 28, 1884, Dr. Wm. Pierson first saw the patient. At that time he complained of very severe pain which followed first the course of one sciatic nerve, then of the other, the pain lasting two weeks, seven days in each thigh.

During this period the patient remained in bed. A very careful examination was made, but there could be discovered no tenderness on palpation at *any* point, neither was there deformity of the spine. Locomotion was not interfered with at that date, although muscular action caused slight pain. At the termination of two weeks he was relieved of pain, but discovered that he could not use his lower extremities. The anal sphincter was paralyzed, the vesical remained intact. The motor paralysis was associated with anæsthesia of the skin below the first lumbar vertebra. An examination of the spine at that date did not elicit any pain or tenderness, or show any deformity. One month later the vesical sphincter became paralyzed, the urine ammoniacal, and showed on examination mucus and pus. His appetite remained good, and digestion did not seem to be materially impaired.

About December 15th a tumor, similar in outline to a circular cyphosis, was observed in the lumbar region. It extended from the last dorsal to the second lumbar vertebra, and was *not angular* as in caries. On either side the spine, the tumor was smooth upon its surface, and gave on palpation an ill-defined sense of fluctuation. The needle of an ordinary hypodermic syringe was inserted into both sides of the tumor, but nothing but blood was drawn, as was shown to be the case when the fluid was examined microscopically.

The tumor increased in size laterally, and after a lapse of two weeks the exploratory needle was again inserted. A small quantity of colorless fluid was withdrawn which upon microscopic examination showed a few disintegrated cells, a few blood disks, and oil globules, *but no pus cells*. At that time Dr. Pierson made a diagnosis of "malignant growth." His opinion was based upon absence of pain, angular curvature, pus, and such constitutional symptoms as

[1] Read before the Orange Mountain Medical Society.

are associated with suppuration, also upon the probability that the paralysis which occurred early, was due to pressure of a new growth upon the cord. He likewise thought that the posterior even curvature of the affected portion of the spine was due to an expansion of the vertebræ occasioned by growth of the tumor. The bilateral bulging, he thought, was due to an extension of the growth on either side the spine.

It was the opinion of a few of the many physicians who were kindly asked to see the patient, that the case was one of "spinal caries." The diagnosis made by Dr. Pierson was verified at the post-mortem examination. Emaciation, which began with the appearance of the tumor, had become extreme, notwithstanding the patient ate largely of various kinds of food.

About the middle of January, a tumor was detected in the abdomen, on the left side, directly in front of the tumor behind, and apparently continuous with it. Palpation of this tumor did not occasion pain, neither did it elicit any fluctuation, nor give any information concerning its character, save that it seemed to be, when very carefully examined, a part of the growth behind. During February the patient became greatly exhausted and emaciated, the tumor increased rapidly in size, the vital forces giving away degree by degree until March 8, 1885, when he quietly died.

It will be well to state just here, that during the entire course of his sickness he ate with good relish, and slept well. It is also a noticeable fact that he was not given a single dose of any anodyne medicine, there being scarcely any pain.

Post-mortem Examination.—Rigor mortis well marked; emaciation extreme; color of skin, pale yellow with here and there a greenish coloration, due to chemical changes. When the abdominal cavity was opened, but little fat was seen in the omenta, and many of the mesenteric glands were enlarged and quite soft. When the intestines were removed, a bi-lobed tumor was seen to occupy about the posterior half of the abdominal cavity, extending from the last dorsal vertebra to the ileo-pectineal line on either side. It had a common covering which in the central line was close to, and at some points in apposition with the vertebræ. This covering, which was tough and tense, bound the growth firmly to the sides of the thoracic cavity, in the axillary lines, and to the linea ileo-pectinea. On the left side, the covering of the tumor was quite adherent to the capsule of the kidney, although it was separable from it by careful manipulation. On the right side the kidney was less adherent. To the touch the tumor was semi-fluctuating, and when accidentally punctured, was found to contain a small quantity of serous-looking fluid. It was found impossible to separate, by dissection, the tumor from its various attachments.

The left ureter was traced from the bladder across the anterior surface of the tumor, between it and the kidney, till it was seen to enter at the hilus. This ureter presented no dilatations. The right ureter was likewise traced from the bladder to the kidney, and at a point about four inches from the bladder was dilated to about three times its normal diameter; it contained clear urine.

The tumor was opened on both sides of the spine, and was found to contain a soft cheesy mass, most consistent near the spine, *very* soft, almost fluid, at the centre of the sac, on either side the spine. In color it was pale yellow. When the covering which lay over the spine was removed, it was found that the last dorsal and first lumbar vertebræ were so disorganized, and so completely detached from all ligamentuous connection, that they were easily removed. The body of the last dorsal vertebra was almost entirely destroyed, and about two-thirds that of the first lumbar was gone. The interarticular fibro-cartilages were normal in appearance. None of the cord substance could be recognized at the level of the two vertebræ just alluded to.

The left kidney was enormously enlarged (four by six inches), and overlaid the abdominal tumor. Its capsule was glistening in appearance, and was quite tense. It did not fluctuate on palpation. When cut into, the capsule was found to be thickened and infiltrated. In that portion of the kidney near the capsule there were many cheesy-looking masses of various sizes. The kidney consisted chiefly of a pultaceous mass, yellow on its surface, but presenting many red points at and near its centre.

The right kidney was slightly enlarged, and presented pale yellowish markings in the cortical portion. It also contained five small masses in the medullary portion, which had a cheesy appearance, and a chalky consistency. The lungs were normal; the liver paler than in health, otherwise natural in appearance.

Microscopical Examination.—The tumor which was connected with the spine consisted of a great variety of cells, viz., giant cells, spindle-shaped cells, small and large round cells, and stellate cells.

The cortical portion of the left kidney showed an almost entire obliteration of the Malpighian bodies, the tubules and vessels. Instead of the above normal elements, many small spherules could be seen. Some of these spherules were about as large as white blood-globules, others about one-third larger, and some were considerably smaller, about the size of red blood-globules. The pultaceous mass which filled the central cavity of the kidney, consisted almost entirely of spherules, such as have already been referred to. An examination of the right kidney showed a tumefaction of its epithelial elements, a dilatation of the convoluted tubes, and an apparent thickening of their proper tunic. The Malpighian tufts seemed to be much dilated, and had a fatty appearance. Some of the tubules were clogged with swollen epithelium, casts, and oil globules, and all the tubes were in contact. The five small collections of cheesy and cretaceous looking substance consisted of uric acid crystals, phosphate of lime, and spherules such as were found in the left kidney.

Dr. Wm. H. Porter, of New York, to whom I sent a number of sections of the sarcoma, agrees with me concerning the character of the tumor, and thinks "composite sarcoma" a good name for such growths.

MEDICAL PROGRESS.

New Mode of Drainage Employed in Cold Abscess.—Dr. Houzel, at the last meeting of the French Surgical Congress, described a new method of drainage

employed in cold abscess, by which the pus is evacuated as fast as it is secreted, and the dressing of the abscess is not only not soiled, but escapes altogether contact with the pus. The plan is as follows:

The suppurating cavity, no matter what may be its nature, is thoroughly cleansed and rendered aseptic. Two tubes are then introduced into the cavity as deeply as possible—in contact, if the cavity is small, divergent at a point beneath the skin if the suppurating cavity is larger. The calibre of the tubes must depend upon the abundance of suppuration. Before they are introduced, they must be thoroughly fenestrated so far as they are engaged in the suppurating cavity. At the point of exit from the wound the two tubes are united and surrounded with iodoform, and a collar of charpie slightly elevated, in order to form a dressing for the cutaneous wound. Over the whole is placed a dressing of carbolized gauze or antiseptic wadding, and Mackintosh perforated so as to allow the exit of the two tubes, which extend about six or eight inches beyond the dressing, according to circumstances.

The tubes are then introduced carefully into the perforations of a rubber cork, until the cork reaches the level of the dressing, and finally the tubes are introduced into a flat rubber bladder, containing a small quantity of carbolic acid or chloride of zinc.

The two cavities are by this means connected, air is excluded, and pus is voided without soiling the dressing. Profuse suppuration is no longer a source of inconvenience, and asepsis is perfect. The tubes, when once a flow has been established into the rubber vessel, act as siphons and gently aspirate the pus from the cavity of the abscess, which is thus drained much more freely than by the ordinary method, while its immediate admixture with a disinfectant renders antisepsis still more complete and as perfect as possible.

Encephaloid Sarcoma of the Right Ovary; Laparotomy; Death.—Prof. C. Gallozzi, in the *Gazzetta degli Ospitali* (supplement), April 5, 1885, records an operation of laparotomy, performed on a girl 13 years of age, for sarcomatous degeneration of the right ovary.

The history of the case revealed no hereditary tendency to the disease, which first manifested itself two years previously by pain in the right iliac fossa. The condition of the patient was that of general malaise. There was, however, no disturbance of the digestive or respiratory function. The abdomen was enlarged, but there was no marked prominence nor alteration in color or venous engorgement. The circumference of the body at the level of the umbilicus was 31.6 inches.

Palpation revealed the presence of a tumor, ovoidal in form, of uneven surface, and moderately elastic, extending from the left costal arch into the basin of the pelvis, from which it could be raised by light pressure from below upward, though such manipulation was painful to the patient. The tumor had a transverse diameter of eight inches, and a longitudinal diameter of 9.2 inches. Vaginal examination of the uterus was impossible. Diagnosis was made of sarcoma, probably involving the right ovary.

The twenty-second day after the patient's admission to the hospital, operation was performed at the request of her father. Median incision was made, extending from the umbilicus to the symphysis pubis, and on opening the peritoneum a large quantity of serous fluid escaped, tinged slightly with blood. The tumor, which was sarcomatous, was found adherent to the great omentum at numerous points, and had for its point of origin the right ovary. In order to facilitate the operation the incision was enlarged. It now became manifest that, owing to adhesions, the whole tumor could not be removed, except with immediately fatal result, and accordingly the abdomen was closed; portions of the tumor being left in the abdominal cavity in two localities, one the size of a fist on the left of the spinal column, another, somewhat smaller, in the cavity of the pelvis. Antiseptic dressings were applied, and the patient during the following day and night was in a satisfactory condition, with only a slight rise of temperature (99.5° F.), but febrile symptoms were further developed, and death from peritonitis ensued a day later.

Orchitis Produced by Strain; Atrophy of the Testicle.—Dr. Feuillon reports an interesting case of orchitis produced by strain, and followed by atrophy of the testicle.

The patient, a man, aged 45 years, married, healthy, denied ever having had any venereal disease, and that previous to the injury related below, both testicles were normally situated in the scrotum.

Two months previous to his entrance into the hospital, while attempting to lift a bar of iron, he suddenly experienced pain in the left testicle, so severe that he fainted. No direct blow was received, nor, indeed, was there any trace of violence.

The patient affirmed that he then found the testicle drawn up into the left groin. It was very painful, and at the same time affected the corresponding side and abdominal region. Vomiting, obstinate constipation, and swelling, were also experienced for a measurable period. These symptoms finally abated, but the testicle remained fixed and painful in its new position. After three weeks the pain in a great measure disappeared, but at once returned when the patient attempted to rise from his couch. In this condition he came to the hospital. The testicle was found firmly fixed at the external inguinal ring; it was atrophied and reduced to about one-fifth of its normal size. All efforts to release it were ineffectual, and while the least manipulation caused extreme pain, the patient also suffered from all the symptoms of ilio-lumbar neuralgia. This condition having been persistent for three months, castration was decided upon as the only means of relief. The tunica vaginalis was found adherent to the adjoining tissues by fibrous bands, and a portion of the epididymis had disappeared within the inguinal canal.

The operation was concluded without difficulty, and the patient made rapid recovery, being able to walk without difficulty in less than four weeks. Examination of the testicle showed an almost complete destruction of the tubules of the testicle, which were encroached upon by dense peripheral fibrous tissue. The epididymis likewise had completely lost its normal structural peculiarities, and was composed almost entirely of cicatricial tissue.

The possibility of the occurrence of this accident in

the manner related has been questioned, but the present case removes all doubt on the subject. Retraction of the testicles from other causes has been previously noticed by other writers, among whom are Kocher and Lewin, to whose papers the report of M. Feuillon makes an interesting addition.—*Annales des Maladies des Organes Génito-Urinaires*, April, 1884.

LARGE URETHRAL CALCULUS IN A WOMAN PAINLESSLY REMOVED BY INJECTION OF HYDROCHLORATE OF COCAINE.—M. JULES BATUAD, in the *Gazette Médicale de Nantes*, April 9, 1885, reports a case of urethral calculus removed from a woman in whom the operation was rendered entirely painless by the use of hydrochlorate of cocaine. The patient was 67 years of age, and complained of extreme pain and burning on urination, together with the appearance of blood at its completion.

Vaginal examination revealed the presence of an extremely hard tumor situated at the bulb of the urethra, larger and of the shape of an almond. On introducing a catheter it came in contact with a hard body, and urethral calculus was diagnosticated. On account of the age of the patient, the administration of chloroform was considered dangerous, and it was determined to resort to hydrochlorate of cocaine. Previous to the operation the urethra, which was very much contracted, was dilated with Huguier's dilator. On operating, a solution of cocaine, 1 to 10, was then made, and the vulva, anterior portion of the vagina, and the meatus, painted freely. A portion of the solution was then injected into the pocket containing the calculus, with the effect of rendering the parts completely anæsthetic.

The operator, M. Chéron, introduced a curved trocar into the meatus, and passed it through the utero-vaginal septum immediately in front of the calculus. A platinum wire was then introduced and connected with a galvano-cautery brought to a red heat. No pain was experienced by the patient, and in four minutes the stone was extracted without loss of a single drop of blood.

The calculus weighed 310 grains, and was one and two fifth inches in length, about one inch wide and four-fifths of an inch thick.

The wound was washed with boracic solution, and iodoform dressing applied, and kept in position by appropriate bandages. The sphincter of the bladder was intact, and the patient suffered from no complications, urethral fever, or secondary hemorrhage. The case is interesting:

1. On account of the relative infrequency of large urethral calculi in women.

2. Owing to the complete anæsthesia obtained by the application of a 1 to 10 solution of cocaine in an impressionable patient.

3. As illustrating the advantages of the galvano-cautery in such operations, and on account of the complete preservation of the function of the sphincter of the neck of the bladder after its use.

FEMORAL NEURALGIA; RESECTION OF THE ANTERIOR EXTERNAL CUTANEOUS NERVE, RESULTING IN CURE.—DR. W. HAGER reports a case of femoral neuralgia cured by excision of the anterior external cutaneous nerve.

The patient, a young woman with no history of previous nerve affection, received, at a dance five years previously, a blow upon the left hip. The blow—a kick—was so powerful that in attempting to parry it she sprained her right ankle. From this she recovered, but there remained a continual dull pain in the hip, which never abated. Occasionally, after great exertion, the pain assumed a lancinating character. As a result of the constant pain the patient had become pale and emaciated, and complained of sleeplessness. No treatment was in the least beneficial, and though quinine, iron, arsenic, salicylic acid, and hot baths had been tried, no relief was obtained.

Dr. Hager first saw the patient September 13, 1884. Examination revealed extraordinary hyperæsthesia of the external portion of the thigh, especially in the region of the anterior superior spinous process. The least motion was painful, owing to the extreme sensibility of this region. Attempt made to rise from a sitting posture by means of the left leg was futile, resulting only in excessive tremor of the limb, and its falling powerless to the floor. No disease or swelling of the periosteum was recognizable, and pressure upon the great nerve trunks caused no unusual pain. At the second examination, made September 29, Dr. Hager discovered a thin cord-like structure in the region above referred to, which, under pressure, was painful in the extreme. The course of this cord corresponding to the anatomical position of the anterior external cutaneous nerve convinced Dr. Hager that the neuralgia had its origin in a diseased condition of the nerve, and he decided upon its resection. The operation was accordingly performed, and two and a half inches of the diseased nerve tissue were removed, and the wound closed with three catgut sutures. The day succeeding the operation there was complete anæsthesia of the region supplied by the nerve, and also of the entire outer third of the thigh as far as the knee. The dull pain, moreover, disappeared, and has not since returned. Careful treatment by rest and massage was instrumental in relieving the remaining symptoms, and the patient declares herself perfectly cured.—*Deutsche medicinsche Wochenschrift*, April 2, 1885.

ERYSIPELAS AND SEPTICÆMIA.—In a discussion upon the nature of erysipelas held at a recent meeting of the French Academy of Medicine, M. HERVIEUX expressed the view, based upon observation and experience, that:

1. Identity evidently exists between erysipelas and septicæmia, whether the latter be puerperal or surgical.

2. That erysipelas being only an expression of septicæmia, may on occasion produce the latter just as septicæmia may produce erysipelas.

2. That erysipelas demands therefore from the surgeon the same remedial measures as are required in septicæmia.

M. Trélat, in discussing the views of M. Hervieux, said that the identity of the two diseases, as yet, is not a recognized scientific fact, and that science has not yet determined the nature of the agent or microbe which produces erysipelas. Whatever may be the differences or analogies which exist between the agents producing erysipelas and septicæmia, the fact remains that erysipelas ordinarily does not pursue the course of septicæmia, but, nevertheless, though the question is still undecided, it is true that all antiseptic precautions are also precautions against erysipelas.—*L'Union Médicale*, April 23, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MAY 30, 1885.

THE TREATMENT OF TUBERCULAR ABSCESS.

AMONG the interesting topics which were discussed at the recent Congress of French Surgeons was that of the management of cold, strumous, or tubercular abscess, an account of which may be found in the weekly medical periodicals of Paris for April. Although there was some difference of opinion as to the best mode of treatment, the discussion disclosed a great advance over the old method of leaving such collections of pus unopened until they were ready to evacuate themselves spontaneously, or of resorting to aspiration. As will be seen, the majority of the speakers were in favor of effecting riddance of the wall of the abscess, or of the so-called pyogenic membrane, and effecting union by the first intention.

Cazin resorts to extirpation of the wall, which is rendered easy by the method practised by Pozzi for the ablation of cysts. The fluid having been evacuated by an aspirator, melted paraffine is injected into the sac, and its solidification promoted by the ether spray. The sac is then readily dissected out, the parts approximated by sutures, and a drain inserted. Bouilly also advises extirpation of the sac.

Pozzi, on the other hand, prefers attacking the wall of the abscess with the spoon, actual cautery, and iodoform, while Socin resorts to incision, scraping, and removal of the greater portion of the sac, with subsequent suture and drainage. Of 25 cases of tubercular abscess connected with caries of the vertebræ, treated in this way, 5 were completely cured, 16 recovered with fistulæ, and 4 were failures, and of 20 connected with disease of the ribs, or sternum, 12 were cured. Of 25 idiopathic cases, 19 were cured, and 6 failed. Bœckel agrees with Socin, and reports 5 cures out of 7 examples of psoas abscess. Access to the sac is secured by an incision from two and a half to three inches long parallel to Poupart's ligament, and a second incision over the femoral prolongation of the sac, and free drainage is obtained by an opening made in the loin.

Houzel favors ablation of the sac, and recommends a special form of drainage, which we think possesses no particular advantage. Verneuil, however, has abandoned extirpation and scraping of the sac in favor of an injection of an ethereal solution of iodoform, which permits the deposit of the remedy, on the evaporation of the ether, in all the recesses of the sac. He states that he has recently successfully treated in this way a cold abscess which contained six pints of pus, and which extended from the knee to the diaphragm.

In the present state of our knowledge we believe that the proper treatment of tubercular abscesses may be summed up as follows: Extirpation of the sac when it is small and the operation is practicable; early, free, and dependent incision, with irrigation with a proper solution of corrosive sublimate, and adequate drainage, in spinal abscesses; or the injection of iodoform dissolved in ether or glycerine, in similar cases, when the patient cannot remain in bed, or when, for other reasons, aseptic incision and drainage are impracticable. In this connection we may recall the fact that the iodoform treatment originated with Mikulicz, and that Verneuil has never done him the justice to give him the credit for it.

A RECENT MALPRACTICE SUIT.

THE beauties of the jury system are well illustrated by a trial recently concluded in Cincinnati; and the fact is once more brought before us that care and skill, and the conscientious performance of even the plainest duties may fail to protect a surgeon when placed at the mercy of "twelve good men and true;"—good enough, perhaps, in the ordinary relations of life and true to their sympathies, but too often utterly incapable of forming a correct judgment on any subject beyond the limited range of their experience.

It would be difficult to imagine a plainer case of practice than the one that was made the basis of a recent suit against Drs. Williams, Ayres, and Sattler, of Cincinnati, and no hospital surgeon passes a day without incurring at least equal risk. The case is briefly as follows: A boy, sixteen years of age, while at work in a machine shop, was struck in the left eye by a piece of iron, and was brought, about an hour afterwards, to the office of these gentlemen for treatment. Intense congestion of the eye had already appeared, there was blood in the anterior chamber, and hemorrhage in the vitreous prevented ophthalmoscopic examination, the iris was tremulous,

and the lens partially dislocated, the ball had lost all tension, and a wound in the sclerotic showed plainly the entrance of the foreign body. The course to be pursued in such a case is too evident for discussion. Supposing it to have been possible to remove the foreign body, so much injury had been inflicted that it would not have been safe to let the eye remain. Even when much less mischief has been done, the attempt to remove foreign bodies from the vitreous may be considered questionable. In a discussion of this subject at the last meeting of the American Ophthalmological Society, Dr. Knapp expressed himself as follows: "It is a very nice thing to attempt their removal, and occasionally we succeed, but, from my own experience and a study of the literature, I have sometimes thought it would be best to take all such eyes out, without any scruple. I am sure that by proceeding in this way, the greatest good would be done to the greatest number." The three surgeons, against whom the suit was brought, examined the eye and advised enucleation, but the boy's parents positively refused to allow it.

After a few weeks of treatment, the patient ceased to attend and commenced a course of migration from one surgeon to another. During a period of more than two years he was under the care, at different times, of four other surgeons, all of whom urged enucleation in vain, until at last it was consented to when too late to save the other eye. The foreign body was found, at some distance from the point of entrance, encapsulated in the ciliary region.

One would have supposed that such a case as this would be too strong for the smartness of any lawyer or the stupidity of any jury, and that no attack could make any impression upon its defences. Nevertheless, there was not only a vigorous and prolonged campaign, but a partial victory. The jury, after deliberating for two days, were unable to agree, but stood eight for the plaintiff and four for the defendant. $20,000 damages were demanded.

The prosecution first charged neglect to remove the eye, but a change of base soon became necessary, and the plea was made of neglect to remove the piece of iron. It was supported by the quotation of a case recorded in Mauthner's work on *Sympathetic Diseases of the Eye*, in which a small piece of iron was removed from the wound in an eye not seriously injured; and by the deposition of an entirely unknown self-styled oculist of New York, who detailed what he would do in a hypothetical case arranged by the lawyers. This, with an eloquent peroration on the poverty of the plaintiff and the wealth of the defendants, did the business for eight of the jurymen.

A new trial will probably take place, and it will be interesting to all who are liable, at any day, to be placed in the position of our Cincinnati *confrères* to watch the result. It is a comfort to remember that even if twelve men can be found to equal the stupidity of the eight in this case, there still remains one possibility to redeem the jury system from hopeless absurdity—a righteous judge may set aside a monstrous verdict. This was the ending of an equally groundless and shameless suit brought against a well-known ophthalmic surgeon of Philadelphia, some years ago; but not until he had endured nearly two years of persecution. Fortunately, such suits, if bravely met, usually in one way or another come to naught; but the loss of time, the interference with work, the expense, the worry and anxiety—who can estimate but those who have been the victims?

PODALIC VERSION—A NEW INDICATION FOR IT.

In the May number of the *Edinburgh Medical Journal*, in an interesting paper upon podalic version, Dr. S. Lawrence reports that, in 500 cases of labor, he resorted to podalic version forty-three times, once for puerperal convulsions, twice in arm presentation, twenty-two times on account of obstruction of the pelvic brim, and eighteen times because of insufficient uterine action threatening tedious labor.

A brief consideration of the results of podalic version in the cases of contracted brim may prove instructive. In nine of the twenty-two, premature labor was induced about the end of the eighth month; all of the children were born alive, and two of the mothers died. In the remaining thirteen cases, labor occurring spontaneously at or about term, there were nine living and four dead children. Now, without having the very great faith in statistics which George Eliot attributed to Mr. Buckle—who looked for the time when superstition would be banished, and statistics reign forever and ever—it seems to us that the facts Dr. Lawrence mentions in relation to version in contracted brim show, so far as they show anything, that this operation is admirable when premature labor is induced, but fails if labor occur at full term; in the former case the delivery can be effected so much sooner—the head being smaller, and more easily moulded — that the probability of the child being born alive is very great. On the other hand, delay in delivery of the head being not rarely a cause of death in pelvic presentation, even when the birth canal is in every respect normal, how much more likely is such an event to occur if the canal be narrowed.

Dr. Lawrence had lost three mothers out of the twenty-two cases of podalic version; that is, the mortality was 1 in 7. Sir James Simpson, who so strongly advocated podalic version in narrowed brim, claimed that the maternal mortality in craniotomy was 1 in 6. It will thus be seen that Dr. Lawrence's statistics are only very slightly better, that podalic version is very little superior to craniotomy; but, when we add the

saving of infant life, the value of the method becomes greatly enhanced. Still, the question is not always between podalic version and craniotomy, for it may be asked, might not the forceps have saved as many lives as podalic version did in these cases?

In the eighteen cases in which podalic version was resorted to because of inefficient uterine action, all the children were born alive, and all the mothers made excellent recoveries. Certainly this showing is excellent, but ought the new departure to be imitated? That podalic version is useful in such cases is proved by Dr. Lawrence's results. But here, as in life generally, the application of a rule or principle to a particular case or condition presents the difficulty. How do we know in a given case that a labor will be tedious, or may become powerless? How often are the prognostications of the obstetrician put at naught, and a labor that has threatened to become lingering, changing its character, rapidly goes on to a favorable termination! It is easily seen that one may needlessly resort to this treatment in some cases.

Further, the plan is liable not only to mistake in application, but also to abuse. Impatient obstetricians, finding how certain a means they have for ending a labor and saving their time, may resort to podalic version unnecessarily, and a needless operation is liable to be an injurious one.

We must believe that this new indication for podalic version ought to be very fully considered in all its aspects before being adopted or, on the other hand, rejected.

THE SANITARY ASPECTS OF CABLE ROADS.

The construction of cable roads by the plan adopted in Philadelphia suggests an inquiry into the possibility of the conduits causing an offensive nuisance by the decomposition of refuse matter collecting in them. The main feature in the construction of these roads is an underground passage-way of iron for carrying a steel cable, by which the cars are to be drawn over the streets. It is about one foot wide at its base with sides gradually curving upward a distance of about two and a half feet to a central slot about three-fourths of an inch wide, and opening at the level of the street. The capacity of this channel is about equal to that of a small sized sewer.

As might have been expected, dust and mud are constantly forced through the slot and filthy washings from the street surface flow through this opening during every rainfall, and form accumulations within the conduits. To get rid of liquid matter, connections have been made with the sewers at numerous places, and traps are made use of to prevent the escape of sewer air. Manholes have also been constructed at close intervals for the purpose of cleaning out the accumulations of solid matter, as well as for making examinations and repairs. It is to the interest of the company that the conduits shall be kept as free as possible from extraneous matter; it is to the interest of the public that they shall be kept free from filth and foulness. How well these objects will be carried out remains to be seen.

It would appear from the limited observation which has thus far been permitted and by reasoning from the conditions likely to occur, that unless the filthy accumulations are frequently removed, and the ducts as frequently cleansed by the scouring action of a large body of water, a very objectionable nuisance will be created by the escape of foul air upon the streets. Unless the traps upon the sewer connections are made effective, and thus maintained, the conduits will become as noisome as the sewers themselves.

The means to be adopted to prevent the occurrence of a nuisance are therefore the frequent and complete removal of solid matters, the frequent flushing of the surfaces of the conduits by an effective body of water, and the maintaining of traps on all sewer connections in good working order. Careful attention to these three points will, without doubt, do much to prevent any just cause of complaint against the cable road from a sanitary standpoint.

LITHOLAPAXY AND LITHOTOMY IN INDIA.

From a paper contributed to the *Lancet* for February 28th, and March 7th and 14th, 1885, we find that Dr. Freyer, surgeon to H. M.'s Bengal Army, has performed 291 operations for stone in the bladder, which were attended with some remarkable results, and which are interesting as recording the experience of a single operator in a special field of surgery.

That litholapaxy is a most successful procedure in India is shown by Freyer's 111 cases. Of 108 cases in adult males, 4, or 3.7 per cent., died, while in the 3 examples in female children below the age of five, the patients were running about the following day, without the slightest inconvenience. The safety of litholapaxy is moreover shown by comparing it with lateral lithotomy, 50 operations in adult males having been attended with 9 deaths, or a mortality of 18 per cent., in the hands of Freyer, or a mortality of 11 per cent., based upon 2730 cases which occurred in six presidencies or provinces of India, in 1882. In male children or boys, on the other hand, Freyer's 132 cases of lateral lithotomy were uniformly successful, a result which is without precedent.

These results confirm the rule now recognized everywhere, except perhaps in Germany, of resorting to litholapaxy in adult males and females of all ages, and lateral lithotomy in males below the age of puberty, a rule which should not be departed from, unless it be in those exceptional cases in which epicystotomy is clearly indicated.

SPECIAL ARTICLE.

PRELIMINARY REPORT OF THE SECOND SERIES OF SESSIONS OF THE GERMAN CHOLERA CONFERENCE.

THIRD SESSION, MAY 4, 1885.

IN July last a Cholera Conference was held at the Imperial Health Office at Berlin, at which Professor Virchow presided, and a full report of which appeared in THE MEDICAL NEWS of August 23 and 30. It will be remembered that Dr. Koch opened the proceedings with an address upon his researches in India and Egypt on the origin and dissemination of the disease. At the close of the Session, it was resolved to meet again this year, and the Conference was held on May 4, 5, 6, and 7.

There were present, besides the earlier members, Prof. v. Pettenkofer of Münich, and Dr. Günther, as associates of the former Imperial Cholera Commission, and the Director of the Imperial Health Office, Dr. Köhler. The Conference entered into the discussion of the first question on the schedule of the proceedings to wit: *The demonstration and discussion of the experimental data obtained since the preceding session concerning the bacteria of cholera, with especial reference to their qualities of duration.*

PROF. KOCH opened the discussion by referring to the results published since the last meeting of the Conference. He held that the arguments of the opponents (Finkler and Prior, Klein, and Emmerich) of the bacillar origin of cholera had been critically refuted, and that from confirmed experiments the conclusion had been reached that the comma-bacillus is present nowhere else than in cholera, and that in this disease it is never absent. In proof of this conclusion, he cited the results of his examinations of cover-glass preparations of the choleraic secretion of seventy-five patients sent from Calcutta, and he showed that they were identical with a series of pure cultures of the comma-bacillus from France, Italy, and Germany. He considered it established that the comma-bacillus is exclusively a concomitant of cholera, that it may easily be distinguished from all other forms of bacteria, and is of positive value in diagnosis.

He then gave a description of his experiments upon guinea-pigs with pure cultivations. For these experiments five c.cm. of a five per cent. solution of soda, and twenty minutes afterwards ten c.cm. of meat infusion containing comma-bacilli were injected into the stomach; immediately afterwards laudanum was injected into the abdominal cavity (one c.cm. for every two hundred grammes of weight). The animals were thereby narcotized for one-half hour or an hour, but afterwards fully recovered. The following day they appeared ill; their hair was rough; there was weakness of the hinder extremities and of the muscles of the back, and they died in from one to three days. Dissection showed infiltration of the small intestine, which, as well as the stomach and cæcum, was filled with a colorless alkaline flaky fluid which contained a pure culture of comma-bacilli. Experiments of this kind were performed with eighty-five guinea-pigs.

Moreover, the use of the solution of soda and opium has been found to render the animals more easily susceptible to the pathogenic action of other bacilli; and the same experiments, but in a less degree, succeeded with the bacillus of Finkler, and that of Denecke. But in these latter experiments other phenomena were manifested. Thus, Finkler's bacillus caused a true decomposition, as is evidenced by the odor of the contents of the intestine. Therapeutic experimentation upon animals injected with the comma-bacillus has to the present time only shown that large doses of calomel, or the administration of naphthalin prolonged the life of the animal one day.

The comma-bacillus is quickly destroyed by drying and by certain disinfectant agents—*e. g.*, solution of carbolic acid of a strength of one-half per cent. To the observations upon men—which may be considered as infection-experiments (Klein, Macnamara)—Dr. Koch added some new data. One of the one hundred and fifty physicians who attended the course at the Health Office was attacked with the disease. In his dejections the comma-bacilli were found, and pure cultivations were made.

Concerning the vitality of the comma-bacillus, investigations have shown that in spring water it is maintained for thirty days, in sewerage seven days, in privy wells twenty four hours, upon damp linen three to four days, in the harbor water of Marseilles (according to Nicati and Rietsch) eighty-one days, and upon agar-agar longer than one hundred and forty-four days. This peculiarity of duration in active condition was not recognized as belonging to the spores of other bacilli.

PROF. V. PETTENKOFER declared himself not thoroughly convinced by the statements of Dr. Koch—since but little is proved by the experiments upon animals, and much better results had been obtained by Emmerich, who brought from Naples to Münich the pure culture of the comma-bacillus. The manner in which Dr. Koch infected guinea-pigs gave no explanation as to how human beings are affected by cholera. He could not acknowledge the comma-bacillus as the special cause of cholera, but considered it more probable that cholera induced certain conditions which favor the development of bacilli, and thus its uniform presence during the disease is explained. The laws of the epidemic manifestations of cholera were strained in the assumption that the comma-bacillus is the exciting cause of the disease, for whereas the bacillus is destroyed by dryness, in Lower Bengal the dry season directly favors the disease. Then, admitting that the comma-bacilli are present only in the intestine and not in the organs, it must be assumed that they produce an intensely active poison in the choleraic intestine, which has but little power of absorption; but in the pure cultures made at Münich such a condition has not been recognized. Cholera does not appear to be a combination of infection and intoxication, but a purely infectious disease. In the future, it remains to be decided whether Emmerich's bacilli can be regarded as the excitant of the disease. These were found in the different organs, as was shown by pure

culture, but were invisible in microscopical sections. Animals infected with them died with symptoms of cholera, having been seized with vomiting and diarrhœa. However the verdict as to the bacilli may be decided, there must first be demonstrated an agreement with the laws of epidemics. If those sick with cholera are not directly infected, the cholera fungus cannot be the cause of the disease, and if cholera is dependent upon season and locality, then also a cholera fungus cannot determine it.

DR. B. FRÄNKEL called attention to the fact that the only bacterium of the intestine which is morphologically similar to the comma-bacillus, is a comma-shaped vibrio occurring in the mouth. Like many other investigators, he had endeavored to cultivate this organism, which he had shown Dr. Koch before the previous Session of the Congress. He could positively affirm that this special form will not grow in gelatine culture.

DR. KOCH, replying to the observations of Prof. v. Pettenkofer, pointed out that the methods employed by Emmerich were open to objection and to error. It is entirely without analogy that a bacillus should exist and be secondary to a disease with which it was solely associated. The dry season of the year, Koch maintained, in no wise makes Calcutta dry, but diminishes the rich water-supply of the city. In contrast to the negative results reached at Münich to obtain a poison from pure cultures of the comma-bacillus were experiments not yet concluded, which he was making, giving positive results. As yet there has been no recognized case in which cholera, like anthrax and smallpox, has been spread by dry conditions, and experience was opposed to there being a permanent state of the bacillus.

FOURTH SESSION, MAY 5TH.

PROF. V. PETTENKOFER, in resuming the discussion, pointed out that the supposition that the comma-bacillus, or Emmerich's bacillus, is the cause of cholera, leaves unexplained many phenomena of the disease—*e. g.*, its latency in winter, and the subsequent renewed activity of the disease and its recognized dependence upon season and locality. Continuing, he compared the cholera infection with that of malaria, which although communicable by inoculation, still depends upon the soil. He insisted that a distinction should be observed between artificial and natural infection, and declared himself not convinced by the results of experimental infection that epidemics of the disease arise in the same manner as experimental infection.

PROF. VIRCHOW gave, as his opinion, that experiments with animals are not absolutely required, inasmuch as not all the diseases common to mankind are transmissible to animals. The symptoms present in animals infected with Emmerich's fungus, may easily be mistaken for those of cholera, while there are many substances which can produce precisely similar conditions. As long ago as 1847, by the injection of putrid material into the blood of dogs, he produced not only similar anatomical changes, but also excited vomiting, diarrhoea, and other symptoms of cholera, thereby producing parallel manifestations, but he had guarded himself against considering the two conditions identical. In Koch's experiments the opium may have prevented diarrhœa and vomiting, and therefore the experiments were in a certain sense defective, and their repetition is necessary. Emmerich, who otherwise had used extreme care, took the living venous blood, and therein cultivated his bacillus, and perhaps has obtained an accidental form of bacillus.

An argument in favor of Koch's bacillus is the fact that it is found constantly in the intestine, which is the especial seat of cholera. The secretion of the stomach is not always acid, and possibly dyspeptic conditions may render a previous preparation of the animals superfluous. Even in the diseases long recognized as dependent upon fungi—*e. g.*, "muscardine" or potato disease—the question cannot yet be answered why the epidemic arises and why it disappears, and in spite of the knowledge gained respecting morbific fungi, but little progress has been made in explaining the cause of epidemics. Although the comma-bacillus had no permanent form, yet it had a certain duration of life, for Dr. Babesch, who is pursuing his investigations in the Pathological Institute, has found, after six months diligent labor, a special form of vegetation, composed of broad, longitudinally striated spirilla, that was very durable. They originate in low temperatures, and quickly change into short comma-shaped forms. The bacillus shows distinct forms under varying external conditions. The vesicular forms described by Ferrán as evolved from the spirilla, are disintegration products and are sterile. The length of the life of this bacillus is sufficient to explain the slow progress of the disease from year to year. In other directions the discovery of this bacillus was a positive gain to knowledge in the surer recognition of the facts concerning the disease. It was not opposed to what experience has shown, as pointed out by the excellent labors of Pettenkofer, as to the dependence of the disease upon season and locality, but speculation must not be too deeply entered upon while the practical side of the question is lost sight of.

DR. HIRSCH considered that investigations in connection with the pathogenesis and prophylaxis of the disease are deserving of at least as much attention as the study of its bacteriology.

After some further remarks by Drs. Koch, Pistor, v. Pettenkofer, and Virchow, the discussion of the first question closed.

The second point for discussion was, *The Spread of Cholera by Human Intercourse, by Pilgrims, and Ships.*

PROF. KOCH opened the deliberation concerning this question by emphasizing the fact that cholera is spread by pilgrims in India, and cited additional examples of long-continuing ship epidemics, and showed how unreliable were the accounts given by sailors.

PROF. V. PETTENKOFER, in reply, attributed little importance to pilgrimages and railroad travel in the spread of cholera, and urged caution against assuming that cholera is spread by travellers.

After the close of the meeting, Prof. Koch gave a demonstration of dead and living guinea-pigs which had been infected with the comma-bacillus.

FIFTH SESSION, MAY 6TH.

The discussion of the second question was continued in conjunction with that of the third, *The Influence of Soil, Air, and Water upon Cholera.*

DR. GUNTHER cited instances to prove that intercourse between individuals does not always produce cholera, but that the occurrence of an epidemic is dependent upon the influences of time and place.

PROF. HIRSCH replied that human intercourse did not invariably cause the spread of cholera, but that every epidemic has such communication for a cause.

PROF. KOCH exhibited the results of the demonstrations made the day previous. Of the fourteen inoculated guinea-pigs only two had survived, and these also showed symptoms of infection. He suggested that possibly the same condition obtains with the cholera fungus as has been observed in other plants, namely, that sometimes especially favorable conditions for their existence are found temporarily; but, nevertheless, they afterwards die for lack of these conditions.

Dr. Koch brought forward examples to show that an acquired immunity from cholera may exist. We cannot expect in all cases to recognize such condition directly, but must be content to establish it indubitably in a certain number of cases. The fact was of the greatest importance in view of the prophylactic measures to be taken by the authorities. The long duration of cholera upon ships cannot be explained, if the soil is considered the only requisite for its outbreak, but it could be accounted for on the view of transmission from man to man, for the incubation period of cholera is short.

PROF. GÜNTHER said the incubation period of cholera lasted usually four days, but that cases were known to him in which the period had been from ten to seventeen days.

DR. MEHLHAUSEN cited instances of the spread of cholera by disbanding troops; and DRS. HIRSCH and EULENBERG gave similar instances of its spread by rafts.

PROF. V. PETTENKOFER did not deny the fact of an acquired personal immunity after an attack, but asserted that it was the local immunity which determined the occurrence of an epidemic. The disposition of a locality for an epidemic consists in part of local constant conditions, in part of local transitory (seasonal) factors. He did not deny at all the influence of traffic upon the spread of cholera, but this alone does not suffice to call forth an epidemic, and for this reason season and place must be entered as factors. In what manner the infective germ is taken from land upon shipboard he does not know. The simple shipment of a cholera patient does not suffice to cause the disease to spread.

PROF. VIRCHOW said that the supporters of the contagion theory of cholera do not assume that the transference must be directly accomplished from man to man; that is proved by infection through cholera linen, and still more by the pure cultures in which the propagation and sustenance of the cholera germs take place outside the body. It is certainly shown by pure cultures that it is not the earth wherein the germs thrive, and to the present time no case has been known where the existence of the cholera germs in the soil was proved. Notwithstanding this, he does not deny its possibility, but only disputes the exclusiveness of the soil theory. Experiment and observation of separate cases yield more certain conclusions than whole epidemics, which were only considered on a large scale. He had personal knowledge of the transference of cholera from man to man in 1871 and had published a conclusive observation in his collected works. Reference was made to an instance in which, while but one case of cholera existed in a hospital, three men were attacked who had assisted in the care of this patient. Upon board of ships transferences of cholera occur which are in nowise connected with the soil. As an example, he cited the transatlantic steamer Franklin. Although there is no doubt that the spread of cholera does not depend upon a poison, or germ arising from the soil, or is connected with an infection arising therefrom, still what is as yet known of the history of the comma-bacillis does not exclude the possibility that the disease may not, under certain circumstances, be contained and propagated in the soil. He, therefore, saw no difficulty in coming to an agreement with Prof. v. Pettenkofer, provided he abandon his exclusive standpoint of view.

PROF. V. PETTENKOFER said that he originally considered the contagion of the disease as of the highest importance, but that observation of the varying behavior of cholera, according to time and place, had compelled him to ascribe to these special importance.

DR. MEHLHAUSEN cited instances observed in Thorn in 1873, of undoubted transmission of cholera from person to person.

The next session was held May 7, and the report of the discussion will appear in our next issue.

SOCIETY PROCEEDINGS.

ILLINOIS STATE MEDICAL SOCIETY.

Thirty-fifth Annual Meeting, held at Springfield, May 19, 20, and 21, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, MAY 19TH.—FIRST DAY.

THE Society was called to order, at ten o'clock, by THE PRESIDENT, DR. D. S BOOTH, of Sparta. After prayer, by Rev. F. H. Musgrove, an

ADDRESS OF WELCOME

was delivered by His Excellency, GENERAL RICHARD J. OGLESBY, Governor of the State of Illinois. His remarks were brief and felicitous. He welcomed the members of the Illinois State Medical Society to the Capital as gentlemen, citizens, and physicians. He congratulated the people of the State that so many representative medical men could be found willing to leave their homes, with absolute unselfishness, to consult together for the public good. To physicians, more than to any other body of men, are entrusted the health and life of the people. He recognized in the science of medicine and surgery a field of infinite possibility as regards development. It is the function of these annual meetings to lift the subject above illiberal and envious criticism, and establish it upon a more enduring basis

than that of empiricism. It is true that the science of medicine and surgery is not as exact as geometry—a necessary consequence from the complex character of the phenomena. It is, however, absolutely the only guardian standing between society and the effects of disease and accident. There are dubious matters in every department of human activity, but in the practice of medicine and surgery that doubt assumes enormous importance, as human life is the issue at stake. Uncertainty in diagnosis and treatment—and every physician must at times be puzzled—only increases the dignity of the profession, since the mental agony experienced by an honest, conscientious man, under these conditions, is greater than in any other pursuit. This sense of moral responsibility must be greater in the physician than in the pure scientist, lawyer, or divine.

Dr. E. P. Cook, of Mendota, replied in appropriate terms to the address of welcome.

The President, Dr. D. S. Booth, of Sparta, delivered the usual

ANNUAL ADDRESS,

in which he discussed, in a humorous way, a variety of topics. He said that at the ninth annual convention of the American Academy of Medicine, at Baltimore, 1884, a committee was appointed to memorialize our national legislative bodies, with reference to the appointment of State Examining Boards in Medicine. The Illinois State Legislature should be memorialized in a similar way by the members of the Illinois State Medical Society.

A compliment was paid to female physicians and to one of their important functions in the repression of criminal abortion. The subject of female education was discussed at length, and many allusions were made to Dr. Goodell's excellent essay upon the topic. The germ theory of disease, the dangers of specialties, and sanitary science, received attention.

AFTERNOON SESSION.

Dr. David Prince, of Jacksonville, presented the

REPORT ON GYNECOLOGY.

In the treatment of uterine hyperplasia and plastic exudates within the pelvic cavity, he recommended that, in addition to vaginal irrigation with hot water, as suggested by Dr. Emmet, the interrupted current (faradic) be employed. A variety of gynecological instruments were exhibited.

Dr. Charles Warrington Earle, of Chicago, presented

THE REPORT ON OBSTETRICS.

He referred, in detail, to progress during the past year in various departments of the subject.

Anatomy and physiology; the ring of Bandl. Many valuable contributions to our knowledge of the condition of the cervix uteri during pregnancy and labor have been recently made. Dr. W. W. Jaggard, of Chicago, reviewed the literature of this subject in a paper read before the Obstetrical Section of the American Medical Association, at New Orleans. A marked tendency to revert to the original doctrine of Roederer and Stein, Sr., has been evinced by modern investigators. The researches of Carl Braun, Wilhelm Braune, and Ludwig Bandl, supported as they are by many clinical and pathological observations, go far to establish the fact that Schroeder's contraction ring, Spiegelberg's obstetrical internal os, Lah's pelvic-inlet stricture, Ebell's clinical or mechanical os, the ring of Bandl and Küstner, are different names for the true, anatomical internal os; that the cervix does not persist in a relatively unchanged condition until the end of pregnancy, but that, during the later months of utero-gestation, the entire supravaginal portion is usually drawn up into the cavity of the uterus.

Therapeutics. Dr. J. Suydam Knox, of Chicago, had recently read a paper entitled, "The Influence of Cimicifuga Racemosa upon Parturition," before the Chicago Gynecological Society (see The Medical News, April 11, 1885), which demanded careful consideration. Dr. Knox claimed very decided oxytocic properties for black cohosh. His conclusions were based upon the analysis of one hundred and fifty cases.

Dr. Svanberg, of Sweden, had recently written a paper upon the external use of chloroform in labor. A flannel saturated with equal parts chloroform and olive oil was applied over the surface of the abdomen, and all the benefits derivable from inhalation of the anæsthetic were secured. The subject was worthy of thorough investigation. Cocaine had been used in cases of rigid os with benefit.

Dr. Earle had written a paper, published in 1874, upon the function of electricity in post-partum hemorrhage. He referred to the excellent paper by Dr. Bater, of Texas, appearing in the April number of the *American Journal of Obstetrics*, in which the value of electricity in pregnancy and parturition is maintained. Dr. Earle agreed with Dr. Bater that electricity (faradic current) may profitably be employed in the following conditions: 1. Vomiting of pregnancy; 2. Accidental hemorrhage; 3. Induction of premature labor; 4. Aid to natural labor pains; 5. Oxytocic; 6. Prophylactic against post-partum hemorrhage.

Among antiseptic agents, the bichloride of mercury is, at present, the most popular; it has supplanted carbolic acid; real danger of mercurial toxæmia exists.

Pathology of midwifery. The association of albuminuria and eclampsia had been observed from the time of Dr. C. W. Lever, in 1843, up to the present day. Recent observers are inclined to believe that puerperal convulsions are not necessarily uræmic. He endorsed fully the treatment, recently advocated by Dr. H. D. Fry, of Washington, D. C. (see January number, *American Journal of Obstetrics*). Dr. Earle had used, with marked benefit, apocynum cannabinum.

Occipito-posterior positions, in vertex presentations, are of more frequent occurrence than old English text-books would lead one to believe. Leishman, in particular, was in error upon this subject. The mechanism of labor is difficult for the reasons that there are waste of uterine force, less resistance to the head, longer distance to traverse, and unfavorable adaptation of the presenting part. The etiology is a comparatively unknown subject.

In the management of such cases it is almost always necessary to resort to forceps. Dr. Edward Warren Sawyer, of Chicago, had read a paper upon this subject before the American Gynecological Society, at its last meeting in Chicago. Dr. Sawyer had seen forty-two cases of occipito-posterior position in vertex presentations—thirty-nine right, three left. Dr. Sawyer has been compelled to change the position of the occi-

put by bimanual manipulation, or by the application of forceps, in almost every case.

Face presentations. Schatz's method of correcting face presentations—transforming them into vertex—by flexion of trunk and allowing occiput to descend, is worthy of recommendation.

Application of the forceps in breech presentations. Dr. Earle had successfully applied the forceps in cases of breech presentation, before he became aware that the attention of the profession was directed to the subject.

Functions of the membranes in labor. Dr. Henry T. Byford, of Chicago, in the discussion of the possibility, probability, and utility of the preservation of the membranes from rupture until they dilate or aid in dilating the vulvo-vaginal orifice as well as the cervix, had advanced a most valuable method of prophylaxis against cervical, vaginal, and perineal tears.

Immediate operation for lacerated perineum. Dr. Alloway, of Montreal, had simplified a very complicated operative procedure, by the advocacy of the introduction of a single suture.

Treatment of retained membranes. Dr. Earle would select a course intermediate between immediate interference and pure expectancy. In labor, at term, it is necessary to distinguish between simple retention of a detached placenta, and retention on account of pathological adhesions. In the former case, Credé's method of expression fulfils every indication; in the latter case, it is necessary to introduce the hand into the cavity of the uterus, and sever the adhesions. While he recognized the danger of retention of the secundines in abortion, premature labor, or labor at term, he could not assent to the proposition of that gentleman who advocated the inversion of the uterus, and the peeling off of membranes and placenta in extreme cases.

Extrauterine pregnancy. Dr. Earle referred to the greater frequency of ectopic gestation than was formerly believed. He thought the plan of treatment advocated by Dr. Thomas the most rational method: 1. In the early months of pregnancy, fœtus living, its life should be destroyed by the interrupted current. 2. Fœtus alive at the expiration of the full term of utero-gestation, laparotomy is indicated. 3. Fœtus dead and the normal period of utero-gestation passed, the plan of treatment should be expectant.

Dr. David Prince, of Jacksonville, thought that the affusion of cold water upon the abdomen is a more simple and effective method in the treatment of post-partum hemorrhage than electricity. He narrated the history of a case of post-partum hemorrhage, occurring in an eclamptic patient, treated by the affusion of cold water upon the surface of the abdomen, with recovery.

Dr. C. Truesdale, of Rock Island, always advised the immediate operation for laceration of the perineum, but thought a very exact approximation of the surfaces necessary in order to avoid the formation of pockets in which pus and the lochia might collect. An imperfect closure of the rent is productive of more harm than benefit, and he did not think one suture adequate.

Dr. Wenger, of Gilman, is in the habit of rupturing the membranes when the *os uteri* is fully dilated. The dilatation of the cervix is the sole function of the membranes during parturition. He thought the configuration of the head, when the membranes are not ruptured, is less favorable to its passage through the parturient canal.

Dr. F. E. Waxham, of Chicago, had treated over one hundred cases of abortion and had only used the curette once. He had never lost a case. If the secundine cannot be removed by the finger, he allows them to remain *in situ*, and irrigates the cavity of the uterus twice daily with large quantities of carbolized water at a temperature that causes the patient no pain. Ergot is also exhibited under these conditions.

Dr. Kreider, of Springfield, exhibited an improvised rubber coil, mounted on cardboard, for mediate irrigation by Petitgaud's method.

Dr. T. M. McIlvaine, of Peoria, read a paper entitled,

MEDICINAL AND NON-MEDICINAL THERAPEUTIC AGENTS.

Between the optimists, who had unlimited faith in the action of remedies, and the pessimists, who had no faith at all, the majority of medical men take their position. Common sense is all important. All stereotyped rules and formulas must be departed from at times. He had recently treated a desperate case of typhoid fever. The patient rejected everything exhibited *per orem* but continually craved beer. The prognosis was so unfavorable that Dr. McIlvaine finally acceded to the patient's demands. Nine and one-half gallons of beer were consumed in the seven days following, and an uninterrupted convalescence ensued. A woman, with pelvic cellulitis, had been able to retain very little food, and that of a fluid character, for a period of ten weeks, urgently demanded saur kraut. One evening she ate six or seven ounces of raw kraut, the next day a larger quantity of boiled kraut, and after that no nausea was experienced, and the patient went on to full recovery. Professor Austin Flint, Sr., in a paper published in the *Transactions of the New York State Medical Association* had taken substantially the same ground upon this important subject.

Dr. E. P. Cook, of Mendota, would divide therapeutic agents—that is, drugs—into three classes.

1. Drugs, through which *positive medication* is possible. These drugs are few in number, and embrace the specifics.

2. Drugs, which may be *rationally* exhibited, but in regard to the action of which it is impossible to speak dogmatically.

3. Drugs, in regard to whose action we have actually no knowledge, are referable to "moonshine" therapeutics, and to transcendental schools of medicine.

Dr. N. S. Davis, of Chicago, said he thought there are few medical men who believe that drugs can *cure* all or most diseases. Such extravagant statements do injustice to the profession, lessen its dignity in its own ranks, and in the outside world. Dr. Chambers's statement that all disease is a retrograde movement, and that all treatment should be of a supporting character, was simply an extravaganza. Sedatives are indicated in pathological exaltation and increased functional activity, just as stimulants should be exhibited in depression. The nearer we keep to the true representation of facts, the better for ourselves and the community at large. Therapeutics is the most important and difficult of all the medical sciences, and the one to

which specialties have been of severest injury. In the enthusiasm roused by the germ theory of disease, old clinical methods of the observation of the course and cure of disease have been sadly neglected. He had no objection to putting salt on the microbe's tail, but he objected to the killing of the patient in the process. It is better to allow the microbe to kill the patient than in mistaken zeal to kill the patient in the hunt after the microbe.

Dr. T. F. Worrell, of Bloomington, referred to the modern school of therapeutics as being one of polypharmacy. He had grown up in the old Anstie school, where few remedies with known actions were exhibited. Recently he had seen a prescription from a celebrated physician in which eight distinct physiological actions were united—purgative, diuretic, diaphoretic, alterative, emetic, tonic, refrigerant and antipyretic were united in accord with shotgun principles. He still used *veratrum viride* in pleurisy and pneumonia, and accomplished good. Among emetics, he knew of nothing better and more harmless than ipecac. Among purgatives, rhubarb, calomel, blue mass and senna retained their old places. He had recently observed the foolish combination of strychnine in a laxative pill, upon the absurd theory that peristaltic action would be increased. Bleeding had been rejected *in toto* by the modern therapeutist—a most unwarrantable procedure. "Gentlemen, I exhort you not to forsake the paths which your fathers have trodden with so much benefit to their patients and honor to themselves!"

Dr. W. T. Montgomery, of Chicago, in his report on

OPHTHALMOLOGY AND OTOLOGY,

referred to the following topics: *Jequirity* in chronic granular conjunctivitis might be compared to iridectomy in glaucoma. Two years ago, while in attendance upon De Wecker's Clinic in Paris, he had seen jequirity used for the first time. Upon his return to Chicago, he had employed the drug in 250 cases of chronic granular conjunctivitis—all varieties of the affection, except the muco-purulent variety, with non-vascular cornea. A three per cent. infusion was an eligible preparation.

The lids were everted, and a brush saturated with the infusion was carried over the conjunctiva twelve times. In twenty-four hours, the desired inflammation, a peculiar membranous exudate, followed, with little local or constitutional disturbance.

Ten per cent. of all his cases were cured by one application. Twenty-five per cent. by two or three applications. Thirty per cent. by three to fifteen applications. Twenty per cent. were improved by one application. Twenty-five per cent. were not improved at all.

The applications were separated by intervals of at least twenty-four hours. In no case was more than the fourth application necessary to produce the inflammation. In two cases, the application three times was successful in producing the inflammation. Time required for recovery was one to three weeks. He had not seen a case of sloughing of the cornea, but three cases of dacryocystitis resulted from the treatment.

The drug should be used under the following precautions: 1. Never employ jequirity when the cornea is clear. 2. Never repeat the application within twelve hours. 3. Allow previous inflammation to subside before a second application.

Cocaine might be compared to the ophthalmoscope, in the inauguration of a new era in ophthalmology. Nothing so important has been invented or discovered since the days of general anæsthesia. Since November 1, 1884, Dr. Montgomery has performed the following operations with cocaine as a local anæsthetic: 2 cataracts, 15 needle operations, 5 iridectomies, 2 iridectomies for glaucoma, 1 foreign body in anterior chamber, 30 tenotomies, removal of numerous foreign bodies from cornea, Bowman's operation for pterygium. He employed a two to four per cent. solution. In iridectomy for glaucoma, the removal of foreign bodies from the anterior chamber, cocaine had yielded unsatisfactory results in his hands. In tenotomy of the recti, the injection of a few drops of the solution into the cellular tissue was of advantage. 10 cases of phlyctenular keratitis had been treated with the drug, and excellent results secured. In 12 cases of iritis, results were only partly satisfactory; relief from pain was incomplete.

One case of episcleritis was treated by the bichloride of mercury and potassium iodide internally and cocaine locally. He was unable to decide whether or not the anti-syphilitic treatment was the active agent.

Professor Graefe's substitution of *evisceration of the bulb* for enucleation was important, as there is no danger of meningitis, and the stump is superior. Although Professor Graefe claims the operation as original, Professor E. L. Holmes, of Chicago, had performed the operation years before, and Dr. Montgomery himself, at Professor Holmes's suggestion, had used this method in 1876.

Chancre of the eyelid, produced in an unusual way. A patient, two months ago, while at work in the kitchen, spilled the pepper-box into her face. A domestic endeavored to clear the conjunctival surfaces by the insertion of her tongue under the palpebral conjunctiva. Two weeks later, a characteristic sore appeared.

Dr. S. J. Jones, of Chicago, thought that it was not justifiable to employ jequirity in chronic granular conjunctivitis in the present state of our knowledge. The local effect and constitutional reaction are not always insignificant. Sloughing of the cornea and dacryocystitis are well-known effects of local application; chill, high fever, and nervous symptoms have followed as evidence of systemic reaction. The entire treatment is empirical. De Wecker received the drug from a South American patient, found it effectual in a few cases, and based his deductions on too little experience. The drug should not be condemned, neither should it replace old, tried, effectual, and *harmless* agents. In his own case, he would not employ the remedy; patients deserved the same consideration.

He thought hydrochlorate of cocaine is valuable in the production of superficial anæsthesia. It may be employed when general anæsthesia is contraindicated. He had used the drug in two iridectomies, but the patients complained of pain. He thought the reaction following the local use of the drug due to the mental effect of the operation. Finally, he thought that there is danger of claiming too much for the remedy, as reaction must set in and may result in its total rejection.

Dr. Montgomery said that if he had chronic granular conjunctivitis, he should not hesitate to use jequirity. With reference to the physiological action of the remedy,

it produced a peculiar membranous inflammation as the result of ulceration of a very superficial character, much in the manner of bluestone. He had kept a solution of cocaine for over three months, and had not observed any deterioration as suggested by Dr. Skeer. Cocaine constricted the bloodvessels, rendering the parts anæmic.

Dr. J. D. Skeer, of Chicago, suggested that the action of jequirity might be explained by an ulceration of fibrinous deposits in the submucous tissue.

Dr. Robert Tilley, of Chicago, read a supplementary

REPORT ON OPHTHALMOLOGY.

He referred to the *relation of optic neuritis to brain tumors*, and his remarks were based on the one hundred and seven cases tabulated in the *Transactions*, for 1884, of the Ophthalmological Society of the United Kingdom, by Messrs. Walter Edmunds and J. B. Lanford, of England. They had previously expressed the opinion that optic neuritis, when it exists as a consequence of brain tumor, is the result of a secondary meningitis. In the examination of the reports associated with their post-mortem examinations, the statement of the existence of optic neuritis refers only to its manifestations early in the clinical history of the cases reported, at such time, in fact, when the other symptoms were of such a character that there could be no doubt of the existence of some special disturbing influence in the brain.

In the study of the one hundred and seven cases, they were arranged into ten groups, according to the location of the tumors, thus:

Tumors in	Optic neuritis.	No optic neuritis.	Total.
1. Anterior frontal convolution	8	2	10
2. Motor convolutions		12	12
3. Occipital lobes	5	4	9
4. In hemispheres (not otherwise specified)	6	4	10
5. Ganglia at base	17	3	20
6. Temporo-sphenoidal lobes	1	2	3
7. Cerebellum	20	3	23
8. Medulla and pons	3	6	9
9. Meningeal growths at motor convolutions	4	1	5
10. Meningeal growths elsewhere	4	2	6
Total	68	39	107

In summing up the groups those situated in the convex region of the brain, groups 1, 2, 3, 4, and 9, were added together, and fifty per cent. of the cases were found to have exhibited optic neuritis when first examined. whilst of the cases situated rather towards the base, groups 5, 6, 7, 8, and 10, seventy-four per cent. revealed optic neuritis and the estimation, so far as it was possible, was thought to favor the supposition that the optic neuritis was due to an extension of the meningitis. A curious fact in the investigation was that nine out of twenty cases of tumors in the cerebellum were associated with absolute blindness before death.

Under the subject *Operative Measures for the Relief of Glaucoma*, he referred to the fact that nine per cent. of all the blind are probably so affected as a result of glaucoma and that whilst operative measures are usually very successful in acute cases, similar success is not by any means so certain in chronic cases. As proof of this reference was made to the various operations which have been devised as remedial measures. For instance, drainage with gold wire, sclerotomy, internal myotomy, trephining the sclera and later the operation of Dr. Geo. E. Walker, of Liverpool, and the one described in the monograph of Dr. Geo. Lindsay Johnson, of London, England. The first making an incision through the external border of the cornea, through the periphery of iris and dividing the ciliary body at the same time, the latter claims great advantage from a paracentesis of the vitreous chamber with special precautions.

The reporter further described the operation advocated by Prof. Alfred Graefe, as a *substitute for enucleation of the eyeball*, which consists in a removal of the cornea and contents of the sclera. The operation cannot of course be adopted where the orbital tissue or the sclera is involved in any malignant morbid changes. The advantage of the operations are larger stump and the leaving of the lymph sheath of the optic nerve intact.

Adjourned.

Wednesday, May 20th.—Second Day.

Morning Session.

After the reports of the Special Committees on State Legislation, a recess of ten minutes was taken in order elect a Nominating Committee.

Upon reassembling, Dr. E. F. Ingals, of Chicago, read a paper entitled *Recurrent Laryngitis, in Relation to Obstruction of the Nares, or Chronic Post-nasal Catarrh.*

Dr. J. P. Matthews, of Carlinville, read a report of a case of

TRACHEOTOMY FOR STENOSIS OF THE LARYNX, PRODUCED BY TYPHOID ULCERATION,

and presented the patient for inspection. The man, 28 years old, of good antecedent history, took cold October 4, 1884. He complained of much hoarseness at that time. In November, 1884, Dr. Matthews attended him during a severe attack of typhoid fever, which lasted about thirty days. The hoarseness and dyspnœa began to subside about the thirtieth day, but the function of the larynx was never perfectly restored. Laryngoscopic examination revealed thickening of the aryepiglottideal folds and stenosis of the larynx. Bloody purulent matter was expectorated, which led to the diagnosis of ulcer below the vocal cords.

January 6, 1885, tracheotomy was performed, and the symptoms of dyspnœa relieved. A large quantity of bloody pus was expectorated, confirming the diagnosis of ulcer below the cord. The patient still wears the tube, although Dr. Matthews thinks it can now be safely removed. The ulcer was probably due to typhoid fever, as there is entire absence of pulmonary disease. Dr. Matthews related the history of a case of spasmodic asthma, cured by the relief of a chronic post-nasal catarrh.

Dr. Prewitt, of St. Louis, alluded to a case of obstruction of the posterior nares, cured by breaking off a portion of the septum by means of Adam's forceps. Dr. Prewitt narrated the history of a patient with pneumonia; sudden dyspnœa occurred, leading to the opinion that obstruction in the larynx existed; tracheotomy was

performed, a fibrinous cast was expelled, and the patient recovered.

Dr. Ingals thought that laryngotomy was indicated in Dr. Matthews' case.

Dr. F. E. Waxham, of Chicago, referred to the treatment of laryngeal stenosis by tubage.

Afternoon Session.

Dr. A. E. Hoadley, of Chicago, presented a paper entitled *Too Frequent Feeding as a Cause of Disease in Infants, and a Protest Against One Cow's Milk.*

Dr. C. Truesdale, of Rock Island, read the report on

TETANUS.

He narrated the history of two cases of tetanus, occurring in his own practice, during June and July, 1882, which terminated favorably. The treatment was local and constitutional. Locally, a saturated solution of carbolic acid (six per cent.) was injected hypodermatically; constitutionally, morphia, calabar bean, choral, and bromide of potassium were successively pushed to their full physiological actions.

Dr. G. G. Craig, Health Commissioner of Rock Island, had recently treated two cases of tetanus with success, by Dr. Truesdale's method.

Hypodermatic injections paralyze the peripheral nerve terminations, while the employment of the most powerful depresso-motors, successively, pushed to their full physiological actions, complete a line of treatment, which Dr. Truesdale is inclined to believe almost specific.

Dr. T. R. Brower, of Chicago, Chairman of the Special Committee on

THE TREATMENT OF EPILEPSY,

read an interesting report. His conclusions were:

1. Surgical procedures offer the most certain methods of cure; the removal of cicatrices, trephining, oöphorectomy, and ligation of the vertebral arteries being the more important operative procedures.

2. The general treatment should be mainly addressed to building up the general nutrition of the patients. Brucia, strychnia, and arsenic are the most important therapeutic agents.

3. Depressing agents, such as bromides, are palliative rather than curative. To be curative, they should be pushed to bromism, hoping thereby so to alter the nutrition of the nerve-centres as to make the epileptic habit impossible when they are withdrawn.

On the report of the Nominating Committee the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—W. A. Byrd, M.D., of Quincy.

Vice-Presidents.—Drs. W. T. Kirk, of Atlanta; and A. Wetmore, of Waterloo.

Permanent Secretary.—Dr. S. J. Jones, of Chicago.

Treasurer.—Dr. Walter Hay, of Chicago.

Assistant Secretary.—Dr. I. H. Luce, of Bloomington.

Place of Meeting.—Bloomington.

Time.—Third Wednesday in May, 1886.

Thursday, May 22d.—Third Day.

Morning Session.

Dr. H. J. Reynolds, of Chicago, read a paper on the

TREATMENT OF ECZEMA.

He uses in the subacute and the chronic conditions (either of which may at any time develop acute symptoms and require the treatment changed accordingly), pure, impalpably fine boracic acid as a dusting powder, having first gotten rid of crusts and scales by soaking with oil and washing with soap and warm water. In the chronic, however, he uses greater stimulating measures, in the way of green soap frequently rubbed in during washing. To relieve intense itching, he has found nothing so effectual as first-class letting alone.

He thinks bandaging and strapping advisable whenever practicable, and prefers the cotton roller to the rubber where there is much exudation or maceration of the skin. He reported two cases of twelve and twenty years' standing respectively, of eczema rubrum of the leg associated with varicose veins and ulceration, where many remedies had been tried without success that he cured by the application of boracic acid and bandaging, and a saline laxative internally.

Dr. W. A. Byrd, of Quincy, read an interesting

REPORT ON SURGERY.

In the consideration of special subjects, he alluded to recent progress in the extirpation of the thyroid gland and Kocher's strictures upon thyroidectomy, published in 1883. Zesas found that thyroidectomy in animals was soon followed by a general morbid condition. Dr. Byrd had removed the thyroid gland once, three or four years ago, from a lovely child four years of age. She did well for a few months, and then wasted away and died. The value of such a work as Dalton's *Topographical Anatomy of the Brain* is made apparent when we see Drs. Lee and Fenger, of Chicago, opening an abscess of that organ, and Mr. Richman J. Godlee, of London, cutting down upon a glioma the size of a walnut and removing it.

Operative procedures for the cure of epilepsy and insanity are becoming more common and he believes more successful. The failure, in some instances, in effecting a cure being, perhaps, due to not removing enough of the irritating bone, as suggested by Dr. W. T. Briggs, of Nashville.

Abdominal surgery is advancing. Dr. Wm. T. Bull, of New York, cuts down upon injured intestine from a bullet wound, resects the injured portions, and the patient recovers. Dr. Edmund Andrews, of Chicago, has had two cases of gunshot wound of the abdomen, with injury of the intestines—in one case the stomach was empty, in the other full of beer—which recovered without operation. Dr. Joseph Grindon, of St. Louis, reports a case of incised wound of the abdomen, with injury to the intestines, recovering after resection of two inches of the tract.

Several cholecystotomies have been performed during the year; Dr. Charles T. Parkes, of Chicago, reports an interesting case of this character. An autopsy made by Dr. R. G. Bogue, of Chicago, showing six gall-stones, the size of a filbert, impacted in the common duct, demonstrates the futility of the method of exploration with an aspirator needle, suggested by Dr. Whittaker and Dr. Ransohoff, and the advisability of exploratory incisions. Dr. Byrd mentioned the ingenious proposition of Dr. J. McGaston, of Atlanta, Ga. That bile is not absolutely essential for life is proven by the case cited by Dr. F. W. Beard, of Vincennes, Ind., of a patient who survived for years with the bile flowing from a fistule he had formed with his scalpel.

All surgeons admit that amputation at the hip-joint is one of the most formidable operations that they are called upon to perform. Not alone from the extensive surface laid bare and the shock, but from hemorrhage and the evils resulting from the means employed to control the hemorrhage. When the abdominal tourniquet is employed, the intestine may be so bruised as to cause enteritis, perforation, peritonitis, and death. Davy's lever, even in his own hands, has so wounded the bowel as to cause death, while introduction of the entire hand into the rectum frequently causes laceration of the colon. To obviate this, Lloyd, of Manchester, adopted the method of passing a stout India-rubber tube around the hip, allowing the ends to cross above Poupart's ligament; under the point of crossing a compress was placed so as to bear on the artery above the ligament. The ends of the tube were then entrusted to assistants. This method was tried successfully by Dr. Wheaton, of St. Paul. The objection to it is that it is tiresome to the assistants, and brings more persons than are necessary around the operating table, to be in the way of the operator. The latter objection applies equally to some of the methods mentioned above.

To obviate these evil effects, Dr. Byrd has devised the method of applying a figure-of-eight of three-quarter inch French elastic tubing around the affected hip and opposite side of the body. Where the tubing passes in front, to go under the perineum of the affected side, it should come on the front side of the anterior superior process of the ilium, and go below the process when it crosses the body on the opposite side. Then to keep the transverse portion from rising over the lax tissues of the abdomen, tie a piece of bandage around the tube about the middle of the back and bring it forward over the perineum and tie down the front part of the tube. Then apply a three inch tightly rolled bandage, two inches thick, over the course of the iliac artery where the rubber crosses, and with heavy thread or twine stitch it to the former by the rubber. Retract the portion of the elastic band behind the affected limb with a piece of bandage passed around it and tied to the back cross rubber, drawing it tightly. This is done to prevent its slipping off when the limb is raised or amputated.

Dr. Byrd has tried this method twice during the past year, and knows nothing that could be more satisfactory. In one case operated upon, near Hannibal, Mo., 29th September, 1884, for osteosarcoma, by amputation at the hip-joint, the patient was a large man, and had had the femur amputated through the lower third, the year previous, for sarcoma of the knee. The disease had returned, and was giving him great pain. After the operation, there were not more than six or eight ounces of blood upon the floor. The vessels were twisted, and the patient was in bed in fifty minutes from the time he was taken from it to the table.

In the other case, the patient had sustained a compound fracture of the femur from falling from the top of a moving railroad car to the bottom of a ravine, the distance being about thirty feet. This was April 4, 1885. The shock was so great, that he was not fit for amputation until April 8th, by which time there were symptoms of acute osteomyelitis. Amputation was performed as above indicated, and he died the morning of the 12th, not from the amputation, but from phlegmonous inflammation in the other limb, which had been greatly bruised, causing septic troubles. The patient did well for two days after the amputation, and it seemed as if he would surely recover, until the swelling commenced in the opposite leg. The vessels were twisted, but an Esmarch's bandage was not applied, as it was deemed undesirable to drive any decaying material into the circulation. There was a good deal of ichorous infiltration, in spite of free drainage, that had been established through the lower portion of the wound with rubber drainage-tubes. The limb was elevated to allow the blood to flow back into the body before the application of the tourniquet. There was some blood escaping from the vessels of the amputated limb, but with that exception there was not a half ounce lost. By this method, hemorrhage from the femoral, gluteal, and obturator arteries is controlled.

Dr. Byrd is firmly convinced that twisting is a much safer method of treatment than the ligature, when applied to large vessels. The femoral vessels were twisted as they emerged from under Poupart's ligament, and he would have been perfectly satisfied to have twisted the common iliac or aorta, should any possibility have required it. If a ligature is applied to an atheromatous artery, the vessel will, most likely, give way, and there will be secondary hemorrhage. Vessels in such condition should be treated by some one of the methods detailed in systematic treatises on acupressure.

How long should a vessel be twisted? Until the elasticity of its coats gives way. Take a leather tube, which is inelastic, and bend it in a twist sharply upon itself once, and try to force water through it, and you will find that it will give way. The artery, when rendered inelastic, will obey the same invariable physical law. What instruments are necessary to perform torsion or twisting satisfactorily? One good, solid-jawed pair of forceps that will not *wabble* during the pressure of the operation, such as the Golding-Bird slide-catch forceps, or the Prince or Lawson Tait ring-handled pressure forceps. The objection to using two forceps is that the vessel is apt to be torn across to some extent, near the jaw of the forceps that holds it cross-wise. Dr. Byrd has not ligated an artery of any size for nearly five years, and does not think he ever will, if his results in the future are as favorable as in the past.

There is one operation where twisting is especially indicated, and that is castration. The whole cord should be caught up in the jaw of a stout pair of forceps, and cut off nearly an inch from the same. By this method the hemorrhage is controlled, and the vessels will protrude from the cut end of the cord most satisfactorily, so that they may be picked up leisurely and twisted. In this instance, the Crop forceps does no harm, since the vessels are surrounded by a mass of tissue that prevents them tearing across at the corners. The cord is dropped, and there is no fear of the agonizing pain, or even tetanus, that sometimes follows the catching up of some filament of nerve in the grasp of the ligature. There will not be the long waiting for the ligatures to come away, sometimes having to be coaxed away with little elastic bands (Ashhurst) fastened to the limb with sticking-plaster.

Some years ago—not many—Dr. Byrd read a paper—a translation from the German, by Dr. Nicholas Senn—in which the surgeon recommended the opening of psoas abscess in the groin, and passing a probe or sound

along the sinus until above the ilium, and there making another opening down to the sound, thus shortening the passage-way of the pus and rendering recovery more rapid and certain. Mr. Frederick Treves, of London, recommends, and has practised, cutting down directly upon the diseased vertebræ, but limits the operation to diseased lumbar vertebræ. Dr. Byrd thinks the operation can be very readily and safely extended to cases of caries of the dorsal vertebræ, resecting if necessary a portion of the rib or ribs near the vertebral column.

On April 10, 1885, a man, thirty years of age, appeared at Blessing Hospital. He had Pott's disease, involving the four lower dorsal vertebræ, with a resultant psoas abscess, pointing under Poupart's ligament, nearly ready to burst. He was anæsthetized, and the abscess was opened at its most dependent point, and a solid tin probe, the size of an American gauge, No. 15 catheter, passed up to the sinus until its point was under the edge of the twelfth rib. It was then cut down upon, a drainage-tube attached to it, and the probe withdrawn, carrying with it the drainage-tube, which was left in the sinus a length of fifteen inches. The sinus was washed out twice daily with a strong solution of boracic acid. In four days after the operation, the patient returned to his home, at Wendon, Ill., recovery assured.

Dr. W. H. Veatch, of Carthage, read a very brief abstract of a paper entitled, *Intestinal Obstruction*, after which the Society adjourned.

The members were entertained at a reception on Tuesday evening, at the Executive Mansion, by His Excellency, the Governor of the State.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, May 6, 1885.

The President, J. M. Da Costa, M.D., in the Chair.

Dr. H. C. Wood presented a paper on

THE BASAL PATHOLOGY OF CHOREA,

in which he stated that he had come to some definite conclusions concerning the basal pathology of chorea, which he should be glad to communicate to the College, and give the grounds for his belief.

The first point which he wished to make is, that the term chorea is simply one which is analogous to the term paralysis, and that the choreic movement is no more the same thing, necessarily, in its basal pathology, than is palsy the same thing in its basal pathology. When we come to study the various forms of disease closely connected with the choreic movements, we find, in the first place, the so-called cerebral or post-hemiplegic chorea, in which, after cerebral palsy, there appear violent convulsions with choreic movements. The seat of this lesion has been assigned by Professor Charcot to the corona radiata, near the lenticular nucleus; and there have been a number of post-mortems made which verify this view of its location. There can be no doubt that, in many cases, the lesion is situated in this position; but, on the other hand, it is equally certain that there have been cases of so-called post-hemiplegic chorea in which the lesion has been in the external capsule and in the cortex. We may, therefore, say that this post-hemiplegic chorea is associated with various lesions in the brain, so far as seat is concerned.

Then again, there has been reported in the *Compt. Rend. Société Biologie*, of Paris, a case of typical post-hemiplegic chorea, having absolutely all the features of organic hemiplegia with chorea, in which the most careful examination made by thoroughly competent persons failed to show any lesion whatsoever of the brain. As there had been a previous history of hysteria, the patient dying of pneumonia, we are forced to the conclusion that we may have post-hemiplegic chorea, which is without lesion, and hysterical in its nature.

When we come to study the more general forms of chorea, leaving out of sight for the present the chorea of childhood, or St. Vitus's dance, we have a chorea which is plainly hysterical; we have the electric chorea of the French, which he believes to be another form of hysterical chorea. We learn that, therefore, we may have a chorea dependent upon lesion of the brain, which also may have various seats, or we may have a chorea independent of any lesion whatsoever in any portion of the nervous system.

When we come to study chorea of childhood, we find that the pathology is perfectly parallel to that of the other forms of chorea. We have a large number of reported cases in which the lesion was evidently capillary embolisms of various portions of the brain, especially of the corpora striata and optic thalami, but also in other portions. We have other cases in which no lesion was to be found Then we have recent cases, especially reported by Dickinson and Ross, in which serious lesion was found in the spinal cord. The clinical history of chorea in childhood also shows conclusively, to his mind, that it may exist without any organic lesion which can be detected. We have it developing in a moment from emotion, passing off in a few weeks, and affected immensely by a few doses of arsenic or other agencies which would be powerless to affect any severe organic lesion.

So far as the study of the disease in the human subject is concerned, he thinks that these remarks sum up all that we can reach to, namely, that we may have chorea with various lesions and without lesions.

Dr. Wood stated that he had been much interested this winter in studying chorea in the dog. It has been affirmed that chorea in the dog is different from chorea in the child. The great reason for believing that the disease is distinct is, that in the dog the movements are chiefly rhythmical, whereas in the child the movements are not usually rhythmical; but he has seen dogs with absolutely arhythmical chorea, and with all the awkwardness of chorea of children; and occasionally, we have more or less of the rhythmical type in children. When we come to look at the points of resemblance in the two diseases we find, in the first place, in each case it especially affects the young animal. In the second place, that in each case the disease is associated with a constitutional disorder—distemper in the dog, rheumatism in the child. In the third place, the symptoms are exactly analogous, except that there is more tendency to rhythm in the one than in the other. In the fourth place, the clinical experience of veterinarians and of physicians has led to the same result, namely, that arsenic is the best remedy that is known for chorea in the dog, and that it is the best that is known for chorea in the child.

Unless, in the case of a contagious disease, where you

can pass the disease from one animal to another, it is manifestly impossible to be perfectly positive that a certain disease in the animal is the same as a certain disease in the child, but when you find the habit of the affections the same, the symptoms parallel, and the therapy identical, you have as good reasons as can be possibly assigned for believing that the diseases are closely similar. It is, however, not necessary for my present purpose to take it for granted that the diseases are the same.

When he came to study chorea in the dog, the first point to settle was the seat of lesion. He therefore cut the spinal cord so low as not to interfere with breathing. He found that invariably the choreic movement continued after section. Before the section the motions of the front and hind-legs were synchronous—that is, a wave of motion starting in the front paw would pass down the hind-foot, but after the section this synchronous movement was wanting. The hind-legs were completely isolated from the upper portion of the nervous system, and yet continued to exhibit the choreic movements, proofs that the movements originated in the spinal cord. He therefore had his search for the seat of lesion narrowed down to a small fragment of nerve-tissue. He found that not only did the movements originate in the spinal cord, but that they orignated, in all probability, in the motor cells, because when he galvanized the bared sciatic nerve, although the animal exhibited no signs of pain, the movements in the hind-leg were at once inhibited. The galvanism of the sciatic nerve could only affect the motor cells. Therefore he came to the conclusion, physiologically, that we had to do here with movement which originated in the motor cells of the spinal cord.

The next step was to examine the cord. Gowers and Sankey found in the cord a peculiar infiltration with leucocytes, and they came to the conclusion that leucocytal infiltration was the basal pathology of this disorder. Gowers had previously examined a cord without finding this condition. Dr. Wood examined a spinal cord and thought that he had found Gowers's lesion, but he was careful not to say so positively, because he had a suspicion that what was supposed to be a lesion was simply a peculiarity of the dog's cord. When he examined the cords of healthy dogs he found the same leucocytes. He did not say that what he saw was the same as the condition described by Gowers.

When he first examined the cord he perceived nothing wrong beyond what has been noted, but, bye-and-bye, as he began to study the specimen more and more closely, he found that the motor cells refused to take the carmine and hæmatoxylon staining as they should do. Then he remembered that he had killed the dog early in the disease. Then he took the cord of a dog which had died of the disease. Under these circumstances the lesion in the motor cells was very marked. They were crumpled up, the processes were gone, and the nuclei had disappeared. They were merely masses of matter, taking very little staining, just enough to show that they were protoplasmic. As he killed dog after dog in different stages, he found that the motor cells were to be noticed in all stages of degeneration. First, the perfect cell, then the cell which stained badly, then one with nuclei disappearing, the margins becoming obscured, the processess dropping off, and opacity occurring; and, finally, the irregular protoplasmic ball. In a few cases he noticed peculiar degeneration, *i. e.*, the formation of vacuoles in these cells. A change, then, in ganglionic cells is what he believes to be the basal lesion of chorea.

It so happens that, some years ago, Putnam, of Boston, studied chorea in the cat. In the first case he found no lesion, but in the second he found the lesion which he had described. The important point is, that he found that this lesion pervaded not only the spinal cord, but the whole nervous system. We all know that the choreic movement is only a part of the symptoms of the disease, and that the moral and intellectual part of the child also suffers. He believes that in children we have an altered condition of the ganglionic cells. The reason that no lesion is found early is, that the disease is at first functional. It is not necessary that he should call attention to the fact that there is no such thing as functional and organic disease. The line which we draw is a purely arbitrary one; for, the moment there is altered function, there is altered protoplasmic change, and, when there is altered protoplasmic change, there is altered nutrition, and then organic disease. Our microscopic eye is so blind and gross that it cannot see these fine changes until they become so distinct that we can detect them, and then we say that organic disease exists.

The history of chorea he conceives to be this: Owing to emotional disturbance, some stopping up of various vessels of the brain, or sometimes to the presence of organic disease, now this cause, and now that, there is an altered condition of the ganglionic cells throughout the nerve centres. If the cause is removed and the altered condition of the nerve cells goes only so far, it remains what we call a functional disease. If it goes so far that the cells show alteration, we have an organic disease of the nervous system.

The capillary emboli, the clots, the tumors, and the various gross lesions which have been found in chorea, are not, in his opinion, the basal lesion, but the cause which produces these changes in the cells which are at the bottom of the choreic movements.

Dr. S. Weir Mitchell asked if he understood Dr. Wood to say that he considers the lesion of the spinal cord as essential to the production of chorea, or does he think that there may be chorea dependent upon a descending lesion?

Dr. Wood said that in his detailed account he would give cases in which descending degeneration is present.

Dr. Osler hoped that he might be allowed to say a few words on the subject, as owing to the kindness of Dr. Wood he had an opportunity of examining these specimens. He cannot say that the specimens carried as much conviction to his mind as have the words of Dr. Wood, to-night. At the same time, the changes which he has described are undoubtedly present. The only question is as to the interpretation of these appearances; whether they are really the result of the disease, or whether they are the result of methods of preparation, is extremely difficult to determine. In regard to presence of vacuoles, they have been seen and described before. We all know that the appearances in the nerve-cells of the cord are, above all other things, most deceptive. It strikes him that these appearances are not altogether conclusive to prove that Dr. Wood has arrived at the true essence of the pathology of the disease.

TORONTO MEDICAL SOCIETY.

Stated Meeting, April 30, 1885.

The President, Dr. R. A. Reeve, in the Chair.

OSTEITIS DEFORMANS.

Dr. McPhedran presented a case of this affection. Mrs. M., aged 63, English, good family history. Healthy till she was 45; since then she has been ailing. Six or seven years ago had a severe illness, in which her right side was paralyzed. She soon recovered from the paralysis, except some numbness in region of distribution of ulnar nerve of right hand. Within a few months she began to complain of pains in right leg, and soon noticed that it was larger and beginning to bend. The curving has gradually increased ever since. Shortly after, the right side became the seat of irregular pains, and it began to "fall in." About three years ago, right hip began to pain her and thigh to bend. For last three or four years has found walking troublesome, the difficulty gradually increasing. At present the right tibia is considerably enlarged and markedly curved; the curve is convex forwards and outwards. The femur of same side somewhat thicker, and its natural curve increased. Standing with heels together, the knees are about two inches apart; were the left leg equally affected, as is usual, the knees would be very far apart. The ribs on the right side are considerably contracted. No changes are to be found in any of the other bones. There is a tumor, hard, fairly smooth, and painless, about the size of a large orange, below the liver, and apparently free from it. Its inner margin is about two inches external to the umbilicus. The gait in walking is awkward, but does not interfere with her duties as housewife. General health fair; excretions normal.

This disease was first described by Sir James Paget (*Lancet*, 1876, vol. ii.). It seldom begins under the age of forty, and usually later. It is slow in its progress, and may exist many years without detriment to the general health. There are in some cases troublesome pains, but they are neither nocturnal nor periodical. The disease affects the long bones of the lower extremities most frequently, and it is usually bilateral. The vault of the cranium is frequently diseased, also the clavicles. The affected bones become larger and heavier, but so weakened as to bend beneath the weight of the body. The spine may sink and seem to shorten, with increase of the dorsal and lumbar curves; this may be due to the great weight of the head, or disease of its own structure. The loss of stature in some cases has been as much as two inches. The arms are seldom affected; those in whom they are diseased are usually female. Respiration may be interfered with, owing to the increased dorsal curve causing such approximation of the ribs as to interfere with their free movement. There is no fever; excretions are normal.

In examination of the bones after death, the skull when affected is found greatly thickened, the sutures obliterated, the grooves for the vessels much deepened, and the distinction between the inner and outer tables lost. The changes in the long bones are usually confined to the compact tissue of both shaft and articular extremities. It is greatly thickened, sometimes encroaching on the medulla, which in some cases is diffluent and redder than normal. Microscopical examination shows a diminution of the number of Haversian canals, which are enlarged and filled with fibro-nuclear tissue, leucocytes, and occasionally myeloid cells and fat around the vessels. The lacunæ and canaliculi are normal. Chemical examination shows little change from normal bone.

These facts indicate that the disease is a chronic inflammation of a low type. It is distinguished from other inflammations whether simple or gouty, strumous, syphilitic, etc., by the clinical history and the retention of good health. In arthritis "deformans" the general health also remains good, but then the local changes are confined to the articular extremities: this disease is never found associated with osteitis deformans. Rickets and osteomalacia are quite different. In rickets the bones are too short and small and have curves different from the curves in this disease; in osteomalacia the bones are thin and the curves are angular. Nothing is known as to the cause of this disease. Lunn has suggested that it is a constitutional disease causing atrophy and absorption of a large part of the osseous system. (*St. Thomas Hosp. Rep.*) The compensatory formation of bone might be looked upon as an ill-developed callus. A large number of the cases reported have died of malignant disease. Of the five cases originally reported by Sir Joseph Paget, three died of cancer.

Treatment has effected nothing as yet. Potassium iodide has been much used; one case that consulted Wilks came with a pile of prescriptions in all of which this formed the staple. It is useless to give this remedy, as it has no effect on fully formed bone. The disease must be specially rare in America; I have met with no other case nor have I seen a description of such in any of the American Journals.

A CASE OF MOTOR APHASIA FROM INJURY, WITHOUT PARALYSIS OF ANY OF THE LIMBS.

Dr. J. H. Burns gave the following notes of the case. Mr. K. æt. 56, healthy and robust, fell down stairs; he was assisted to his feet and with help walked to a chair. He did not then speak or at any time subsequently. He became unconscious about three hours later. In my absence Dr. Duncan saw him that evening for me, and with me the next morning, by which time he had recovered consciousness and was able to leave the bed. His bowels had been freely moved with croton oil. There was an injury to the soft tissues over the right eye, but no fracture could be made out. He swallowed with great difficulty; there was neither motor paralysis nor anæsthesia of any part of the limbs. Twenty-four hours after injury pulse was 100, temp. 101°. Dr. Workman saw him in consultation following morning, temp. 104°, pulse 120. During the afternoon he had a convulsion and after that convulsions recurred every ten minutes till he died at 2 P.M. next day. The left side was most affected with the convulsions. During this time there was retention of urine. Death took place sixty-eight hours after injury.

Post mortem seven hours after death. Extravasation into subcutaneous tissue over parietal and temporal bones of right side. There was an extensive fracture in this region with slight depression. Dura mater intimately adherent to calvarium. A large clot was found between dura mater and skull at seat of fracture. Great congestion of cerebrum beneath this. Another clot was

found beneath the dura mater on left side of brain opposite seat of injury, with extensive disorganization of the lower part of middle lobe of brain on left side. Heart and lungs normal, liver small but apparently healthy, kidneys healthy.

DR. DUNCAN, who assisted at the autopsy, said there were two distinct clots on the left side; one in the arachnoid space pressing on the temporo-sphenoidal lobe, another beneath this in the brain substance, in which on removal of the clot there was a laceration half an inch deep and one and one-half by one and one-fourth inches in extent. This clot probably resulted from rupture of a branch of the Sylvian artery. From symptoms, he had expected to find some such injury. The presence of *three* distinct clots was an unusual circumstance.

DR. WORKMAN said that he visited the patient in consultation on the 13th of April, and he is able to confirm all that has been stated. The symptoms that most attracted his attention was that of motor-aphasia unaccompanied by any paralysis in the lower or upper limbs. The only mark of external injury was the swollen and blackened state of the right eye. Close examination of the supraorbital region of the frontal bone gave no indication of fracture, nor did examination of the side of the cranium present any. The patient had evidently free use of the muscles of the arms and legs. When he saw him there was no stertorous breathing, neither was pronounced coma present, but there was a certain degree of torpor or somnolence, which he apprehended would culminate in coma. He had not spoken from the time of occurrence of the injury, neither had he taken any drink or food, most probably because of the paralyzed state of the glosso-labial muscles. The large extravasation of blood in the left temporal region, the result of the *contre-coup*, showed that some important vessel, most probably a branch of the Sylvian artery, had been lacerated, and it would appear from Dr. Duncan's statement that the cerebral substance in the Sylvian region was greatly injured. He had no doubt that this part coincided with the foot of the ascending frontal and the posterior part of the third frontal convolution, in which are the motor-centres for the speech muscles and for those of deglutition, etc. The absence of any mark of injury in the vicinity of the fissure of Rolando, accounts for the persistence of muscular power in the arms and legs. He regarded the case as one of much interest, in confirmation of the now so universally admitted doctrine of cerebral localizations.

CASE OF CARIES OF CONDYLES OF OCCIPITAL BONE, DISEASE OF ATLO-AXOID ARTICULATION, CARIES OF ODONTOID PROCESS, AND DISLOCATION CAUSING COMPRESSION OF THE SPINAL CORD AND DEATH.

DR. JAS. F. W. ROSS showed the specimen with notes as follows:

Harry A., æt. 5 years, paternal grandfather and grandfather's brother, father, and maternal grandfather, all died of phthisis. No history of syphilis. As an infant not robust; pale and puny. Had no disease during childhood but scarlatina, strumous keratitis, and post-aural eczema.

In May, 1884, it was noticed that he held his head in a peculiarly stiff position. When the nurse was cutting his hair it was noticed that he could not turn his head freely. He complained of some pain in the back of the neck, and the head was carried with the occipital protuberance towards the back, and the chin held out from the body. This pain became more severe, and he found it necessary to support his head on his hand towards the right side. In November some thickening was noticed over the transverse and spinous processes of the second and third cervical vertebræ. He ate well and did not lose flesh, but his gait was becoming unsteady. About the end of November he fell to the floor, going down by losing the power of the left leg first and falling to the left side. The arms and legs were completely paralyzed, but on this occasion he retained control of sphincters. He had no affection of the speech on this occasion. Remained in this condition for forty-eight hours. He then regained the use of the legs and right arm, but the left one remained almost powerless for some time.

February 14, 1885, he had a second attack, lasting only about four hours. Legs seemed to double under him, and he fell, perfectly powerless. He did not put his arms out to save himself. From this attack on, the least knock would destroy his balance and cause a fall. The speech remained unaffected in this attack. Eczematous patches now appeared on the back and behind the ears, and his general health began to fail. He would occasionally say when swallowing, "I am nearly choked," and required slow and careful feeding. Intellect perfectly clear; was never lost in any attack. Towards March 1, when walking round in the day, he could control his sphincters; but when lying down, the water and feces passed in bed.

March 12 the third attack came on. About 9.30 P. M. he awoke from a comfortable sleep. Had appeared very drowsy in the afternoon, and had no power to assist himself into bed. Usually stepped on a little stool sat on the bed and asked to be laid down, while some one held his head. When awake, he said, "My legs are asleep," "My legs are tired, "My foot might break off," "I can hardly talk," in succession; his speech became indistinct; words were "mumbled;" eyes rolled; nostrils distended; and breathing difficult. Before morning his legs became cramped, and in a few hours were being rigidly flexed on the thighs; the thighs on the abdomen, as in the lithotomy position. He asked to have his legs drawn down, as he could not keep them down. Temperature 100⅔°; pulse 120. Could whistle. Muscles of face and eyes acting normally; hearing, taste, and sight good; sensation in affected limbs variable, sometimes present, at others annulled. Could not distinguish any difference in sensation of the two sides. After this attack he lost complete control of sphincters, urine and feces passing involuntarily. Occasionally regained slight motion in limbs, and eventually died of pulmonary congestion on April 6, 1885.

On post-mortem examination, found the condyles of occipital bone eroded, the atlo-axoid articulation diseased, the cartilage eroded and loosened, the odontoid process gone, and a dislocation of the atlas off the axis to the right side, compressing the cord. No pus was present, and the joint was not filled with any fluid. The cord was marked as if it had been tied with a string.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. John J. Cassidy.

Vice-Presidents.—Drs. Alexander McPhedran and James H. Burns.

Secretary.—Dr. James F. Bell.

Corresponding Secretary.—Dr. G. B. Smith.

Treasurer.—Dr. Bertram Spencer.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 28, 1885.

THE PRESIDENT, ROBERT F. WEIR, M.D., IN THE CHAIR.

DR. R. W. AMIDON, by invitation, read a paper on

ATROPIA IN ETHER NARCOSIS.

DR. G. A. PETERS then presented specimens of

BILIARY CALCULI; PERFORATION OF THE DUODENUM; ABSCESS.

Elizabeth B., æt. 77, of Scotland, widow, was admitted into St. Luke's Hospital January 13, 1885. Family history negative. Three months before admission, she had an attack of sharp pain followed shortly after by a swelling in the right iliac fossa, which was quite painful on pressure. Pain seemed to run towards the median line into the bowels. Was worse at night. She says that on admission the swelling was softer, smaller, and less painful than it has been. On admission an examination revealed a prominent swelling in the right iliac region, tender and distinctly fluctuating, skin normal. Right thigh is readily flexed on abdomen.

January 16.—Patient was etherized and Dr. Abbe incised the tumor and evacuated a considerable quantity of greenish-yellow pus. A number of trabeculæ were broken down. No communication could be detected with vermiform appendix or any internal organ. Antiseptic dressing applied.

April 4.—The discharge has continued, and a probe occasionally introduced discovers only a small cavity beneath the skin, although a free discharge of pus in the daily dressings indicates a deeper secreting cavity. Dr. Peters enlarged the wound, the patient being etherized. After considerable careful searching, the probe dropped into a narrow sinus, downwards and inwards. This sinus was enlarged and a small steel searcher was introduced which could be readily swept round a large cavity, apparently limited by peritoneum towards the median line. The finger in the wound readily detected the lower edge of the right lobe of the liver and to the inside the peritoneum. A rubber drainage-tube, about three inches long, was introduced and stitched to the skin. Edges of the wound were united by a continuous suture of catgut. About a pint of solut. hyd. bichlor. (1 to 2000), warm, was used for irrigating the cavity, and most of this fluid ran out again. An antiseptic dressing was applied. Abdomen became distended and painful.

5th.—Pain and distention much less. Temperature normal. At 6.30 o'clock P.M. she suddenly collapsed and did not respond to free hypodermic administration of brandy. Died of heart failure at 3.30 A.M.

6th.—Autopsy at 2.30 P.M. by Dr. Frank Ferguson. Body is fairly nourished. Rigor mortis is well marked. There is no œdema. There is an incision commencing just in front of the right axillary line, opposite the free border of ribs, and extending downwards and inwards a distance of three inches. This incision communicates with a cavity in the abdominal wall of the right hypochondriac region, measuring, when distended, one and a half inch in length and one inch in breadth, of oval shape. A drainage-tube three inches in length and one half an inch in diameter passes from the incision above described into a compartment within the peritoneal cavity. A sinus extends from the upper limits of the cavity through which the drainage-tube passes and communicates with the gall-bladder, which is filled with biliary calculi. This sinus is two and a half inches in length, and admits a probe one-eighth of an inch in diameter. Section through the abdominal wall in the median line reveals the following conditions within the peritoneal cavity.

The liver and diaphragm are adherent by loose old adhesions, but the anterior edge of the liver is firmly united to the free edge of the costal cartilages in the right hypochondrium.

The ascending colon is buried beneath the liver, and at the hepatic flexure the colon sharply turns upon itself, forming an acute angle, and passes forward and to the left. The portion of the colon thus passing forward is distended and firmly united to the under surface of the liver. The mesocolon of the transverse portion of the large bowel is quite long, and this portion of the colon forms a horseshoe curve, reaching nearly to the brim of the pelvis.

The descending arm of this curve is attached to the spinal column by a broad thick loose plane of omentum. The omentum attached to the transverse colon elsewhere, and arising from the lower border of the stomach, covers in the intestines everywhere, and is attached by firm old adhesions on the right side to the canal of Nuck.

From this it will be seen that there is a compartment within the general peritoneal cavity, limited above by the first portion of the transverse colon, distended and adherent to neighboring viscera, in the median line by the plane of omentum above described; below by the adhesion of the omentum to the canal of Nuck, and the position of the intestines in that region of the peritoneal cavity.

The surfaces of intestine within the peritoneal cavity and the parietal peritoneum are covered by recent lymph. The diaphragm is on a level with the fourth rib on the right side, with the fifth rib on the left side.

There are old adhesions at the apices of both lungs. No fluid in either pleural cavity. The heart is small, brownish in color. There is slight atheroma of the aorta, also of the segments of the mitral and aortic valves. The lungs and spleen are normal.

The kidneys are smaller than normal; their capsules are adherent in places. The markings are not very distinct. There are a few small cysts in the cortex of each organ. Under the microscope the epithelium shows extensive fatty degeneration.

The mucous membrane of the stomach is normal. The pylorus is normal. An inch below the pylorus there are two openings in the wall of the duodenum,

separated by a thin band of mucous membrane, and each opening admits a probe one-quarter of an inch in diameter. The probe readily passes through these openings into the gall-bladder, there being firm union between it and the first portion of the duodenum; thence through the sinus above mentioned into the cavity in the abdominal parietes of right hypochondrium; thence through the incision already alluded to.

The cystic duct is impervious. There are several small calculi in the hepatic duct, whose orifice is normal in size. The gall-bladder contains nineteen calculi of variable sizes, some of them as large as a walnut and presenting several facets.

There is slight increase in the fibrous tissue of the liver. The biliary ducts are dilated moderately. The central vessels are greatly distended with blood, and there are hemorrhages in the liver tissue in places. The mucous membrane of the intestines is normal, except as above stated. The uterus is smaller than normal. The ovaries are atrophied.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 21, 1885.

The President, A. Jacobi, M.D., in the Chair.

Dr. T. H. Burchard presented a paper on

OBSERVATIONS ON THE TREATMENT, MEDICAL AND SURGICAL, OF ACUTE PERITONITIS.

He commenced by saying that peritonitis is the most fatal of the acute inflammatory diseases, the mortality being from fifty to sixty per cent.; while if the so-called idiopathic cases are excluded it is from twenty to thirty per cent. higher. He then said that he believed this rate of mortality is unnecessarily high, and that a threefold conception of the disease is essential for its rational treatment, first, as to the cause; second, as to the natural history; and third, as to the natural tendency of the disease.

The text-books give the causes of death as (1) collapse and (2) asthenia. Clinical observation, however, amplifies them as follows: (1) collapse; (2) asthenia, (*a*) from heart failure, (*b*) from respiratory failure; (3) inflammatory changes in the lungs; (4) inflammatory changes in the kidneys; and (5) hyperpyrexia. A knowledge of the cause in any case is essential to its satisfactory treatment. Everything points to the correctness of the proposition that there is no such disease *per se* as peritonitis. He then alluded to the alleged difficulties of diagnosis, and stated that a correct diagnosis is possible even where the difficulties are apparently very great. In proof of this he cited certain instances occurring in his own experience. Sound surgical teachings demand that we should by all means remove the source of irritation, and surgical interference is to be made early whenever there is reason to suspect that any abdominal traumatism is giving rise to the trouble. Dr. Sims, in the last paper which he read before the Academy, had sounded the key-note of the correct treatment in these very halls.

To perfect himself in such procedures, Dr. Burchard said that he had practised to a considerable extent on dogs. The peritoneum is exceedingly tolerant of surgical interference if proper precautions are taken. During the past three years innumerable Tait's operations had been performed, and with very brilliant results. Tait himself had performed no less than forty laparotomies during commencing peritonitis, and all had recovered. In order to show the comparative impunity with which surgical procedures can be undertaken upon the peritoneum, he then quoted a large number of cases from various sources, and completed the list with the report of a case of his own. This was a case of omental abscess which he saw at Saratoga in consultation with the late Dr. F. D. Lente, and in which he performed laparotomy, with the recovery of the patient. Although distinct fluctuation was not obtained, the aspirator was resorted to, but failed to withdraw pus. An incision was then made in the median line from one inch below the ensiform cartilage to the umbilicus, with antiseptic precautions. Fully a gallon of warm carbolized water was injected among the matted intestines, and, iodoform having been lightly dusted over the walls of the abscess, two drainage-tubes were inserted. This case, with the others by different operators which he had collected, made 40 cases in all, with 24 recoveries, or 60 per cent. of recoveries in otherwise hopeless cases.

In contrast, Dr. Burchard reported a fatal case of ulceration of the vermiform appendix. He was called to see the case in consultation, and having made the diagnosis of perforation, advised immediate operation. At this time the condition of the patient was comparatively good, and the operation was refused. Twenty-four hours afterwards he was again called, and was now asked to operate; but by this time it was too late—the condition being hopeless—and a fatal result rapidly ensued.

In speaking of the medical treatment, he said he wished to call attention to special points which were the result of practical observation of the disease. While opium has been rightly considered our sheet-anchor in peritonitis, there are certain conditions in which it is requisite to use it with the greatest possible caution. One of these is the *initial* collapse of the disease, which has been too little studied, and which is a subject of very great importance. To illustrate, he related an instance in which it was very marked, a case of peritonitis resulting from an epididymitis. This collapse is dependent on a vaso-motor paresis, and, therefore, large doses of opium are likely to be extremely dangerous, though in small quantities it can be used with advantage.

The second point to which he directed attention is the perplexing discrepancy between the severity of the pain and the character of the pulse on the one hand, and the fulness of the heart on the other, sometimes met with; and when this is observed, he thought that no dose of opium should be given except in combination with digitalis, atropia, or ammonia, while auscultation of the heart should be frequently resorted to.

The third point is the complication of hypostatic pneumonia from carbonic acid gas poisoning. At this stage a slight overdose of morphia may put a stop to the respiratory function altogether, as there is imminent danger of respiratory failure. Here also small and infrequently repeated doses of morphia guarded with digitalis, atropia, or ammonia, are likely to prove of service.

As to the method of giving opium, he greatly preferred the hypodermic injection of morphia as being the most accurate and in every way satisfactory. In this connection, he related a case in which a patient had passed a hardened mass by the bowels which proved to be a collection of undissolved opium pills, containing enough opium to have killed her if it had all been absorbed. Yet these pills had been obtained at one of the most reliable druggists in the city of New York.

Atropia is unquestionably the one drug in which the most implicit confidence can be placed in the treatment of collapse, and it may be given in doses of from one-sixtieth to one-tenth of a grain, either alone, or in combination with morphia, alcohol, digitalis, or ammonia. There is no rule for the administration of morphia in peritonitis; each case must be a law to itself. Since adopting the hypodermic method of giving it, however, he had been surprised to find how comparatively small an amount is required in a great many cases. In some instances, however, enormous quantities of the drug are called for. In speaking of external applications, he said that poultices are only useful for their sedative effect on peripheral nerves, for the relief of spasm, and in aiding the absorption of inflammatory products, and unless they are required for these purposes had better not be applied, as they have no effect in controlling inflammation. The external application, which is by far the most efficient of all, is the iced-coil, and in this connection he exhibited what he said was the neatest and most convenient apparatus of the kind which he had seen, made by Codman and Shurtleff. The cold is directly efficient by causing reflex contraction of the bloodvessels, and it is also of much service in restoring tranquility. The most satisfactory food that can be employed is peptonized milk, to which additional cream can be added if desired. He spoke next of the treatment of tympanitis, and said that it can sometimes be relieved by the introduction of a vulcanized rubber tube into the intestines by the rectum. Pneumatic aspiration of the intestines is neither philosophical nor safe. Turpentine is to be condemned on account of its liability to increase the danger of the patient by its irritating effect upon the kidneys, and cases have been noted in which its use gave rise to albuminuria. Finally, he said, the successful treatment of peritonitis involves a personal devotion on the part of the medical attendant which comprehends a complete abnegation of self.

DR. A. L. LOOMIS agreed with the author that the first and most important point to be determined before resorting to any surgical procedure in peritonitis, is the finding out of exact cause. Personally, he is one of those who do not believe in such a thing as idiopathic peritonitis. There are three principal kinds of cases: first, the constitutional variety of the disease, which depends on blood-poisoning of some sort; second, cases which result from an extension of inflammation from some viscus to its peritoneal covering; and, third, those depending on ulceration of the intestines, with perforation and discharge into the peritoneal cavity, or upon the rupture of an abscess or cyst of some kind. So far as his experience went, Dr. Loomis said, he had yet to see a case of recovery where there was unquestionally the presence of gases from the intestines in the peritoneal cavity. This is one of the most certainly fatal causes of peritonitis; but it is often very difficult to determine just where the perforation has occurred. If there were the first signs of perforation, with evidences of peritonitis, in the right iliac fossa, it would be generally regarded as indicating ulceration of the vermiform appendix; but he had known the vermiform appendix to be crowded over to the median line, or even to the left of it. He, therefore, did not believe that the portion of the intestine involved can always be determined. If, however, the exact part and the starting-point of the peritonitis can be made out, he could heartily approve of all that had been said in the paper. If in the case of a recent distinguished surgeon of this city an early operation had been undertaken, he believed that there would have been a good prospect of his recovery. Surgeons, he thought, can sometimes learn something from physicians. In every case it behooves the medical attendant to watch his patient very closely, and be prepared for an operation at any moment. Some years ago he had a patient in Bellevue Hospital with a slowly developing peritonitis from an old inflammatory peritoneal band. He urged the late Dr. Erskine Mason to operate in the case, and he called a consultation of surgeons over it; but they all objected on the ground that they did not know where to find the obstruction, although it was certain to him that it was in the small intestine. The operation was not performed, and the patient died of peritonitis. At the autopsy an old cicatricial band was found which could have been parted with the knife without the slightest difficulty. He would, therefore, advise an early operation in such cases, and did not hesitate to say that if to-night he believed that he himself had ulceration of the vermiform appendix, he would seek out a surgeon who would promptly open the abdomen.

In regard to the medical treatment, he thoroughly believed in opium, though with restrictions. Dr. Burchard's points had been well taken, he thought, and he also considered the indiscriminate use of the drug in the early stages of the disease often highly dangerous. Long ago he had adopted the plan of guarding his first dose of opium with atropia. Afterwards it did not make so much difference.

DR. R. F. WEIR said that the arena of the abdominal cavity is that in which surgeons have been obtaining most activity during the last ten years. Dr. Loomis had touched the key-note when he said there is no such thing as idiopathic peritonitis. He would go further than the author of the paper, and say that no patient suffering from peritonitis should be allowed to die without an exploratory incision. Having remarked that there is no more reason for hesitating about operating than in strangulated hernia, he referred to the views of Mr. Frederick Treves, and said there is need of more early interference than had hitherto generally been made in the so-called perityphlitic abscesses. Perforation with collapse is the snag on which surgeons are apt to get caught. In a traumatic case they cannot tell whether this collapse is due to the entrance of gas into the peritoneal cavity, or results from hemorrhage. Here came in the value of exploratory incision, and in 94 exploratory incisions Tait had had only 3 deaths. After such an incision is made, it can be decided whether to proceed further or not, according to the condition of affairs discovered. In conclusion, he re-

marked that the operation in acute peritonitis dates further back than Mr. Treves had stated in his recent paper.

The President said that the question was whether, in every case of perityphlitis, the operation is called for. All knew of cases in which the perityphlitis remained local, and the patient recovered. There were also other cases in which, although general peritonitis set in, the patients recovered; and, therefore, it is a question of great responsibility whether to operate or not. Very recently he had seen a boy of 15 who had all the signs of perityphlitis. Although the question of operation naturally presented itself, it was deemed advisable to wait, and the patient was treated with morphia, atropia, and plenty of ice. The peritonitis afterwards became general, but the symptoms were not very urgent. Again he hesitated to operate, because the general condition was such as to justify waiting a little longer, although it was certainly a very difficult question to decide. He had, however, seen a number of similar cases recover.

He had found that where a case of peritonitis became well developed rapidly, the patient had almost invariably had one or more previous attacks. He would be inclined to lay down the rule that when perforation and peritonitis set in very suddenly, and the trouble extends rapidly, the operation ought to be performed; but if the process is a slow one, it is advisable to wait.

Dr. Loomis said that when the first sign of perforation occurs, is the time to operate.

The President said that the first sign of perforation is often the first sign of any kind.

Dr. Loomis said that he could not agree to this statement, and believed that when the first sign of perforation is noticed, the surgeon should, at all events, be prepared to operate. In the case before referred to by him, the autopsy showed that for the past two or three days the peritonitis had been local. As to the history of repeated attacks of peritonitis, he thought that if an operation had been performed in the first, there would not have been any return of the trouble.

Dr. Burchard said that in six cases of typhlitis which he had seen ending fatally (in five of which he made autopsies), it was a fact that in every one of them there was a history of one or more preceding attacks. If he saw a patient in collapse or partial collapse, with a history of previous attacks of typhlitis, he would say that there was no perforation. The rapidity with which collapse develops also appears an indication as to whether there is perforation or not.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 18, 1885.

The President, Charles A. Leale, M.D., in the Chair.

Dr. E. G. Janeway then presented

SPECIMENS OF ULCERATIVE ENDOCARDITIS AND OF ATRESIA OF THE LIVER.

The latter specimen was from the first of two additional cases to which he referred at the end of his paper on Abscess of the Liver, published in the *Transactions of the New York State Medical Association*. The origin of the trouble was probably the pressure of the elbow against the side in lifting a heavy stove and carrying it upon the shoulder. Three aspirations were resorted to, and a large quantity of chocolate-colored fluid, in which there were very few pus cells, withdrawn. Twenty-two ounces the first time, sixty-four ounces the second time, and eight ounces the third time. Afterwards the abscess burst through the lung, and an incision was made in the ninth intercostal space. The patient died from exhaustion, and during the latter part of life there was noticed some dulness over the upper part of the right lung, with bronchial breathing. At the autopsy there was found waxy degeneration of the liver, with some peripheral fatty degeneration also. There was an enormous abscess of the right lobe, the walls of which were very firm on account of the waxy character of the hepatic tissue. There was also found perioesophageal and peritracheal suppuration, together with localized empyema in the upper lobe of the right lung, and extensive ulceration of the large intestine.

Dr. A. Flint said he should like to ask Dr. Janeway whether he considered that the intestinal ulceration had any pathological connection with the abscess of the liver, and, if so, whether he was inclined to the opinion that in such cases the interstitial ulceration was consecutive to the hepatic abscess, or whether the association was merely one of coincidence.

Dr. Janeway said there are two sets of cases in which intestinal ulceration is seen in connection with hepatic abscess. In the first, the cause of trouble is dysentery, or other similar disease; but when this is the case, there are generally multiple, though small, hepatic abscesses. In the second, as in the present instance, he believed that the ulceration of the large intestine is consecutive, and probably dependent on the depressed state of the general health and the presence of a septic process in the system. The condition is analogous to that in puerperal fever.

Dr. Herman M. Biggs, who has recently returned from Berlin, where he has been pursuing a course of studies under Dr. Koch, gave a

DEMONSTRATION OF THE THREE COMMA-BACILLI.

The resemblance of the comma-bacillus of sporadic cholera, as described by Finkler and Prior; of that of the mouth, as described by Lewis and Müller; and of that found in stale cheese by Denecke, to the true cholera comma-bacillus, he said, had given rise to much confusion. But similarity of morphological appearances did not constitute identity; identity of growth, culture, and function is essential. Because the English Cholera Commission did not recognize this, their work was practically without value; and even Klein admitted that he had found the comma-bacillus of Koch in greater or less number in all cases of cholera. Dr. Biggs then proceeded to point out the distinctions between the various kinds of comma-bacilli, and in speaking of the mouth bacillus, he stated that it took the followers of Koch four months to isolate it; but at last it was done by Prof. Müller. This was a matter of vital importance, for if the identity of the two had been proven, all of Koch's work would have become valueless. He exhibited cultures of the three comma-bacilli, and, in conclusion, remarked that in the mere matter of diagnosis, Koch had certainly made a very valuable contribution to our knowledge of cholera. The etiological

relation between the microbe and the disease was not at present proven. There was one point yet lacking in the demonstration of this, viz., the test of inoculation; and it was quite possible that this never would be established, since, as far as we are able to determine, there was probably no animal that was susceptible to cholera. The so-called inoculation of guinea-pigs by means of injections into the duodenum, as practised by Rietsch and Nicati, was unsatisfactory, and could not be accepted.

Dr. A. Flint, Jr., exhibited, at the request of Dr. Wm. H. Greene, of Philadelphia, an

APPARATUS FOR DETERMINING THE PROPORTION OF UREA IN THE URINE.

(See page 597.)

A demonstration was then made, by the maker, of a

NEW CLOSED CIRCUIT "GRENET BATTERY" AND INCANDESCENT LAMP, WITH UNIVERSAL ILLUMINATORS FOR DARK CAVITIES.

Also the combined electric light and tongue depressor for laryngoscopic examinations, together with improvements on the Grenet battery. The presentation of the apparatus was prefaced by a few remarks from The President, who said:

Two weeks ago, in the examination of one of the dark cavities of the body, he used for illuminating purposes the small incandescent electric lamp. It proved so satisfactory, and combined so many recent improvements, that it has been deemed worthy of a special notice and of presentation this evening to the Association. The Universal Illuminator is an electric lamp, attached by a ball-and-socket joint, either to a long or a short handle, not much thicker than an ordinary penholder, being so small that it may be passed through an opening in the thorax after collapse of the lung, and the removal of the pus in empyema, to illuminate all the surrounding parts. It may be used in the rectum or the vagina, and also after gastrotomy and cystotomy in searching for localized disease, or a hidden foreign substance. In the abdominal cavity it may be utilized in seeking for the source of a concealed hemorrhage or for an injury to a fixed and obscure part.

For the mouth, throat, nares, and larynx, a combined tongue depressor has been attached, which is easily held in the left hand, while the right is free to manipulate. The improvements on the Grenet battery are the gain in space by the use of square jars, the use of hard rubber caps replacing those of metal, and the increase of the exposed surface by the use of corrugated carbons.

Isolation of the Temperature [illegible]ans of the Muriate of Cocaine.—Sor[illegible]Dr. William Warfield, of this city, an [illegible]e Eye Department of the Baltimore Eye, [illegible]t Charity Hospital, observed in a patien[illegible] surgical operation (under the anæstheti[illegible] cocaine) by Dr. Russel Murdoch, that wl[illegible] bility of the cornea and conjunctiva was abolished, the impact of the instruments was felt as a distinctly *cold sensation*. Acting upon this hint, Mr. H. H. Donaldson, of the Johns Hopkins University, examined the eyes of two patients at the hospital with reference to this singular observation, and found that, when the eye was completely insensitive, a fine metal point, alternately heated and cooled in water—the temperature being 10° C. for the cold and 40° C. for the hot—when pressed against the conjunctiva and the patients directed to state their sensations, the answers were all correct; heat and cold being readily distinguished.

Struck with the original observation of Dr. Warfield, Dr. John N. Mackenzie made a series of experiments with regard to the isolation of the temperature sense in the oropharyngeal cavities and nasal passages. Six patients were taken for the experiments. The uvula and soft palate, and afterwards the nasal passages, were first bathed in a four per cent. solution of the drug. When anæsthesia of the parts was complete, a silver probe, which had been previously immersed in a mixture of ice and salt, was carried over the parts previously rendered insensible to contact and pain, as tested in various ways. A distinct sensation of cold was in every instance complained of. The opposite extremity of the same probe was next heated over the Argand burner of a lamp used for laryngoscopic purposes, and in its heated condition made to impinge upon various spots in the anæsthetized area. While absolutely no pain was felt by any of those experimented upon, there was a marked unanimity of the answers, given voluntarily, in regard to the sensation of heat. In three of the cases, the application of the heated probe was followed by an eschar, and in one a pretty severe pharyngitis developed, yet at the time of application no pain was felt, though the temperature sense remained intact. It may be incidentally remarked, that none of the patients was aware of the purposes of the experiment or the previous preparation of the probe.

These observations are of considerable interest in view of the fact that, while recent physiological research has rendered it probable that the sensations of heat and cold are distinct from those of mere contact and pain, it has heretofore been impossible to demonstrate the fact by the complete isolation of the temperature sense. It is accordingly obvious that its separation from the other senses may open up in the future a fruitful field of physiological investigation.

MONTREAL.

(*From our Special Correspondent.*)

Board of Health and Sanitary Affairs.—The Health Department of this city has been in rather a demoralized condition of late. Owing to want of coöperation on the part of his Committee the Chairman of the Board of Health resigned; then the Medical Health Officer became unfit for his duties and retired. The vaccine furnished by the public vaccinator was found impure and unfit for use, so the whole stock of vaccine was destroyed. In addition to these misfortunes, it is found that all the lanes in the city after the winter's accumulation are in a horribly filthy state, and the public scavengers are making but the feeblest efforts to put them in a cleanly condition. The Mayor brought these

various matters up before the Common Council, who, after refusing to accept the Chairman of the Health Board's resignation, determined to make some effort to put the city in a proper sanitary condition before we are surprised by cholera.

A new medical health officer has been advertised for, salary $2500 a year.

A medical advisory board has been formed, consisting of a representative from each of the four medical schools (two English and two French), whose services are unpaid. The scavenging contract is also to be investigated, and the lanes to be immediately cleaned.

The salary of the medical officer of health is not sufficient to tempt a good man, who must be thoroughly acquainted with French and English; and but little work, I fancy, can be got our of our unpaid advisory board. However, the newly elected mayor seems determined to wake up the health department, and fulfil the promises made to his electors in spite of national and religious prejudice.

Since writing the above we are pleased to state that the Chairman of the Board of Health has withdrawn his resignation, and intends to get his Committee, as well as the city, into somewhat better shape.

New cases of smallpox are still of daily occurrence, and but little effort is being made to vaccinate the masses.

A fatal case of glanders in a young man occurred at the general hospital here last week.

SOCIETY MEETINGS.—The Wisconsin State Medical Society meets at Milwaukee on Tuesday, June 2d.

The Ohio State Medical Society holds its annual meeting at Dayton on Wednesday, June 2d. And the Ontario Medical Association meets at London on the same day.

MEDICAL AND CHIRURGICAL SOCIETY OF MARYLAND.—At its late meeting, the Faculty voted a change in the Constitution by the substitution of the word "person" for "gentleman" in the article relative to applications for membership. This change was made, as was explained by Dr. J. Edwin Michael, the mover of it, in order to have the way open to receive women practitioners, if otherwise eligible for membership.

UNIVERSITY OF THE CITY OF NEW YORK.—Dr. Lewis A. Stimson has been elected Professor of Anatomy in this institution, to succeed the late Professor Darling.

LYONS SOCIETY FOR THE PROTECTION OF CHILDREN.—This Society has offered prizes of gold medals, for the years 1886 and 1887, for the best paper on the following subjects:

1. The different methods of vaccination; the age at which vaccination is best performed; and the prejudices to be combated in reference to the operation.

2. The study upon the influence of occupation upon pregnancy in women, the progress of pregnancy, and the vitality and health of children.—*Gazette Médicale de Paris*, April 11, 1885.

THE ROYAL ACADEMY OF MEDICINE OF BELGIUM has submitted the following subjects for theses; the most meritorious of each of which will receive the prize indicated:

1. The determination by new experiments and applications the degree to which spectral analysis may be realized in the researches of forensic medicine and the medical police. Prize, $300. Closes April 1, 1886.

2. The experimental determination of the influence which desiccation exerts when employed as a means of conserving the simple vegetable medicaments. Prize, $120. Closes July 1, 1885.

3. The physiological effect of sanguineous depletion, either local or general; its indications and contraindications in the treatment of disease. Prize, $300. Closes December 31, 1885.

4. Description and critical review of the different methods of surgical dressing and of the antiseptic treatment of wounds and surgical affections. Prize, $120. Closes January 16, 1887.

5. The study of erysipelas, *charbonneux* or *rouget*, of swine, as relating to its causes, manifestations, lesions, prophylaxis, and treatment, and to establishing eventually its relations with carbuncular bacteridian or bacterian diseases. Prize, $120. Closes January 15, 1887.—*L'Union Médicale*, April 18, 1885.

NOTES AND QUERIES.

PENNSYLVANIA COLLEGE OF DENTAL SURGERY.

At a special meeting of the corporators of the Pennsylvania College of Dental Surgery, the following resolutions, presented by the Committee appointed to report them, were unanimously adopted:

Whereas, Following quickly the decease of our late worthy President, Dr. Samuel D. Gross, we are now called upon to mourn the death of our fellow member, Dr. Ellerslie Wallace;

Resolved, That, aware of the helpful, manly coöperation of Dr. Wallace in the work of dental advancement, the Pennsylvania College of Dental Surgery, of which he had long been a corporator, desires to express its respect for his memory and character;

Resolved, That we hereby tender to his family our sincere sympathy and condolence.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 19 TO MAY 25, 1885.

DEWITT, CALVIN, *Captain and Assistant Surgeon.*—Ordered for duty at Newport Barracks, Kentucky.—*S. O. 107, Department of the East*, May 22, 1885.

DELOFFRE, A. A., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Sissiton, Dakota Territory, and ordered to Fort Totten, Dakota Territory.—*S. O. 52, Department of Dakota*, May 14, 1885.

BRECKEMIN, LOUIS, *Captain and Assistant Surgeon.*—Ordered for temporary duty at Fort Omaha, Nebraska.—*S. O. 44, Department of the Platte*, May 18, 1885.

MUNDAY, BENJAMIN, *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Klamath, Oregon, and ordered to Fort Walla Walla, Wyoming Territory.—*S. O. 72, Department of Colorado*, May 12, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MAY 23, 1885.

MEAD, F. W., *Passed Assistant Surgeon.*—Detailed as member of Board for Physical Examination of candidates for appointment as cadets in the Revenue-Marine Service, May 18, 1885.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

ORIGINAL ARTICLES.

A CASE OF FRACTURE OF THE BASE OF THE SKULL, WITH LOSS OF BRAIN SUBSTANCE THROUGH EAR; RECOVERY.[1]

BY W. H. WILDER, M.D.,
OF CINCINNATI

ON the morning of November 30, 1883, a well-developed man, about thirty-eight years of age, was brought into the Cincinnati Hospital in a semi-unconscious condition, unable to remember the cause of his injury or to give any account of himself. It was only by repeated and persistent inquiry that his name could be obtained, and after giving this he would immediately relapse into a drowsy stupor, from which he was not easily aroused. There was a slow but continuous flow of blood from the left ear. Lodged in the concha and in the external auditory canal, a small mass of white tissue, apparently nervous in character, was found; and on the pillow lay another small quantity, similar in character, which had escaped from the ear. These specimens, aggregating about one drachm in weight, when subjected to a microscopic examination, revealed the presence of nerve fibres, myeline drops, and what appeared to be roots of nerve cells; pus cells were abundant in the field. The respirations were full, numbering 20 per minute; temperature 99½° F., pulse 80. The pupils were active and responded normally to the stimulus of light. No perceptible paralysis of the face or extremities existed.

In the evening of the same day, the condition of the patient was unchanged; the same stupor prevailed and intelligence was no more manifest when he was aroused. The character of the discharge from the ear had changed from that of blood to a clear serous fluid with a slightly sanguineous tinge, which escaped so persistently and continuously that it was necessary to change frequently the cloths which were applied to the part, and supply him with a dry pillow. Pulse 80, temperature 99½°: Breathing quiet and natural; urine had been passed in bed; bowels had not been evacuated.

Dec. 1.—Pulse 80, temperature 99°, respiration 20. General condition was unchanged. The discharge of fluid from the left ear continued. After an enema of castor oil and water the bowels had been freely evacuated. Patient partook of some milk and beef essence during the day; in the evening he became very restless, and gr. xv chloral and gr. xxx bromide of potash were administered.

2d.—Pulse 80, temperature 98°, respiration 20. General condition remained the same; he breathed quietly through the nose unless he was aroused, when the breathing was through the mouth with puffing of the cheeks, the nearest approach to stertorous breathing that had been noticed. A considerable obliteration of the folds of the left side of the face, and a deviation to the right side indicated a facial paralysis of the left side which had appeared in the night. He could not be induced to protrude his tongue or to respond to questions, but partook of some nourishment in the form of milk and beef essence. Pupils were active and symmetrical. Urine withdrawn by the catheter. No paralysis of the limbs existed at any time. The fluid that continued to escape slowly from the ear was almost colorless and perfectly clear.

3d.—A slight improvement was noted; he became more rational, was more easily aroused, took notice of objects around him, and recognized his wife. When requested he protruded his tongue, which did not deviate towards either side. He complained of headache. The dose of potassium bromide and chloral, which had been administered every evening, was discontinued, and gr. j calomel given every three hours, and as much beef essence and milk as he would take.

5th.—The discharge from the ear had become very slight and resembled water. Pulse 88, temperature 98½°. In the evening he was quite restless but brighter. Facial paralysis of the left side continued. Micturition normal; bowels constipated.

6th.—The patient's pulse was weak; he had passed a very restless night, having been delirious at times and having frequently attempted to leave his bed and the room in which he was confined. It was necessary to secure him and to place him under the influence of chloral. The calomel was discontinued and one-half ounce of whisky was ordered to be given every four hours. Pulse 84, temperature 98°. In the evening he was again improved, and much more rational and intelligent. Pulse was stronger.

7th.—He was much brighter and had slept well. No delirium. Micturition normal, bowels constipated. No discharge from the ear.

From this time he began to improve steadily, rationality returned slowly, and he gradually regained his memory and intelligence, but was unable to recount the circumstances attending his mishap. The facial paralysis of the left side had disappeared by December 10th, and a purulent offensive discharge from the left ear was noticed.

An examination of the ear, December 11th, revealed the fact that the superior wall had been pushed downward to such an extent as almost to close the canal; a fissure could be seen in the membrana tympani extending from the upper part down to the umba. The hearing of the affected ear was somewhat impaired on account of the acute otitis media that was present.

The patient was discharged on December 12th, at

[1] Read before the Cincinnati Academy of Medicine, April 20, 1885.

the urgent request of friends, and passed from my notice, although subsequently very correct information was received from his wife concerning his mental and physical condition. The time which he spent at the hospital is a blank to him, but his memory is now so much improved that he remembers some important incidents connected with his injury. He declares he was struck on the head by some one whom he did not see, and thinks he was dragged to a railroad track by the same person. His intellectual faculties have all improved, but at times his speech is rambling, and he is inclined to talk incessantly of past events. For two or three months after leaving the hospital, he experienced severe vertigo, especially when performing suddenly any lateral movement. Ptosis of the left eye was noticed about two months after his discharge, and occasionally he has some pain in the left side of the face. No paralysis of the face is present now.

This case affords several interesting points for consideration, chief among which is the escape of brain substance from the ear. There was no doubt as to the nature of the injury after the examination of this substance; but even before this, the copious hemorrhage from the ear dispelled the thought that the blood might proceed from a ruptured membrana tympani.

The hemorrhage from the ear must be profuse, and continuous for a considerable length of time to afford certain evidence of the existence of fracture involving the petrous portion of the temporal bone. On the other hand, the absence of this sign, hemorrhage from the ear, does not necessarily indicate absence of a fracture implicating the petrous portion of the temporal, and even opening up the cavity of the tympanum; for it is well known that in such cases blood may pass into the mouth through the Eustachian tube when the injury has not caused a rupture of the membrana tympani.

The cases of fracture of the petrous portion of the temporal bone with the escape of cerebro-spinal fluid and brain substance are rare, and of four cases that were found on record only one terminated successfully.

Guillemeau, in 1779, reported, in the *Journal de Medicin.*, tome iii. p. 454, a case of fracture of the base with protrusion of brain matter through the ear.

De Gislain, in 1843, recorded, in the *Annales de Chirurgie*, tome viii. p. 229, a similar case of profuse hemorrhagic flow from the ear, together with particles of brain substance.

Mr. Prescott Hewett mentions a case that he saw in St. George's Hospital in October, 1856. "The accident was caused by a fall from a great height;" and in the blood that flowed profusely from the left ear, were mixed minute portions of brain substance, and two or three pieces of the white substance of the brain as large as peas were lying in the meatus externus. These cases were all fatal.

Surgeon Lockwood, U. S. N., reported, in the *Am. Journ. Med. Sciences*, for April, 1859, a case of recovery after a severe injury of this kind. "The patient, a seaman, æt. 30, fell from the spar to the main deck of the ship and struck fairly on the vertex." There was copious and continuous bleeding from the right ear and nose, the quantity of blood that escaped being estimated at fifty or sixty fluidounces. With the blood were several small pieces of brain matter. On the following day a fluid of watery character was flowing from the ear, and several particles were found in the meatus which, on examination, proved to be brain matter. The patient was comatose for two days, and then became delirious, but in five weeks after the date of the injury he had recovered and returned to his duty.

The cases reported, in which portions of brain matter have escaped from the vault of the skull after severe injury, are much more numerous than the class of injuries just considered, in which loss of brain substance occurred through an opening in the base; and the liability to a fatal termination in accidents of the former class is much less than in the latter, for the reason that the seat of the injury is much further removed from the important and vital centres lying at the base of the brain. At least 112 accidents of this kind, varying in severity, have been reported, and of this number 81 recoveries were recorded.

The continuous discharge of a clear, watery fluid (the cerebro-spinal fluid) from the ear was formerly regarded as the most unfavorable sign that could accompany injuries of the base of the skull; indeed, some observers (notably Robert, who had made considerable study of such injuries) accord to this symptom a fatal significance. This opinion, however, has been proven to be incorrect, for several cases of recovery, after such an accident, have been recorded. In the case recorded by Lockwood, in 1859, to which reference has been made, the discharge of a clear, watery fluid for several days, constituted a very important and interesting feature of the case. In the present case the hemorrhage from the ear was followed by a serous discharge, changing to a watery discharge, which continued slowly for several days. It seems probable, that the fluid was the cerebro-spinal fluid escaping from the subarachnoidean space.

It is interesting to consider the effect of this injury upon the seventh nerve.

The fact that facial paralysis of the left side did not occur until two days after the accident, furnishes conclusive evidence that the integrity of the nerve was not destroyed by the force that produced the fracture; and it also proves that the temporary impairment of function was due to the subsequent pressure upon the nerve, somewhere in its course through the aqueductus Fallopii, either by an effusion or blood clot within the tympanum.

That the pressure was not upon the nerve before entering the internal auditory meatus is evidenced by the fact that the hearing of that side was unimpaired.

In 13 cases of fracture of the petrous portion of the temporal bone, recorded by Mr. Pick, paralysis of the seventh nerve existed in 10. In 8 of these 10 cases, the paralysis did not appear until some time between the second and sixth day; and in the other 2 cases it was present at the time of admission to the hospital.

Fracture of the base of the skull was formerly regarded as a more fatal injury than modern statistics teach us to believe. The records of the *Medical and*

Surgical History of the War of the Rebellion furnish interesting statistics of fractures of the base. One hundred and thirty-five cases of recovery from gunshot fractures of the base of the skull are reported. These cases were collected and reported by Dr. Lidell in the *American Journal of Medical Sciences* for April, 1881. Of this number 49 were in the anterior fossa; 48 in the middle fossa; 6 were cases of fracture of the occipital bone and injury of the posterior lobes of the brain; 27 involved the middle and anterior fossæ; and 5 included the middle and posterior, fracturing the occipital bone.

In the case under consideration the injury to the skull must have existed principally in the middle fossa. There was a fracture, probably implicating the anterior surface of the petrous portion of the temporal, somewhere between the eminence for the superior semicircular canal and the line of union of the squamous and petrous portions. This seems to be indicated by the fact that the superior wall of the auditory canal was pushed downwards, so that the canal was partially occluded. The middle lobe of the left side of the brain was probably wounded in the neighborhood of the middle temporal or inferior temporal convolution; and from this part the extruded particles of brain substance must have escaped. The line of fracture *may* have passed into the posterior fossa, involving the posterior surface of the petrous bone; but of this there was no manifest evidence.

THE CHAMBERLAND FILTER.

By ALFRED C. GIRARD, M.D.,
ASSISTANT SURGEON U. S. A.

The necessity of "sterilizing" the water we are using for dietetic purposes in time of cholera becomes more apparent, the more the proofs are accumulating that the active principle of the disease is closely connected with a germ carried in a liquid medium to the intestinal tract.

Practically, it matters not whether this is Koch's comma-bacillus, or Emmerich's spirillum, or Finckler and Prior's microbe, or a spore or several combined, whether they cause fermentation or disorganization, or whatever their mode of killing may be supposed to be. It cannot be denied that the weight of evidence in favor of the bacterial origin of cholera is becoming every day stronger, and pointing the way in which we may protect ourselves from the infection; it is not my purpose here to discuss the arguments pro and con, the remarks submitted in this paper are mainly intended for those who are more or less convinced of the danger originating in the dietetic use of water containing any of the minute organisms leading to the disorder.

Many different contrivances have been invented and patented for the purification of water, but none have succeeded in doing more than either remove the coarser elements or chemical contamination. The inventors did not know or appreciate the exceedingly minute enemy which had to be "kept out," and naturally failed to insure "sterility," a term which, in this meaning, is probably unknown to most of them.

The remedy had to originate from the same laboratory and the same brains which have enlightened us on the nature of other diseases of the same order: from a man who, during a series of years, has become intimately acquainted with the biology of these germs.

While visiting Prof. Vallin's laboratory of hygiene, at the Hospital of Val-de-Grâce, in Paris, last November, under the polite guidance of Prof. Richard, the assistant Professor of Hygiene, I had my attention drawn to several filters which had been exhibited at the International Health Exhibition at London, and were then being tested.

A filter, invented by Mr. Chamberland, Pasteur's director of laboratory, appeared to me nearer the ideal of practical sterilization than anything I had ever seen. I was looking for something of the kind. Cholera becoming epidemic in Paris,—the prospect of the disease soon reaching the shores of America —my sojourn in Germany in the midst of the heated discussions on Koch's discoveries—everything had prepared my mind to seize upon the possibility of a method of protection. I am a believer in Koch, and naturally anything offering practical exclusion of disease germs struck a ready chord.

Since then I have seen no reports of that filter. I was interested in the preparations made in this country to keep off the cholera, and, finding that they mainly tended to prevent its introduction, and lessen its chance for propagation, it appeared to me that we are still helpless in case it should lodge in our midst.

The water supply of our large cities is the result of drainage of a large surface which, sooner or later, must become infected. We cannot disinfect this water with chemicals, for such substances taken into the system in sufficient quantities will seriously threaten our own lives. Boiling is very properly recommended, because, as the Committee on Disinfectants of the American Public Health Association justly says—the boiling temperature maintained for half an hour kills all known disease germs.

But why should we use boiled germs when we can exclude them? Will our hotels supply their guests with boiled drinking water when ice is dear? Will every private family be able or care to exercise the necessary watchfulness over the cook when the hydrant is so handy? This is only an outline of what we are to expect. Carelessness of prevention against disease is the rule, and the only rational mode of guarding against infection through drinking water is to provide an apparatus requiring no watchfulness or skill, and making the use of purified water as convenient as the ordinary mode of supply.

This seems to be offered by the Chamberland filter.

Remembering the impression it made on my mind, when I first saw it in Paris, and unable to find any mention of it in any literature at my disposal, I wrote to Prof. Vallin, whose name is known throughout the scientific world as an eminent hygienist, requesting such further information as he might be able to give me, in order to have the matter in a sufficiently positive and credible shape to be laid before the profession in this country. I will quote below from his answer, which, however, really is the

essence of an article he wrote on the filters of the London Health Exhibition (*Revue d'Hygiène et de Police Sanitaire*, July 20, 1884), and of which I shall make use in this paper.

A description of the apparatus should now precede any further argument on the subject, as it will be *prima facie* evidence to every thinking mind that its claims are deserved, and thus awaken sufficient interest in the reader to persevere in the reading of this article.

The principle of the filter is to force the water through porcelain porous enough to allow the passage of the liquid, but barring that of even the minutest germs.

The apparatus consists of one or more porous porcelain cylinders, set in metallic tubes of about two inches diameter, and twelve inches length, which are in communication with the water supply,—the whole being encased in a metallic frame attached to a tap. The water enters the interval between the porcelain and metal tubes, and percolates through the walls of the former, which drain into an outlet pipe. All there is needed is a pressure of at least two atmospheres (a difference of level of about sixty feet). With this each tube will allow the percolation of about a quart an hour, and with the apparatus I examined, and which, probably, is the one intended for practical use, containing six tubes, a daily supply of about 36 gallons of biologically pure water can be obtained.

A few experiments related here will fitly illustrate the thoroughness of filtration:

Putrefying liquids filtered in this manner into a sterile receptacle have been preserved indefinitely without change, when further access of bacteria was prevented.

Pasteur, in his experiments to establish that the virus of anthrax was due to the germs contained in the infectious liquids, filtered them through porcelain, the filtrate was injected under the skin of guinea-pigs without in any manner affecting their health, while a drop of the unfiltrated liquids caused in every case death in twenty-four hours.

Chamberland correctly argued that what could be done with a few grammes of virus, could be achieved with a large quantity of water, it being only a question of size of apparatus.

Another convincing experiment was made by Professors Fol and Dunant, of the University of Geneva, (March, 1885, of the above mentioned *Revue*). In their examinations of the water of Lake Geneva, on the effect of prolonged repose of the water upon its biological contents, they found a cubic centimetre of the water which most frequently was stirred up to contain 150,000 germs. Being grafted on meat gelatine, one-tenth of a cubic centimetre of this water produced 5300 colonies at a temperature, too, when the gelatine remained solid, and only 4 per cent. of the germs multiply.

This water was filtered through the Chamberland filter, and, the gelatine, treated similarly, exhibited not a single colony.

These examples ought to suffice as a proof that the filter will accomplish the desideratum. It is true that it does not purify the water from soluble admixtures; but in the water furnished by the systems of our various cities, and, having the necessary pressure, this source of pollution, if it exists, is not the cause of the diseases originating from bacterial infection.

Prof. Vallin says: "M. Chamberland's filter realizes, therefore, with extreme simplicity what yesterday still appeared to be ideal; it provides a water entirely freed from germs; it could not have arrived at a more opportune moment; it cannot be too much recommended."

As to any objections to the practical working of the filter, they are easily answered. In order to clean the apparatus it is sufficient to unscrew the bottom of the metallic tube, the external surface of the porcelain cylinder is then found covered with a thin layer of detritus; the tube is taken out, washed in boiling water, or exposed to the flame of gas, and everything works as well as if it was new, without expense or delay.

As to the defects of the filter I cannot do better than quote Prof. Vallin's letter:

"The Chamberland filter is of great service, but has also defects. It requires great water pressure, at least two atmospheres, about 22 metres of difference of level. It filters slowly, and it is necessary to place under it a glass receptacle, holding 25-50 litres, with a stopcock, to provide always for a good supply.

"The filtration is thorough, and no protoörganisms, even of the smallest kind, can pass, provided the tubes of porcelain have been properly tested, otherwise they may have fissures imperceptible to the eye, but sufficiently large to permit a free flow of water. Sometimes the tubes are faulty, on account of being too porous, so that the microscopic germs can pass through. . . . .

"I told Mr. Chamberland he should not allow any apparatus bearing his name to be sold without their first being tested by the manufacturer. I believe he will watch the manufacturer carefully, for you know that Mr. Chamberland is a very distinguished savant; he is the director of Pasteur's laboratory, and has been associated with Pasteur in most of his researches on anthrax and hydrophobia; he is Professor of Physics, Doctor of Sciences, and graduated among the first from our superior Normal School."

I have drawn the attention of a New York importer to the advantages of the Chamberland filter, and doubtless a number of these filters will soon be brought to this country and exhibited. As to their cost, I know only that the porcelain tubes are about three francs apiece in Paris. Whatever it may be here, it will probably be within the means of those who believe that it will protect their lives.

To recapitulate, I may safely assert that, in his filter, Chamberland has supplied the civilized world with a convenient apparatus, requiring no particular care or ingredients and providing, with the usual water pressure of hydrants, a sufficient supply of biologically pure water.

Fort Porter, Buffalo, N. Y.

OBSERVATIONS ON THE USE OF BOROGLYCERIDE.

By S. MAC. SMITH, M.D.,
resident physician at the Germantown Hospital, Philadelphia.

In the wards of the Germantown Hospital and Dispensary this comparatively recent compound, "boroglyceride," has been employed with such decided success and encouragement that, perhaps, to

state some observations on the use of same will be of interest to the professsion.

Boroglyceride is a marked hæmostatic, antiseptic, deodorant, and germicide, and prevents and arrests fermentation and putrefactive changes.

When applied to wounds, mucous membranes, etc., there is usually experienced a smarting sensation, which quickly subsides; it frequently renders a previously painful wound absolutely painless.

If, after minor amputations, the flaps be turned back, a 25 per cent. solution applied freely, and the edges of the wound coaptated nicely, capillary hemorrhage will be found to have been arrested and granulations promoted, but usually union by first intention is seen.

In anaplastic operations this agent will be found invaluable; a recent operation performed at the hospital by Dr. L. Webster Fox, will illustrate its value:

Daniel E., aged seventy years, had an epithelioma involving the entire upper eyelid; the tumor being removed, it was replaced by a large skin-graft taken from the patient's arm, and was dressed at various times with boroglyceride. When examined, on the morning of the fourth day, it was found that union by first intention, with little or no pain, nor suppuration, was the reward of this treatment; and, at the end of twenty days, the patient was discharged from the ward with a commendable eyelid.

Chronic ulcers, which have resisted the ordinary mode of treatment, have readily yielded to applications of a 50 per cent. solution of boroglyceride, being first washed with alcohol.

Have had several chronic suppurating buboes, which, the patient claimed, resisted all manner of treatment for about two years, but which promptly yielded to boroglyceride 50 per cent. solution and alcohol, used in the manner stated above.

In cases of gonorrhœa and gleet, this agent, with carbolic acid, used as an injection, will be found quite efficient and reliable. Out of ten cases treated recently, eight are pronounced cured, and the remaining two marked progress; also, where the urethra is subjected to irritation from passing a bougie, sound, etc., a weak solution used as an injection will be beneficial to allay the inflammation thus produced.

Gynecologists will also find this agent of much value in metritis, endometritis, vaginitis, leucorrhœa, etc. Boroglyceride, with carbolic acid, will render valuable service, and frequently accomplish the desired result with greater rapidity than the ordinary agents. A tampon can be left in the vagina, "first being moistened with boroglyceride" for six or eight days without becoming offensive.

Most inflammatory diseases of the skin, especially those of an itching or burning nature, are greatly benefited by this therapeutic agent.

In cases of inflammation of the throat, as tonsillitis, pharyngitis, etc., a 50 per cent. solution, diluted about one-half with water, and carbolic acid added, used as a gargle, has rendered most satisfactory results. Tannic acid may be added with advantage; great relief is also afforded in cases of acute coryza, by diluting a 50 per cent. solution one-half, and drawing it through the nares by a forced inspiration.

I have just been informed by Dr. Muller, surgeon to this hospital, that he has preserved perfectly pathological specimens for four years, and will probably remain as such for an indefinite time.

The ointment of boroglyceride, "unguentum boroglyceridi," appears especially adapted to, and efficacious in, the treatment of ocular diseases, more particularly, perhaps, on account of its convenient form, and being more suitable to add other ingredients. The following is the formula for making the ointment:

R.—Boroglyceride, 50 per cent. solution in glycerine		℥ij.
Vaseline		℥vi.
Ol. rosæ		q.s. M.

Heat the boroglyceride, and, while hot, add it slowly to the vaseline, stirring it constantly until thoroughly mixed.

MEDICAL PROGRESS.

Comparative Value of Lumbar and Iliac Colotomy.—M. Reclus, at the recent meeting of the French Surgical Congress, read a joint communication of himself and M. Verneuil upon the comparative value of lumbar and iliac colotomy. After reviewing the recent advances in the operation of lumbar colotomy and the operation of iliac colotomy as practised by M. Verneuil, preference was given to the latter's operation for the following reasons:

1. Lumbar anus is not less disagreeable nor better tolerated by patients than that of the iliac region; and the iliac anus is, moreover, under the hand and eyes of the patient, who thus is enabled to pay much attention to himself and to preserve the strictest cleanliness.

2. Hernia of the mucous membrane is not more frequent in the anus of Littré than in that of Amussat; it is due to the extent of the intestinal incision, and may disappear altogether by progressive destruction of the artificial anus—a process which takes place as frequently in one operation as in the other.

3. The union of the intestinal loop after suture to the cutaneous wound does not prevent fecal matter from passing to the lower end of the bowel after the operation for lumbar colotomy, or after the operation for iliac anus; but, in the latter, the lower orifice permits thorough washing of the rectal segment.

4. The sigmoid flexure is more easy of access, and more frequently reached in the iliac fossa than in the descending colon in the lumbar region. In general, there is too little account taken of the anomalies of that intestine in the operation of lumbar colotomy.

5. The peritoneum is not always avoided in lumbar colotomy; and a statement in the affirmative cannot be invoked as an argument for the operation. On the other hand, the mortality of operation of iliac colotomy for cancer of the rectum is only 10 per cent., a lower percentage than that of lumbar colotomy.

In view of the above argument, it is evident that the iliac anus is more advantageously located; that the operation is easier of execution, is of less gravity, and is to be preferred as a palliative procedure in cancer of the rectum, where the disease is located too high to render operative interference upon the lower extremity of the bowels possible.—*L'Union Médicale*, April 23, 1885.

OCULAR TRAUMATISMS.—DR. DEHENNE, in a short but excellent study on ocular traumatisms, reaches the following conclusions:

1. Every lesion of the eye, however slight it may at first appear to be, should be examined with the greatest care. Above all, examination of the visual field should not be neglected.

2. The prognosis in every case should be made with extreme reservation. Frequently many days may elapse before the result of the injury can be determined exactly.

3. The ciliary region is a veritable *noli me tangere* of the eye. Traumatism of this region much increases the gravity of the prognosis.

4. In every instance of resulting anterior synechia there is great necessity for reserve on the part of the surgeon as to the future condition of the patient, even when the wounded eye has regained its functional integrity. Adhesion, however slight, of the iris to the cornea is a perpetual menace to the integrity of the eye.

5. Every foreign body in the eye may produce severe sympathetic inflammation. Wounds of the ciliary region frequently entail slow sympathetic inflammation of which the point of departure seems to be choroidal calcification.—*Revue de Thérapeutique*, April 15, 1885.

CARDIAC RHEUMATISM.—DR. VAISSE records an exceedingly interesting case of primary cardiac rheumatism. Study of the progress and history of the case has led him to the following conclusions:

1. Acute rheumatism may attack the heart before the existence of articular complications.

2. In primary cardiac rheumatism death may result from lesion of the heart due to such cause, though the cases are extremely rare and exceptional. In the case under consideration the cause of death was myocarditis consecutive to pericarditis.

3. Degeneration of the cardiac tissue in analogous cases may result frequently in death.

All efforts to relieve the cardiac symptoms have failed, and no remedy has succeeded in preventing the progress of the disease toward a fatal termination. Digitalis and citrate of caffeine are only temporarily beneficial, and the therapeutics of the disease are entirely unsatisfactory owing to the profound lesions undergone by the cardiac muscle.—*L'Abeille Médicale*, April 13, 1885.

SURGICAL INTERVENTION IN BILIARY LITHIASIS.—DR. J. THIRIAR, in a paper read at the recent French Surgical Congress, expressed the following views:

It is a well-established fact that the gall-bladder is not indispensable for the regular performance of the digestive functions in man. The organ is entirely absent in many mammifera, and it not rarely happens that it is found completely atrophied in man.

If it be admitted that it is not alone in the gall-bladder that calculi may be formed, it is, however, very rare that this is the case outside of such pathological conditions which produce the formation of gall-stones in the biliary ducts and canals. These pathological conditions (cancer and obstruction of the biliary ducts) are contraindications to cholecystotomy.

The operation is very delicate and difficult to practise, but when strict attention is paid to antisepsis experience has shown the danger from peritonitis to be small. He thinks of all laparotomies, that practised for extirpation of the gall-bladder is the least serious and dangerous, and it is an operation which is justifiable in those cases of biliary lithiasis which have resisted treatment and are attended with violent crises. As to cholecystotomy, proposed by Lawson Tait, it is more easily performed than cholecystectomy, but is inconvenient in that it leaves a biliary fistula with its accompanying dangers, and does not remove the organ in which the calculi are produced, and which are liable to be reproduced.

MERCURIC CHLORIDE OF UREA: A NEW ANTISYPHILITIC.—DR. JOSEPH SCHÜTZ, in the *Deutsche medicinische Wochenschrift*, of April 2, 1885, brings to notice a new remedy for syphilis which he claims to have used with good results. The bichloride of mercury and urea are combined in the proportion of their atomic weights, thus producing the mercuric chloride of urea. The preparation, which is used hypodermically, is said to be less unpleasant in its effects than other mercurials heretofore used. It deteriorates less rapidly than some other forms of mercury, produces less pain, and diarrhœa as a result of its injection has never been noticed. The preparation recommended is the following: 15 grains of corrosive sublimate are dissolved in 3.38 ounces of distilled hot water, and when the solution is cold 7½ grains of urea are added. For the practical physician it is recommended that 7½ grain portions of urea be kept and added in the required proportion to a 1 per cent. solution of corrosive sublimate as occasion may require.

OVARIOTOMY AT IMOLA AND PARMA.—DR. VINCENZO LESI performed at Imola, on the 17th of March, ovariotomy on a woman aged 54 years. The cyst involved the right ovary and the pedicle was very long. Omental adhesion was extensive and necessitated many ligatures. After the operation the temperature did not exceed 100.4° F., and the progress of the case was free from complications, with the exception of slight colic. The woman is in excellent condition.

DR. GIOVANNI CALDERINI, during the present month and in April last, performed successfully two operations for ovariotomy. In the earlier operation (in which the peritoneum was extensively adherent to the growth) he removed an enormous tubo-ovarian cystoma of the left ovary. In the second case he performed a double ovariotomy, which was rendered especially difficult by the complications presented. The first case is entirely cured, and the condition of the second woman is such as to render her recovery probable.

NEPHROTOMY.—On the 8th of March, 1885, Prof. Vincenzo Dattilo performed the operation of nephrotomy for suppurating hydro-pyelo-nephrosis.

For the successful performance of the operation resection of the twelfth rib was necessary. The case is progressing rapidly toward recovery.

LAPAROTOMY.—PROFESSOR LORETA, on the 18th of April, 1885, successfully performed the operation of laparotomy in his clinic, for the removal of a large fibroid tumor of the left ovary. The woman has perfectly recovered.—*Gazzetta Medica di Torino*, May 5, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 6, 1885.

THE ABORTIVE TREATMENT OF TYPHOID FEVER BY MERCURIAL INUNCTION.

NONE of the measures as yet suggested to abort typhoid fever have materially influenced its treatment by physicians in this country or in England, whatever may have been the impression they have made upon the continent of Europe. The latest treatment, although a modification of the mercurial plan which has been for some time before the profession, promises results which demand for it a trial, based as it is on an experience with one hundred cases, recently published by DR. KALB, in the *Berliner klin. Wochenschr.* for January 19.

Dr. Kalb's method is to rub into the skin 90 grains of mercurial ointment, daily for six days, the first application being made to the abdomen, and at least half an hour being consumed in the friction, which must not, however, be trusted to the patient himself. On the second day the ointment is to be rubbed on the inner side of one thigh, on the third on the other thigh, on the fourth again on the abdomen, on the fifth on one of the thighs, and on the sixth on the remaining thigh. The inunction is preferably made in the evening. The ointment is not quite fresh, but slightly rancid, since it is believed that a greater uniformity of result is obtained.

Coincidently, Dr. Kalb administers a powder containing 7.5 grains of calomel and three-quarters of a grain of opium every five or six hours, the opium being added to prevent the calomel from acting as a purge. No other medicine is given except alcohol, which is, however, administered in full doses.

The results are described as follows: On the second day the temperature falls half a degree or more, but rises again the next day to its previous height and remains at this seven days. On the eighth day of the treatment—that is, the second day after the inunction is completed—the temperature falls to normal or almost normal, and continues thus with slight variations. Occasionally the temperature sinks to normal even during the inunction, but it is necessary to carry the treatment to its end, or the temperature may again rise.

The pulse remains for a few days at 100 to 120, though it also often falls with the temperature to the normal, or even to 60 or below. With the fall in temperature, perspiration becomes freer and shows itself especially on the abdomen and thighs. With the disappearance of fever there is a return of normal sensation; there is a mere trace of bronchitis, but the spleen remains enlarged for from ten to fourteen days.

Kalb has not neglected to compare these results with those produced by cold baths, by calomel and alcohol, or alcohol alone, and has invariably found that the inunction treatment contrasts favorably, and has been repeatedly reproached by patients who had not been anointed because they were still confined to bed, while others treated by inunction had completely recovered.

He does not claim, however, that the method is always successful, but only that 80 per cent. of those thus treated become free from fever within ten days of the beginning of the treatment. The treatment is also only efficient if adopted within the first nine or ten days, in general before the rose-colored rash has made its appearance; indeed, after this time it is useless.

While he has observed salivation, it has always been slight, and confined to transitory swelling and sensitiveness of the gums, and Kalb holds responsible for it the calomel rather than the mercurial ointment.

Our readers will not fail to have noticed that the treatment is really a combined one of stimulation with mercurials, but the results are certainly such as should not be lightly passed by. Stated with positiveness and confidence, and substantiated by so large a number of cases, it would indeed be strange if they were entirely erroneous. We strongly commend them to the attention of our readers, and as the treatment is so easily carried out, we ought soon to have an abundance of testimony bearing upon its value.

OUT-DOOR LIFE AND HEALTH.

The desire to flee the town and breathe the fresh, invigorating air of the country when spring returns to reanimate the outer world, is an irresistible and salutary prompting of our nature. City life to most persons is enervating. More or less confinement to artificially heated and badly ventilated rooms, short days and long nights, limited out-door exercise, together with the influences of the customs and conventionalities of city life, tend to depress and weaken the physical energies, and debilitate the system, so

that when the open season arrives there is a natural yearning for "pleasant fields and pastures new."

According to high authority, the body-weight is lightest, and the physical functions least vigorous towards the end of winter and in early spring. Then until midsummer there is an increase of flesh and energy, which is largely due to change of habits and food, and the invigorating influences of sunlight, fresh air, and out-door exercise. Bearing this in mind, we see how advantageous to health are all such diversions as require the open air for their enjoyment, provided, of course, that proper moderation and judgment are exercised in their use

The old adage about "all work and no play" is quite as applicable to the mature as to the young. Both mind and body require diversion, change, and recreation, to be healthy in their functions. Continuous, undiversified application of the physical or mental energies tends to unbalance the harmonious action of the organism, and seriously interfere with the healthful performance of the functions of the system. That arrangement of the plan of life is most rational which permits of a healthful exercise of the powers of the mind and body without overtaxing the one or the other. The interrelations of mind and body are such that neither can maintain a healthful state without a sound condition of the other. Physical exercise is essential to bodily health, and, therefore, to a sound mental status. When combined with pleasure the best results are to be anticipated, and this is one of the reasons why out-door sports are so advantageous in restoring and maintaining the vigor of both mind and body.

Whatever may be the avocation or employment, it is wise to renounce it for a season to seek rest, recreation, and the restorative influences of out-door life.

The idea that the preservation of health requires an occasional relaxation from the pressure of the usual pursuits is winning its way into favor. Its influence may be seen in the reduction of the hours of toil, in the early closing of business houses, in the practice of granting summer vacations to employés, in restricting the activities of business to the early hours of the day, and in the increasing number and popularity of summer resorts. How different from the practice in vogue years ago, when even the night was trenched upon by business, and when recreation was indulged in only by the opulent.

It is encouraging to notice an increased attention given to out-door sports, some of which have become so popular as to assume a national character. Intense interest is manifested in hotly contested matches, which are publicly announced and witnessed by multitudes of spectators, who are thus induced to seek a means of diversion from their ordinary pursuits. These exhibitions foster a desire to indulge in recreation, and in this way are indirectly advantageous.

That irreparable physical injury, from excessive muscular strain and fatigue, has occurred in some instances, is not to be denied; but such mishaps are rare, and might be largely prevented if careful physical examinations were made of the contestants in all sports requiring the highest development and concentration of the physical energies and endurance, with the view of warning such persons as are unfitted for the severe ordeal, of the risk they are liable to incur. If we mistake not, some such regulation has already been adopted by one or more of our colleges, with the object of preventing, as far as possible, any serious mishaps from indulging in severe physical contests.

The lighter sports and recreations, such as are enjoyed by the multitudes, are those which afford the widest field for beneficial results. The country, the mountains, the seashore, the rivers and parks, all offer diversified and healthful means of recreation, which the denizens of cities wisely take advantage of at this season of the year. The severe strain and tension upon the system, incident to the American methods of acquiring a livelihood, make it all the more necessary to unbend the bow for a season, and give nature an opportunity to invigorate and restore the overtaxed and damaged energies of both mind and body.

In recognizing the important relation of fresh air and recreation to health, the wants of the helpless poor have not been overlooked,—such noble charities as the Children's Country Week, the Sanitarium, St. John's Guild, and kindred institutions, coming to their rescue by affording advantages which otherwise must have been denied to a large class of the population.

THE NURSING BOTTLE AND THE ÆSTHETIC FACULTY.

Whatever theory of æsthetics may be accepted, from Plato's to that of Oscar Wilde, many believe that the love of the beautiful has greatly lessened. In our day not even the eloquent utterances of Ruskin, calling on men to worship the beautiful in nature and in art, have had enough power to make æsthetic culture general. A few years ago Oscar Wilde believed he too had a mission, but though he invoked men and women in poetry and prose, from the press and from the platform, his words were as the voice of one crying in the wilderness; the human race moved steadily on, trampling under foot all flowers in its persistent pursuit of the utilities, though a big helianthus was waved before them in passionate remonstrance. Disappointment seems to have struck the oracular Oscar dumb, he is as silent as the grave, and no one has come to take his place, while the average man and woman plod on in life, giving more attention to justice and truth, or at least to bread and butter, than they do to beauty.

The real difficulty in the work of the reformers, the reason they have not succeeded in reviving æsthetic love, is that they have not understood the cause of its decline. Physicians are wise enough to cure disease by removing its cause, when they can, and æsthetic missionaries must adopt a like plan. We must know the source of the love of the beautiful, the fountain of the æsthetic faculty, and see whether the evil so greatly mourned does not originate there. This fountain is woman's mammary gland; if women had no breasts, there would be no love of the beautiful possible for the human race. The Amazons, those unhappy creatures who took off one of their breasts, became celebrated as athletes, but not as æsthetes.

That the female breast is beautiful we might prove by showing that it has the chief characteristics, such as its lines, color, and smoothness, which Plato indicated in *Philenus*, as essential to beauty. But this is unnecessary, and we prefer at once explaining its connection with the æsthetic faculty, which can be best done by quoting from Darwin's *Zoonomia*. Erasmus Darwin in this work, which in some respects is as remarkable as any of the productions of his illustrious grandson, Charles Darwin, tells us that soon after a babe "is born into this cold world it is applied to its mother's warm bosom, ... which the infant embraces with its hands, presses with its lips and watches with its eyes, and thus acquires accurate ideas of its form. Its pleasure at length becomes associated with its form. And hence in our maturer years when any object is presented to us, which by its waving or spiral lines bears any similitude to this form—whether it be found in a landscape with soft gradations of rising and descending surface, or in the form of some antique vases, or in the works of pencil or chisel—we feel a generous glow of delight."

Accepting Darwin's theory of the origin of the æsthetic faculty, it is self-evident that those infants who are brought up artificially, "by hand" instead of by breast, must be deficient in this faculty. In short, the use of the nursing bottle is the cause of the decline in the appreciation of beauty.

Now we are safe in saying that a large proportion, probably not less than one-third, of babies in the so-called enlightened countries depend the first six months of their lives exclusively or partially upon "nursing bottles." Hence entire absence of the æsthetic faculty in some, and a very imperfect condition of it in others.

Those who love the beautiful, and who mourn its decline, must seek the remedy for the latter by encouraging maternal lactation, and banishing the nursing bottle, when there will be hope that the coming race will attain the poetic ideal in this regard. In an age when so much is accomplished by voluntary organizations, such as for the promotion of charity, the suppression of vice, etc., there might be a society for the promotion of this object. As women do not nurse because they can not, their breasts not being sufficiently developed, or because they will not, this society would have its work divided into two great sections—one devoting itself to the culture of the moral sentiment which will compel a mother to nurse her infant, and the other to discovering the best means for cultivating mammary glands. The latter section at least would be divided into several subsections, each of these giving itself to the special study of these organs. Thus one subsection would investigate the typical form, another the embryogenic development, a third the blood-supply, a fourth the minute anatomy of the glandular structure, and thus on, while a final class, a very large one probably, would be composed of those who do not see the purpose of this article, and would be occupied with lymphatic investigation. A society with such various and elaborate breastworks would be invincible. It, of course, would be international, and could be bisected, trisected, and quadrisected—in fact, divided into so many sections that everyone could occupy an official position.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

The annual session of this Society, which has just been concluded at Scranton, seems to have been a harmonious and in other respects a pleasant one. While no papers of great importance were read, at least two matters of business were resolved upon, which cannot be regarded as unimportant. The first of these was the passage of a series of resolutions declaring in favor of a State Board of Examiners and Licensers, independent of the Medical Colleges of the State, and the appointment of a committee to draft a bill embodying this principle, to be reported at the next annual meeting of the Society. If approved, the passage of the bill is to be secured, if possible, at the next biennial session of the Legislature, that is, in 1887. The evident majority by which these resolutions were carried shows that the profession of the State are ready for such a bill, which seems now to be required more particularly to protect them against the large number of poorly educated men who are being graduated by the extra-State schools, adjacent to our boundaries. At the same time, it is no more than fair that the graduates from the schools within the State should be subjected to the same examination.

The second resolution, also passed by a decided majority, inhibits county societies from attempting to secure legislation on matters affecting the conduct or interests of the profession of the entire State. It is evident that the initiation of such legislation should be, not with a county society, but with that of the State, in order that the profession throughout it may have a voice, and all interests be fairly represented.

SPECIAL ARTICLE.

PRELIMINARY REPORT OF THE SECOND SERIES OF SESSIONS OF THE GERMAN CHOLERA CONFERENCE.

SIXTH SESSION, MAY 7, 1885.

PROF. KOCH opened the Session with a demonstration of inoculations of Brieger's bacillus in guinea-pigs, and of pure cultures of comma-bacilli obtained from the intestines of guinea-pigs shown the day previous. He then resumed the debate, which he said had simplified the subject, for the points of difference between himself and Prof. v. Pettenkofer were diminished by the latter's conceding the influence of traffic and the existence of personal immunity. Prof. Koch, in return, did not entirely deny the influence of humidity of the soil—especially in the upper layers, where organic matter undergoes decomposition—upon the origin of an epidemic, but this condition is only one, and not the foremost, of many factors. Thus, local immunity, which is the sum of very complex conditions, as was shown for example at Lyons, is not explained by it solely. In India, there is only one place of immunity from the disease, and this is the town of Mooltan, which is situated in the desert.

He then adduced further examples to show that intercourse with cholera patients is not without danger. The dangers arising from ship traffic do not depend on the extent of the epidemic on individual ships, but on the number of vessels attacked; and this is comparatively great.

PROF. KOCH then directed attention to the third point proposed for discussion. He held that there is no authentic fact by which the transference of cholera by means of the air can be proved. Such an influence might exceptionally occur, but ordinarily the only influence exerted by the air upon an epidemic of cholera is by the fact that in moist air the infecting principle remains active for a longer time and dies quickly in dry air.

Soil can exert an influence upon the spread of cholera, but this is physical, and not geological, in its nature. Clayey soil, according to the hitherto accepted opinions, should afford some protection against the disease; but examples were cited by the speaker to prove that such protection does not always exist. Ground water can give no index of the extension of cholera, as was shown by marked examples from India, Egypt, Paris, Genoa, and Naples. The important condition in the soil as relating to the disease, is the decomposition occurring in the upper strata. Prof. v. Pettenkofer has declared three factors—*x*, *y*, and *z*—necessary in order to produce an epidemic, and Prof. Koch asked whether the bacillus represents the "*x*" or the "*y*" of the theory.

Drinking water has at all events some significance. A certain percentage of individuals will, through pure water, be protected from cholera. This fact he demonstrated by charts and tables, from Calcutta, especially Fort William, and from Bombay, Madras, Nagpoor, Pondicherry, Alexandria, and Cairo.

DR. GÜNTHER declared that in Saxony, during the epidemics of 1865, 1866, and 1873 physicians, nurses, transporters of the sick, and gravediggers, exhibited no higher mortality than the average among the general population. Laundresses of infected linen, as in 1865 and 1866, suffered a higher rate of mortality, but not in 1873, and in this connection it is to be remembered that in 1865 and in 1866 they were able to take the linen of deceased patients. He adduced further examples from Elsterberg and Gerbergasse, in Dresden, which seemed to favor the opinion that protection from the disease is afforded by clayey soil. The acme of the cholera epidemic in Saxony, in 1873, coincided with the height of the temperature of the soil at the depth of thirty-nine inches.

PROF. V. PETTENKOFER then read a paper entitled "The Drinking Water Theory and the Immunity from Cholera at Fort William in Calcutta." He pointed out that, according to Dr. Mouat, not only by the opening of a new water supply, but by further and exceedingly comprehensive hygienic measures, through which the sanitation of the soil was accomplished—the cholera epidemic at Fort William had been brought to a close; and the same had been claimed in other places, where improvement in the water supply had been regarded as the cause of the disappearance of the cholera; but more careful scrutiny had shown that the supposition was erroneous, or that many other hygienic measures of a different nature have coöperated to produce the effect. Pure drinking water *per se* is not a specific protection against cholera, and he considered it important to explain this, since, if the introduction of a pure water supply has been accomplished, our people will consider that sufficient has been done towards prophylaxis, and thus neglect the more important considerations of soil sanitation, even apart from an epidemic.

SEVENTH SESSION, MAY 8TH.

PROF. V. PETTENKOFER continued the discussion by saying that when he had proposed to consider the ground water as an index of cholera, he had not particularly meant the rise and fall of the ground water, but only the variation in the humidity of the soil overlying the ground water, occasioned by the rising and sinking of the water level. These variations only had any etiological value, and only such wells as do not vary from other causes could be used for measurement; for example, not those whose condition plainly depends on the height of the neighboring river. He postponed his further reply to Dr. Koch's criticisms until another occasion, since he had not at hand the data referring to many of these, and time did not allow of his considering them all.

DR. FRÄNKEL said that since the communications concerning the life duration of cultures of the comma-bacillus had clearly established the winter latency of an epidemic, there remained of the reasons advanced by Prof. v. Pettenkofer against the view that the comma-bacillus is the cause of cholera, only this, viz., that by the life peculiarities of the comma-bacillus the epidemiological laws of the local and

periodical characters of cholera epidemics cannot be explained. But this difficulty might be easily overcome, if we once admit the comma-bacillus to be the cause of cholera. It traces the cause of an epidemic to something outside the human body, with certain special conditions, which we designate as local and periodical, in addition. He asked Prof. v. Pettenkoker if, in what is known of such conditions, there are any facts which preclude the acceptance of the theory that the comma-bacillus is the cause of the disease.

PROF. V. PETTENKOFER replied that such conditions depend upon:

1. The physical peculiarities of the soil (permeability).

2. Its humidity, and the variations therein.

3. Its impregnation with organic matter.

He could only recognize the comma-bacillus, or any bacillus which bacteriology considers the cause of cholera, as the special virus of the disease, and have all doubt as to its causative influences removed, when it is proved that the microörganism in question answered to the epidemiological facts of local and periodical conditions of the disease. For this it is necessary that, like the virus of malaria, it have a relation to the soil.

PROF. VIRCHOW said that when Prof. v. Pettenkofer began his studies upon cholera, is was presupposed in Munich that a fungus was the cause of cholera, but through Thiersch's experiments upon white mice the idea was brought forward that the virus was developed later in the dejections. Although these experiments have been shown to be erroneous, yet Prof. v. Pettenkofer has not abandoned the idea of this late development of the cholera germ. In the investigation into the various conditions in which fecal products were concerned, the soil naturally occupies great prominence, and in this connection the labors of v. Pettenkofer had given much information. But while he gave deserved recognition to these investigations, nevertheless, he could not understand their exclusive standpoint. Why could the matter which causes cholera, and which is present in the soil, pass into drinking water? Theoretically, no objection can be made against this supposition. In practice, the somewhat crude question presents itself, to wit, whether improvement in drinking water is able to limit an epidemic of cholera. But there are many kinds of impurity in drinking water. If, in opposition to the experience advanced in this connection from Fort William, Calcutta, by Prof. Koch, Prof. v. Pettenkofer objects that other sanitary changes were effected, it must also be inquired whether they also were of value. Through the introduction of good drinking water, the drainage was also improved, and both, without doubt, exerted a favorable influence. What obtains in cholera is true also of typhoid fever. Thus, for example, the introduction of drainage produced a sudden and permanent reduction in the frequency of typhoid fever in Halle, and the buildings supplied with good drinking water remained free from the fever.

Yet it does not follow that typhoid fever and cholera are in no wise connected with the soil. It is established that the comma-bacillus can exist in water, and were another fungus allowed to be the cause of cholera, this same must be proved of it. By subsoil water he does not understand, with Prof. v. Pettenkofer, the water which oozes through the upper strata. In Berlin, for example, the water courses only to a moderate extent impregnate the soil, while the water they contain comes mostly from more remote and elevated regions. The subsoil water is a uniform substance, and it is impossible to draw distinctions in it. He had always maintained that only in the uppermost layers of the soil can fungi obtain their nourishment; and this was important, since every kind of impurity could not be drained off. According to the investigations made by Dr. Babes, in the Pathological Institute, the comma-bacillus, in the struggle for existence with other bacilli—*e. g.*, the putrefaction bacillus—was speedily stifled, and, therefore, it was dependent upon special and distinct conditions, whereby it can thrive. Further investigations, which must be made in connection with the ground water, drinking water, linen, etc., are required to give decisive information concerning how the bacillus could best thrive. A personal predisposition to cholera is not to be disputed, and in this relation it is important to consider that the occurrence of cholera usually takes place at a period of digestion, in which the contents of the stomach are more quickly passed into the intestine, and thus a living organism may reach the more deeply situated portions of the intestine, without being long in contact with the acid chyme of the stomach. He must also attribute some importance to the influence of the air. Thus by the simple handling of linen moist particles could be dispersed in the air, and thence enter the mouth.

PROF. KOCH said that he had much to say against the views of Prof. v. Pettenkofer, but on account of the necessity of concluding the Conference to-day, he would postpone his observations until another occasion.

The fourth point in the discussion was then considered, viz.: *Practical considerations in connection with the measures to be taken against cholera.*

PROF. KOCH summarized the principal measures which may be instituted against cholera under the following heads:

1. General measures which directly destroy the infective principle. Disinfection of the discharges. Destruction, or thorough disinfection of linen, etc. 2. Sanitary measures to remove the infectious matter from the neighborhood of the population. Drainage and care to obtain good water for drinking and household purposes. 3. Intelligent supervision of communities, so as to diagnosticate the earliest cases of the disease immediately, and thus to nip the epidemic in the bud. The sick must be isolated, or at least so dispersed that the transmission of the disease by the infecting germs may be avoided. Houses in which the disease occurs should be vacated, *i. e.*, the unattacked must be removed, and be kept under close observation. 4. Instruction of the public so as to allay their fears, and they must be warned of the danger of using infected food, *e. g.*, uncooked food, unboiled water, and especially of the dangers arising from the use of infected linen.

PROF. GÜNTHER called attention to the fact that, in the present status of our knowledge, it is very difficult to say what water is dangerous to health, and in what cases the wells should be closed.

PROF. KOCH said that no general rule could be laid down. It is, however, not only necessary to take into consideration the chemical properties of the water, but also to discover how many, and what kind of microörganisms are present in it.

PROF. GÜNTHER alluded to the supervision of railroad travellers. This he held to be difficult and often impossible of execution, and of doubtful advantage.

PROF. KOCH held that the provisions in this relation must be conceived in a humanitarian sense, as a general measure for the protection of the patient himself, and in the interest of his fellow travellers.

DR. S. NEUMANN called attention to the fact that the premonitory diarrhœa is excluded from control and yet must be regarded as cholera.

PROF. KOCH agreed, provided that the comma-bacillus was present in the dejections.

PROF. KÖHLER, in view of the strict control of maritime traffic, would like to support a practicable revision of railway travel without embarrassment to travellers, so that charges may not be brought against the authorities of neglecting precautions for the protection of travellers on land.

DR. MEHLHAUSEN urged the importance of keeping clean the water-courses. This is important not only for the larger but for the smaller streams whose waters are in general use.

DR. EULENBERG adduced examples in this connection, and cited the spread of cholera through the Saltzbach in Wiesbaden, and the Schwartzbach in Liegnitz.

PROF. VIRCHOW said that, according to the investigations of Prof. M. Wolff, all bacilli could be killed in the portable disinfection apparatus of Bacon. This apparatus can anywhere be easily used. The Town Council of Berlin built, in a very short time, stationary disinfection establishments, but in many cases a portable apparatus would succeed well. The isolation of cholera patients, since they undoubtedly can transmit the disease, is necessary. Land quarantine under the complex regulations of commerce is impossible, and in practice is no longer a question for discussion. One could, however, not censure an insular people if they sought to protect their island from the plague by insulation.

PROF. KOCH held that thorough drying is useful for disinfection. On every side his observation is confirmed that the comma-bacillus is quickly destroyed by drying. When disinfection through hot steam and carbolic acid, from any cause, is not practicable, he recommended the application of thorough drying for the destruction of the infectious principle. For example, in the disinfection of dwellings and furniture the drying process can be hastened by keeping-up fires in the rooms. In some way it is always possible to obtain at least thorough dryness. Fresh whitewashing with lime, in other cases, will suffice. In reply to the question of Dr. Pistor, Prof. Koch said that corrosive sublimate also destroys the comma-bacillus, but he did not, however, recommend this agent as a disinfectant on a large scale.

PROF. V. PETTENKOFER maintained that general directions which aim at the isolation of cholera patients, at disinfection, etc., do not determine whether the cholera will appear in a place or not—or whether the epidemic will be mild or severe. He acknowledged, however, that something must be done for the reassurance of the people.

DR. KERSANDT warned the authorities against inaction in the presence of an outbreak of an epidemic. The interests of the State demand that the public should feel that protective measures were taken. This is the best means to reassure them. The State can do much to guard against the transmission of cholera—the sick must be isolated so far as possible, and the dwelling-houses of cholera cases vacated after the outbreak of the disease. Supervision must be maintained over the water supply, and nothing neglected which, in the light of experience, may be able to afford protection.

PROF. VIRCHOW said that in the years 1848 and 1849 the physicians had acted on the supposition that cholera was not contagious. The mortality in that epidemic (12 per thousand) was the greatest which had ever been experienced in Berlin. As a measure of what could and should be done, the experience of this special epidemic is more useful than the observations of epidemics in the aggregate.

DR. MEHLHAUSEN said that the bodies of patients dead from cholera should not be transported. They should be enveloped in cloths soaked in carbolic acid, and, after standing a short time above ground in thick tarred boxes, without exposure, they should be buried.

The debate of the fourth point was then concluded.

On the fifth point, viz.: *Other subjects which may be named for discussion by the participants in the debate*—no one spoke.

PROF. VIRCHOW then closed the Conference and thanked the foreign members for participating in the discussion.

PROF. V. PETTENKOFER, in his own behalf and that of Dr. Günther, acknowledged the kind reception extended to them. The Conference, he said, had a common aim, and they could all meet together, even if their opinions were at variance.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 12, 1885.

THE PRESIDENT, ROBERT F. WEIR, M.D., IN THE CHAIR.

DR. LANGE read a paper entitled

OBSERVATIONS ON ACUTE SPONTANEOUS OR INFECTIOUS OSTEOMYELITIS.

DR. POST, a few years ago, saw a boy, fifteen years of age, who had been stopping at some watering-place, where he was attacked with multiple osteitis affecting one arm, the opposite forearm, and one thigh near the knee. He was brought to the city within five or six

weeks, when he had a large abscess at the upper fourth of the arm, which Dr. Post cut down upon, and found necrosis at the upper part of the shaft of the humerus, and removed a piece of bone about one and one-fifth inches in length. The shaft afterwards united with the epiphysis, and formed a solid arm. The affection in the neighborhood of the knee became so serious as to require amputation.

The case was remarkable for the multiplicity of bones affected and the rapidity with which the disease pursued its destructive course.

Dr. Gerster said that the question raised by Dr. Lange as to whether early operation was capable of preventing necrosis was an interesting one, and he had had a single experience which might throw some light upon the answer to be given. About six years ago a middle-aged woman presented herself at the German Dispensary. She had a very high temperature, and her intellect was considerably clouded; but when she was shaken out of her listless condition, she said she had fearful pain in the lower portion of one of the arms, and on examination the usual signs of acute infectious osteomyelitis involving the lower portion of the diaphysis of the humerus was found, consisting of doughy, white swelling, pitting on pressure, and sensitiveness to the touch, etc. The elbow-joint was semiflexed, and contained an effusion which was not purulent, as subsequent puncture and aspiration demonstrated. The symptoms were so grave that, having the necessary attendance and having the means of moving the patient, Dr. Gerster cut down upon the bone at once, thinking that if the pus could be released symptomatic relief would follow, although he did not expect to prevent necrosis. By a long incision, therefore, he laid bare the posterior portion of the humerus, taking care not to injure the joint or the musculo-spiral nerve, and ascertained that then, three days after the inception of the disease, extensive necrosis already existed. The necrosis extended into the epiphyseal body. The periosteum was found infiltrated, and here and there discolored; the bone of a yellowish-gray color, and not bleeding when cut.

He mentioned the case to show how early necrosis will sometimes take place in these cases, and he believed that a few hours were sufficient where extensive involvement occurred and where one or more of the large vessels became obstructed. In the present case, a portion of the bone was removed by chiselling and gouging, an antiseptic dressing was applied to the limb, and the patient was sent home. He observed the case for five or six days after the operation, and then the patient was removed to a hospital, where he lost sight of her. But the fever and local symptoms, the pain especially, did disappear after this operative measure, and the woman's general condition was very much improved. It was probable, however, that suppuration followed.

With regard to early interference, it should be borne in mind how difficult sometimes an early diagnosis is. He recalled a case, which he saw in consultation, where the seat of the disease was in the pelvis, and in one of those portions of the pelvis which are not accessible to exact examination. The os ischii was diseased, and the patient was in a typhoid condition. Regarding the causation, it may be stated that he had suffered for many years from purulent catarrh of the middle ear. Being in an unconscious condition, the patient was unable to give any account of symptoms, and only a suspicion of osteomyelitis could be arrived at until, on the third day, when a very marked and extensive œdema of one of the lower extremities developed, which was especially distinct about the upper part of the thigh, close to the pelvis, and then they felt sure of the diagnosis of osteomyelitis. In that case operative procedure was out of the question, as the disease was within the pelvis. The autopsy revealed extensive destruction of one of the os ischii, and a purulent accumulation extending to the sacrum, with purulent infiltration of all the muscles attached to the pelvis and passing down to the thigh.

With regard to the long-continued quiescence of pyogenous bacteria retained at the point of the primary osteomyelitic attack, Dr. Gerster mentioned a case observed in the German Hospital, subsequently treated by Dr. Lange, who followed him in the surgical service. A man apparently had had acute osteomyelitis at the lower portion of the diaphysis of the femur when eighteen years of age, which was followed by extensive necrosis and removal of sequestra, and finally cure within three years after the attack. The quiescence continued until he was sixty-five years of age, when the disease was renewed in the old focus. Dr. Gerster found no sequestrum, but a quantity of deciduous ulcerating granulations.

SECONDARY CARCINOMA OF THE AXILLA; AMPUTATION AT THE SHOULDER-JOINT; SUDDEN DEVELOPMENT OF HEMIPLEGIA WITH APHASIA; DEATH.

Dr. L. A. Stimson presented a specimen consisting of a tumor removed from the axilla of a woman forty-five years of age, with a history of cancer of the breast beginning at the age of thirty-five years, which had been removed three times; twice by caustics, and the last time by the knife. Four and a half years before she came under his observation, about the first of last April, she was then a thin, spare woman, in apparently good health, without cachexia, but complained of pain in the axilla, which had steadily increased and was accompanied with swelling of the right arm. On examination Dr. Stimson found in the scar, left by removal of the last tumor, one or two nodular masses, and in the axilla, the skin of which was tightly retracted, a cauliflower-like surface, moist but not ulcerated, and adherent to the tumor, which passed upward behind the pectoralis major muscle, and was quite firmly fixed to the deeper parts. There was no evidence of any glandular enlargement above the clavicle, and no signs of intrathoracic disease. The patient was exceedingly anxious to be relieved of the tumor, but Dr. Stimson told her that it was improbable that it could be removed and the arm saved, as it so involved the bloodvessels of the axilla that if they were left only a portion of the tumor could be removed, which it was not worth while to do. A fortnight later the patient returned and asked to have the operation performed. On the 22d of April the involved skin was circumscribed by an elliptical incision, extended down the arm to expose the vascular and nervous bundle; this was traced upward until it was lost in the tumor, and then the dissection was carried over the anterior surface of the tumor until the nerves and the artery were again found coming out from the

upper part of the growth, making it evident that they had passed entirely through the mass. There were present at the operation Drs. Sands, Post, and Detmold, and at this stage of the operative procedure a consultation was held, and it was agreed by all that the arm should be removed at the shoulder, which was done, and the artery was tied just below the clavicle. All of the tumor was completely removed. The wound was closed and dressed and the patient placed in bed, when her temperature was taken and it was found to be normal, the pulse 90 and fairly good. Two hours afterward, after she had partly recovered from the ether, the pulse suddenly fell to fifty, and the patient again became unconscious. The unconsciousness continued through the night, and she constantly moved the left arm, waving it to and fro; in the morning her temperature was 102° F., and pulse 140. Although conscious, she was unable to speak, and when addressed would point to her mouth, as if to indicate inability to speak. She was hemiplegic on the right side, including the face. The patient remained in this general condition until five o'clock in the afternoon and died.

Some of the medical gentlemen regarded it as a case of cerebral embolism, but where the embolism came from Dr. Stimson was unable to say. The patient, however, had given a history of some heart trouble, the exact nature of which had not been ascertained. She had on several occasions had distress in the region of the heart with disturbance of breathing, and it was supposed that she was troubled with cardiac disease. No autopsy could be obtained.

The tumor showed the stump of the artery and nerves running through it. The loss of blood during the operation was trifling. The sudden fall of the pulse to fifty after coming from under the ether, followed by unconsciousness with waving of the arm to and fro followed by hemiplegia and aphasia, pointed very plainly to some cerebral lesion.

In reply to a question by Dr. Gerster, Dr. Stimson said there was no thrombus observed in the artery when it was divided.

STRAPPING THE TESTICLE.

DR. POST mentioned a case with reference to some details in the mode of procedure. It was one of gonorrhœal epididymitis in which, in the subacute stage, he resorted to strapping the testicle. In isolating the cord for this purpose there is often difficulty in preventing the adhesive plaster from cutting the skin. Lint is usually interposed, and sometimes there is difficulty in keeping it in position. To obviate these difficulties Dr. Post adopted the following plan: after having the scrotum shaved and the opposite testicle drawn out of the way, he passed a roller bandage, about fifteen to twenty millimetres in width and half a metre in length, around the cord and over the upper part of the testicle, and then used a strip of India-rubber adhesive plaster about twelve to fifteen millimetres in width and half to three-quarters of a metre in length, passing it spirally over the testicle until he reached nearly the lower extremity of the organ and then applied the radiated straps in the ordinary way.

The peculiarity of the method consisted chiefly in using one long strip of plaster instead of several short ones, and it facilitated the operation very much and accomplished the object in a much more satisfactory way.

THE PRESIDENT raised the question concerning the advantage of strapping the testicle at all. His experience was against its usefulness, and had been such as to lead him to abandon it altogether.

DR. POST said his experience had been entirely the reverse of that of the President. He did not strap the testicle in the acute stage, but when there was a disposition to chronicity he had invariably found that the pain was promptly relieved and the swelling rapidly subsided when the pressure was made in the proper manner and at the proper time. In the present case from the time of the first application there was a marked sensation of comfort to the patient, and a marked diminution in the size and hardness of the swelling.

DR. BRIDDON did not favor strapping of the swelled testicle, and had had much better results by the use of a very thin elastic bandage. In order that it may lie smoothly over them it must be very thin, and not more than an inch wide.

DR. POST thought it difficult to cover the testicle completely with the elastic bandage. He thought everything depended upon carrying out the details of the procedure, and in that respect he found a number of turns of the narrow bandage to answer a much better purpose than a single strip of lint, which is apt to crowd against the upper part of the tumor, and he had found difficulty in keeping in place the strip of lint usually employed.

THE PRESIDENT remarked that the narrow bandage was used in the New York Hospital twenty years ago, the plan of treatment being identical with that mentioned by Dr. Post, except the use of rubber plaster. His impression had been that the swelling would go away nearly as quick without it as with it, and more painlessly.

DR. POST remembered one case in which he was called in consultation; one of prostatic disease, where the use of the catheter had caused swollen testicle, and where one of the gentlemen present was a specialist in genito-urinary diseases, and a man of considerable eminence. It was determined to have the patient's testicles strapped, and this gentleman undertook it, and did it in an extremely bungling way, which did no good whatever. If well done, and done at the proper time, Dr. Post felt positive that the strapping almost always, if not invariably, proved useful.

DR. GERSTER thought the President's remark entirely correct—that is, that in most of these cases treatment by strapping is unnecessary. He believed that indiscriminate strapping or elastic compression is unnecessary, and therefore harmful. There were, however, some cases in which the infiltration remained stationary, sometimes eight, ten, or twelve weeks elapsing without improvement, and which did not yield so readily to any other method as to compression of the organ. But in general, he thought strapping of the testicle after orchitis was overdone.

DR. POST said, Suppose a person found that invariably it was a source of comfort, was there any reason why it should not be done?

THE PRESIDENT said it was a procedure which could not always be accomplished satisfactorily, even by specialists.

DR. GERSTER mentioned one complication which

may arise from strapping the testicle, namely, a disagreeable eczema of the scrotum, which is more difficult to cure than the infiltration for the removal of which it has been applied.

Dr. Yale could add his testimony with reference to the frequent occurrence of eczema of the scrotum, which rendered it necessary to abandon all local treatment.

The President directed attention to the fact that in the New York Hospital the House Surgeons had obtained very good success in the treatment of acute epididymitis by the use of the Paquelin cautery, making half a dozen stripes running over the swollen cord down to the middle third of the testicle.

Dr. Briddon said he had heard of like success in the Outdoor Department of the Roosevelt Hospital.

Dr. Gerster had been unable to ascertain which had been most relieved—the pain, or swelling, or infiltration.

The President remarked that the pain was notably relieved, but the infiltration took the usual time to subside.

Dr. Hutchison had for a number of years treated painful epididymitis by making an incision half an inch in length through the tunica albuginea, and invariably with the result of relieving the pain at once.

Dr. Gerster had treated three cases by pricking the tunica vaginalis, allowing the fluid to ooze out, this giving great relief from pain.

The President had adopted the method mentioned by Dr. Gerster several times with satisfactory results, and in several instances had carried the bistoury into the tunica albuginea, but had never made an incision in it as mentioned by Dr. Hutchison. He should fear the occurrence of atrophy or eversion of the testes.

Dr. Gerster thought there was nothing more sure to relieve the pain than the application of five or six leeches to the inguinal region along the cord.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 18, 1885.

The President, Charles A. Leale, M.D., in the Chair.

Dr. E. G. Janeway read a paper on

ADVANCES IN THE STUDY OF THE ETIOLOGY OF DISEASE.

When invited by the President to read a paper at this meeting, he said, he had chosen the subject of the advance in our knowledge of the etiology of disease because of some of the circumstances attending the present occasion, when the Association met in a building (the Carnegie Laboratory) which is to be devoted to the study of the anatomy and etiology of disease. No greater inducement to study exists than that innate desire for knowledge which can best be compared to the hunger for food which seizes upon the starving; but oftentimes those well adapted for research and investigation have been absolutely unable to succeed from the want of the necessary means, appliances, and place for such work. Having spoken of the encouragement afforded to those engaged in original scientific research by the Government in Germany, he said that any one in this country, unless possessing a private fortune, must give up a large share of his time and thought to acquiring the means of subsistence, and for the apparatus and other expenses of his work; and this must be either by teaching or practice. He is thus subject to interruptions, is obliged to work at scientific subjects not when fresh and vigorous, but when weary and jaded, and hitherto too often in places little adapted to encourage work under such disadvantages. But, thanks to the liberality of the gentleman whose name this building bears, one of the great obstacles to successful labor has been overcome.

The history of medicine until within the last forty years, he continued, has contained much that has been grossly theoretical. He did not mean to deny that there were not those who had the foresight to see through the mists that clouded the scientific horizon; but they lacked the means and appliances to prove the correctness of their surmises. While it has been the merit of many gradually to lead in the pathway of a true explanation, none will deny to certain a preëminence in this respect, not alone for what they have accomplished, but also for what they have suggested, which has been the occasion of a successful result by others. In speaking of Virchow, he said that some might hesitate to ascribe to him a prominent place amongst the advancers of etiology; but without his labors and those of his pupils in ascertaining the exact anatomy of disease, and in constructing a rational explanation or theory of its recurrence, we should be far behind our present attainments. Having alluded to the indirect benefits which had resulted from the labors of Jenner in regard to vaccination, he said that the origin of the idea that a number of diseases called infectious spring from organisms which have entered from without and grow and multiply in the body, to infect others again, has probably sprung in most minds from the established instances of parasitic development as witnessed on the skin and in the interior. The objections which are urged to-day against what is called the germ theory of disease were formerly employed against the parasitic skin diseases, both as regards scabies and the fungoid varieties.

To Schwann we owe the idea that putrefaction and fermentation are dependent upon the presence of germs or vegetable organisms, and to Pasteur the dogmas that without such organisms there is no fermentation, and that for the different kinds there exist specific varieties; as well as the method and idea of endeavoring to separate the different varieties by fractional culture. Having explained the plan of procedure adopted by Pasteur, he said that after the acceptance of the belief that fermentation and putrefaction were dependent upon germs which rapidly multiplied under favoring conditions, the search after the organisms productive of infectious diseases could not be long delayed, nor the idea, which many already entertained, that in all of these disorders there must be a specific infectious agent, which might be obtained for further research, be hindered from obtaining more adherents. The proof demanded, and which Dr. Janeway did not doubt would in time be afforded in regard to all infectious diseases, is of the following character: 1. The disease-exciting germ must be found constantly present during the presence of the disease, or at least of its earlier stages. 2. It must admit of cultivation out of the body under such circumstances as to assure us of its purity. 3. Reintro-

duced into the system, it must excite in susceptible individuals the same disease phenomena. 4. In the individual so made ill by the introduction of the culture, we must again find the same germ as the cause.

In Virchow's *Archives*, vol. ii., of the year 1857, are recorded the researches, findings, and experiments of Prof. Brand, of Dorpat, who barely escaped being a great discoverer in 1856. He inoculated animals with blood taken from the cadaver of those that had suffered with splenic fever; found the peculiar organism in the blood, not only after death, but during life, found that the blood was capable of exciting the disease in others, and followed the microscopic examination of the blood for several days. He then studied the blood of animals dead of other diseases, in order to ascertain whether the organisms which he saw were common to others or peculiar to the disease in question. Unfortunately, he thought that these bacilli were vibrios and similar to the organisms found in putrefying blood; only he derived the conclusion that their presence during life or within a few hours after death in the blood was characteristic of splenic fever. Dr. Janeway said he had introduced this case because it was the disease of which later (in 1877) Robert Koch was able to trace the history, and which was the first to prove that there is a specific organism which can be grown out of the human or animal body, which can be reintroduced, the introduction of which into a wound will reproduce the disease, and which during the disease is again found in large numbers in the blood. Moreover, he found that the bacilli grew and produced spores which had a far greater tenacity of life than the bacilli, and that the secret which had puzzled others as to the reason why blood from an animal sick with the disease which did not contain the characteristic rods should yet be able to reproduce the disease; as well as to show that the earth, etc., was not necessary as a place for change, but that this development of bacilli into rods, followed by the characteristic production of spores, occurred as well on the microscopic slide, provided that air had access to the germ, that a certain temperature was maintained, and that nutrient material of a proper kind was supplied.

Previous to this time, 1877, there had already been found, by Obermeier, an organism in the blood of patients suffering from relapsing fever, which was so peculiar in its appearance that so far it has not been found in any other disease than this. The discovery of the spirillum in this disease was made in 1873, and it has been found in those affected with the disease in India, Russia, and Germany. To the origin by inoculation in human beings, the objection has been raised that the disease might have already been contracted by exposure during its epidemic existence. So far the life-history of the spirilla of relapsing fever is incomplete in that its methods of growth and development are not known with certainty, and, hence, it is urged by some recent writers that the spirilla are simply concomitant; but Dr. Janeway expressed the opinion that the final outcome of the investigations would undoubtedly be in favor of the view that these organisms are the cause of the disease manifestations, either of themselves or in their process of development.

An immense advance has also been achieved in our comprehension of the cause of many inflammations, such as abscesses, erysipelas, pyæmia, etc. Whilst the opinions were beginning to be moulded in this regard, and prior to any established connection between micro-organisms and these states, Lister (1871), by his efforts, which had in view the prevention of the entrance of supposed disease-exciting germs, created a revolution in surgery. There are some who do not adopt Listerism in its full sense, but yet claim good results; but he who is conversant with the past knows that the disbelievers, as a rule, exercise more care as regards cleanliness in all particulars than the most careful of their predecessors. While, however, such results as have been obtained by the exclusion of air and germs do not establish a definite causative nexus between germs and inflammation, these opened the way to more active and painstaking endeavors towards their discovery and cultivation, and Koch has again proved of special service in this regard, As a result of his labors, together with those of a host of others, it has been shown that either the micrococci or bacteria are present in inflammatory processes connected with acute abscess, pyæmia, septicæmia, erysipelas, and osteomyelitis. During the past winter, Dr. Janeway on two occasions injected a cat with pus from a localized empyema occurring in a young man who had pyæmia following typhoid fever. On the first, the pus was withdrawn from the chest by exploratory puncture; on the second, it was taken at the autopsy from the pleura. The cat showed slight ill-health for a day after the first, but no marked effect after the second. The sites of the disease showed micrococci in large numbers.

Erysipelas is a disease of such a characteristic type that it is not to be wondered at that attempts have been made to isolate and develop its organism, if one there were. Schleiden has succeeded not only in showing the presence of micrococci in the disease, as others had previously done, but also in cultivating these germs and in inoculating human subjects with the culture, with the result of producing typical instances of the disease. Pneumonia in many respects resembles erysipelas, especially as regards its method of spreading in the affected tissue, its clinical course, and its comparatively sharp crisis. Patient and continued research has resulted in the recognition of micrococci. These can be found in the sputum, and Leyden has obtained them in the fluid drawn from the lung by hypodermic injection during life. It is claimed that after cultivation they may be inoculated with success in the lungs of mice. Dr. Janeway said that recently four out of five Italians living in the same shanty, at Tarrytown, sickened with pneumonia, and at the autopsy of one of these, held four hours after death, he was able to find in the red hepatization, and particularly in the pleural exudation and the lymph vessels of the pleura, numerous micrococci. For a considerable time it was difficult to think of pneumonia as one of the acute infectious diseases, but he had heard of a number of illustrations of the sickening of several people in the same household with the disease.

Having spoken of the existence of micrococci in variola, vaccinia, scarlet fever, and measles, he said that in diphtheria there was not yet that sure proof that the organisms which had been observed in the disease bore a causative relation to it. There is no difficulty whatever in establishing the presence of a gonococcus in gonorrhœa, and micrococci can be found in large numbers in endocarditis in the little so-called vegeta-

tions which form on the heart-valves in this disease. Dr. Janeway, of course, alluded to Koch's researches upon tubercle and cholera, but did not enlarge upon them on this occasion.

In numerous cases of typhoid fever, he said, a bacillus had been found, not alone in the intestine, where it is commingled with a variety of others, but also in the mesenteric glands and in the spleen. Eberth has described this, and his description has been confirmed by Koch. In five cases of typhoid fever in which he made autopsies last autumn, Dr. Janeway found it present, but with one exception the autopsies were made twelve or more hours after death. The bacilli of typhoid, he said, had been found capable of growth upon culture fluids, but it would be difficult in this way to prove the disease, as the germs would necessarily have to be fed to individuals susceptible of typhoid fever, and not exposed to its influence. The history of medicine furnishes strong arguments for the existence of a germ in this disease, and few will be found more marked than the reports of the outbreak at Plymouth, Pa., as the facts have been gathered from medical journals and from conversation with Dr. Taylor, of the New York Health Board, who visited Plymouth by order of the Board.

For typhus exanthematicus there are no known experiments as regards culture or demonstrations of the peculiar exciting agent. Dr. Janeway has examined the blood taken from a spot of skin the site of petechial rash, and has found a few micrococci separate. Leprosy has been found to contain a specific germ or bacillus somewhat resembling the tubercle bacillus in its reactions. This germ was first discovered by Hansen, and afterwards by Neisser, and has been found present in the different manifestations of leprosy. Neisser succeeded in causing a leprosy nodule to grow in the subcutaneous tissue of two dogs. These leprosy bacilli are capable of producing spores by means of which they can be reproduced. Bacilli have also been found in glanders which are capable of cultivation and reintroduction into the system of the horse, with the effect of reproducing the disease.

The subject of the connection of organisms with disease is a large one, and growing constantly. Koch has proved himself the most thorough and reliable of those who have undertaken this study, and the knowledge which has been gained will not simply be for scientific accuracy, but will avail much in our subsequent efforts to cope with disease, since nothing is more essential to a correct prophylaxis than a true etiology.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, April 20, 1885.

The President, Samuel Nickles, M.D., in the Chair.

Dr. W. H. Wilder reported

A CASE OF FRACTURE OF THE BASE OF THE SKULL, WITH LOSS OF BRAIN SUBSTANCE THROUGH THE EAR; RECOVERY.

(See page 625.)

Dr. Ransohoff gave a brief history and the post-mortem record of a case which had been under his attention, in which a fracture of the base of the skull occurred in a woman, æt. 30, who threw herself from a window. There was extensive extravasation of blood into the eyelids and conjunctiva and vomiting of blood, but no hemorrhage from the ear. Four days after the injury the patient died. The autopsy revealed a fracture of the left frontal bone, passing backward across the greater wing of the sphenoid and the petrous portion of the temporal, opening the tympanum and exposing the ossicles of the ear. The membrana tympani was not ruptured. The case is interesting as an illustration of a small class of cases in which the tympanum is laid open, but the membrana is not ruptured, the blood passing into the mouth through the Eustachian tube.

Dr. Ransohoff cited two other cases of recovery following fracture of base of skull and escape of brain substance from the ear, which, he said, are recorded by Bergmann, and had escaped the notice of Dr. Wilder. He also thought that the hemorrhage attending injuries of the membrana tympani was not always slight and absolutely devoid of danger. As a rule it is slight, and when hemorrhage from the ear is excessive it is almost always associated with fracture of the base of the skull. Two cases, however, are reported in which hemorrhage from the ear terminated fatally, and the autopsy revealed no lesion, but rupture of the membrana tympani. Considerable specu lation had been indulged in to determine the exact seat of the fracture, and he thought Dr. Wilder was hardly justified in concluding that the fracture was limited to the point he mentioned, between the eminence for the superior semicircular canal and the line of junction of the squamous and petrous portions of the temporal bone. Dr. Ransohoff also mentioned a case recorded in a German surgical journal by Fischer, which was as interesting as the celebrated case recorded by Dr. Harlan, in which a crowbar was driven through a man's head. A man, while on a hunting expedition, had an iron ramrod accidentally fired through his head. It pierced the occipital bone on the left side, passed directly through the head, and emerged in the right frontal region. The patient was brought to Hanover, where Fischer saw him, and forced the ramrod out by blows with a hammer. He made an excellent recovery.

Dr. Taylor supplemented the previous speaker's remarks by the statement that the friends of the injured man, in their endeavors to extract the rod, had dragged him several yards over the ground.

Dr. Young said that, in military works, it is stated that there is no wound of the brain, however severe, that may not recover, and none so slight that may not terminate fatally. Cases in which balls have traversed the brain in various directions have recovered,—the ball being sometimes removed by trephining on the side opposite the wound of entrance. It therefore appears that patients with penetrating wounds of the skull may recover completely, or live a long time after the injury. He had met with two patients suffering from an injury of this character who had lived from the 15th of March to the 12th of April. Both had penetrating wounds with loss of brain tissue, but no paralysis or loss of consciousness. He had seen but one case recover where there was escape of blood from the ear.

He believed that many mistakes are made as to the diagnosis of the source of the hemorrhage.

Injuries to the base of the brain are naturally more fatal than are those in other regions. He had seen two men with fractures at the base of the skull who were affected with a disposition to perform rotatory movements. He remembered to have seen a negro woman who had sustained a fracture of the skull and the entrance of a piece of brick, and considerable dirt and hair, into the skull cavity. Together with this foreign material, about one or two drachms of brain tissue were removed, and the woman recovered, but with slight paralysis of the opposite side, which finally disappeared.

DR. ZENNER remarked that some of the cases are very remarkable, and yet the injuries themselves need not be considered fatal if the vital centres of the brain be not destroyed, and if subsequent hemorrhage or inflammation do not occur. The idea that such extensive injuries occur to the brain without subsequent impairment of intellect in some way is probably fallacious. Such cases, probably, never regain their former condition of intellectual power. The changes are manifested especially in the working capacity, both physical and mental, notably the latter. In a case like Dr. Wilder's, the injury to the brain is probably not limited to the exact location of the trauma, but involves distant parts of the convexity, as evidenced by the stupor and delirium.

DR. WILDER thought that his conclusions in regard to the location of the fracture were correct. The absence of paralysis of the seventh nerve until three days after the injury was proof positive that the nerve was not injured primarily. In attempting to use the ear speculum the canal was found to be almost closed by the superior wall (a condition of things which did not exist in the other ear), indicating that the force had acted diffusely from above, and concentrated upon this portion of the bone. It was not claimed that the fracture was *limited* to the part indicated; it may have extended in other directions, but must have existed somewhere in the anterior surface of the petrous bone, because the brain tissue escaped through the ear.

DR. RANSOHOFF said he had previously misunderstood the speaker, and supposed he had intended to convey the impression that the fracture was limited to the region of the tympanum.

MEDICAL SOCIETY OF THE STATE OF WEST VIRGINIA.

Eighteenth Annual Session, held at Weston, May 20 and 21, 1885.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, MAY 20TH.—FIRST DAY.

THE Society was called to order by THE PRESIDENT, DR. GEORGE BAIRD, of Wheeling, and the roll call showed thirty-seven members present.

DR. A. H. KUNST, Chairman of the Committee of Arrangements, delivered an address of welcome on behalf of the profession, and HON. R. W. STERLING, Mayor of Weston, gave the Society a welcome on behalf of the citizens. THE PRESIDENT then delivered

THE ANNUAL ADDRESS,

which was largely devoted to the consideration of sanitary questions. He referred to the good work inaugurated by the State Board of Health and its late efficient Secretary, Dr. J. E. Reeves. He condemned quackery of every form and kind, both in the regular profession and out of it, and gave some telling hits at the many mushroom specialists now abounding in every city and community.

THE TREASURER'S REPORT showed a balance of $158.76 in the Treasury.

THE SECRETARY REPORTED

a total membership of 116. He made several suggestions which resulted in the adoption by the Society of the following resolutions:

Resolved, That it is the sense of this Society that removal from the State forfeits membership, unless the member so removing continues to practise in the State, but under the Constitution—Art. X., Sec. 3—no non-resident member is eligible to election as an officer in the Society.

Resolved, That physicians who live near the border of this State in adjoining States, and whose practice may be partly in this State, are eligible to membership.

Resolved, That the communications from the Secretary of the Nebraska State Medical Society, touching interstate representation, be referred to a special committee consisting of Drs. Kunst, Shriver, and Dickey, to report at the next annual meeting.

A communication was received from the Department of Hygiene of the West Virginia Branch of the Women's Christian Temperance Union, asking the Society to appoint a committee to report at the next regular meeting on the injurious

EFFECTS OF ALCOHOL.

The communication was referred to a committee, who reported the following resolution without recommendation:

Resolved, That a committee be appointed, as requested, to prepare a report to be read at the next meeting of the Medical Society of the State of West Virginia, on the physiological effects of alcohol upon the human system, its hygienic uses, and its influence in the formation and hereditary transmission of mental, moral, and physical defects.

On motion of Dr. Harris, the motion was laid on the table.

A paper on *The Errors of Refraction* was read by Dr. John L. Dickey, of Wheeling.

DR. JOHN FRISSELL, of Wheeling, read a paper on

SOME THOUGHTS ON BLOODLETTING, AND THE USE OF THE OBSTETRIC FORCEPS.

He thought that venesection should be practised more frequently than it has been for many years. He cited cases from his own experience, which began more than fifty years ago, showing excellent results following very free bleeding. He condemned the use of the forceps except in very rare cases. He has himself used that instrument only about half a dozen times. He thought that opium, ergot, and time will generally obviate the necessity for using the forceps, to which he attributes cervical and perineal lacerations, and vesico-vaginal fistulæ.

DR. CHARTER, of West Union, stated that he had attended about two thousand labor cases, used the forceps but once, and had never lost a mother in childbed.

The sentiment of those who spoke was in favor of

venesection in puerperal eclampsia and other unusual cases, where depletion seems desirable. It was also overwhelmingly in favor of the judicious and skilful use of the forceps, which the members thought prevented and not caused vesical and rectal fistulæ.

THURSDAY, MAY 21ST.—SECOND DAY.

DR. FLEMING HOWELL, of Clarksburg, read the report of a

CASE ILLUSTRATING THE USE OF CARBOLIZED CATGUT LIGATURE IN SECURING UNION OF DIVIDED TENDONS.

The case was briefly as follows: A policeman had a cut an inch and a half long, extending obliquely across the back part of the thumb, dividing completely the tendon of the long extensor of the thumb, with its sheath. The ends of the divided tendon were at once united with fine carbolized catgut; the divided sheath was then united in the same manner, and the external wound closed. He was at once able to extend the thumb, which, of course, he could not do before. A splint was applied so as to keep the thumb extended. The wound healed promptly, and the thumb is as sound and useful as before the injury.

DR. D. PORTER MORGAN, of Clarksburg, read a paper on

OPERATIONS IN MALIGNANT DISEASE.

The subject was discussed by many of the members, nearly all agreeing with the writer of the paper in the propriety of the early removal of malignant growths, or even those of a doubtful nature, if removal is practicable.

DR. T. A. HARRIS, of Parkersburg, read a paper entitled *Mens Sana in Corpore Sano.*

A paper on *The Signs of Impending Death*, by Dr. T. R. Evans, of Nuttalsburg, was in his absence read by the Secretary.

The Society then proceeded to the

ELECTION OF OFFICERS,

which resulted as follows:

President.—Dr. T. A. Harris, of Parkersburg.

Vice-Presidents.—Dr. A. H. Kunst, of Weston; Dr. J. F. Lanham, of Newburg; Dr. J. L. Fullerton, of Charleston.

Secretary.—Dr. Samuel L. Jepson, of Wheeling.

Treasurer.—Dr. John A. Campbell of Wheeling.

Board of Censors.—Drs. John L. Dickey, C. C. Hersman, J. T. Carter, H. N. Mackey, A. F. Stifel, Fleming Howell, and L. D. Wilson.

Charleston, Kanawha County, now the capital of the State, was unanimously chosen as the *next place of meeting*, and Dr. J. L. Fullerton, of that city, was appointed Chairman of the Committee of Arrangements.

After the usual votes of thanks for courtesies extended, the Society adjourned.

THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Thirty-sixth Annual Meeting, held at Scranton, May 27, 28, and 29, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE PRESIDENT, DR. EZRA P. ALLEN, of Athens, Bradford Co., occupied the Chair, and called the Society to order.

DR. I. F. EVERHART, Chairman of the Committee of Arrangements, delivered an address of welcome on behalf of the profession of Scranton, and the Hon. Alfred Hand on behalf of its citizens.

DR. HENRY H. SMITH, of Philadelphia, announced the receipt of a telegram from Harrisburg stating the passage of the Bill for the establishment of a

STATE BOARD OF HEALTH.

The following resolutions were then adopted:

Resolved, That this Society has learned with great satisfaction of the final passage through the Legislature of this State, of the Act to create a State Board of Health, and that it hereby tenders its thanks to the Hon. Robert Adams, Jr., Senator from Philadelphia, and to the Hon. Henry K. Boyer, Representative from Philadelphia, for their earnest, untiring, and successful efforts to secure to the people of this great Commonwealth so important a safeguard as is anticipated from the organization of this Board.

The Committee on the State Board of Health presented its report, and on motion it was accepted, and the expenses of the Committee, $49.25, ordered to be paid, and the Committee was discharged with the thanks of the Society.

The next order of business was the consideration of the

AMENDMENT TO THE CONSTITUTION,

presented by Dr. Allis (see page 46 of the volume of *Transactions*, for 1884). After the reading of a letter from Dr. Allis advocating their adoption, the amendments were laid upon the table.

DR. TYSON, of Philadelphia, on behalf of the Committe on the

COLLECTIVE INVESTIGATION OF DISEASE,

read a preliminary report on pneumonia based upon returns from sixty cases which occurred up to May 1st.

MEDICAL LEGISLATION.

DR. H. H. SMITH, of Philadelphia, offered the following:

Resolved, That any county society that shall hereafter seek general medical legislation at Harrisburg, without previously obtaining the consent thereto of the Medical Society of the State of Pennsylvania, shall forfeit all its privileges and connection with this Society, until relieved from their contempt by the report of the action of the Judicial Council.

DR. TRAILL GREEN, of Easton, favored the resolutions heartily, and was especially glad there was a penalty attached to them.

DR. J. SOLIS COHEN, of Philadelphia, moved that the following clause be introduced after the word Harrisburg —"which shall compromise the interests of the State Society."

A general discussion followed, after which the amendment was laid upon the table.

The original motion, which was stated by Dr. Smith to be a standing resolution, not a by-law, was then adopted.

DR. S. S. SCHULTZ, of Danville, in the absence of Dr. John C. Curwen, then read the report of the

COMMITTEE ON LUNACY AND IDIOCY.

The Committee report that, though a large number of questions calculated to obtain histories of different forms

of mental disorder, were sent out to members of the profession in different parts of the State, the answers received have been so few that, though they are excellent in themselves, they are not sufficient for purposes of generalization, and the Committee begged leave to present the following report on the general

MANAGEMENT AND TREATMENT OF MENTAL DISORDERS IN THE EARLY STAGE,

in place of the report on different forms and characters of mental disorders.

Treatment, in the earliest stages is important and essential to restoration — the earliest symptoms are peculiar restlessness, and singular ideas and actions. These may be slight—but, when out of the usual course of conduct and mental action, they must be considered as indication of disordered action, and if allowed to progress more serious disorders must be soon anticipated.

Inability to attend to casual duties, loss of sleep, failure of appetite, etc., are other symptoms, but the most serious is loss of sleep. Sedatives and narcotics are not the most efficient means to effect a cure of these symptoms. If their use be continued for some time, they are apt to lead to a habit of reliance on them, which, after a time completely enslaves the patient and leads to serious disorders of the stomach and constipation; and they produce such a state of the nervous system as greatly interferes with the processes of assimilation and creates a morbid condition, for which no special name has yet been found, but which is of serious import to the continuance of healthy action.

The whole system, or more particularly the nervous system, is in an asthenic state which cannot be relieved, but is rather increased by sedatives and narcotics, so that other more efficient means must be used to build up and produce a more healthy action and condition. Care must be taken to relieve constipation which is so constant a concomitant of each case, and this must be done in the first place by the use of such medicines as will act on all the internal organs, and after their free operation, dependence must be placed on diet; the use of such articles as are nutritious and at the same time have a relaxing influence, as oatmeal Graham bread, fruit, etc., and above all, insisting on the establishment of regularity in the time of visiting the closet, fixing the specified hour and adhering to it very steadily.

Massage over the region of the colon, and a plain, nutritious diet of meat and vegetables at regular times, are important. Too much stress is often laid on exercise. Asthenic cases should husband their strength, and strength must not be sought at the expense of nerve power.

It may be necessary, at the commencement of treatment, to give sedatives to produce sleep, but such should not be continued steadily.

One great deficiency, to judge from what has come within the writer's experience, arises from the disposition to be constantly changing the form and character of the medicine, not giving any one sufficient trial to produce a decided result. It may take days or weeks to produce a decided effect, and the patient must be urged to persist in the treatment prescribed.. Pyrophosphate of iron is cheap, soluble, and pleasant to the taste, especially when combined with compound tincture of gentian. The use of stimulants should be ordered in asthenic cases. They may produce a temporary feeling of relief, but afterwards the immediate condition is rather increased or made more sensible to the individual.

AFTERNOON SESSION.

Dr. S. S. Schultz, of Danville, delivered the *Address on Mental Disorders.*

Dr. J. G. Richardson, of Philadelphia, then delivered the *Address on Hygiene and State Medicine.*

Dr. Charles S. Turnbull, of Philadelphia, then delivered the

ADDRESS IN OTOLOGY.

He deprecated syringing, and the use of water in any way, in connection with cleansing of the external auditory meatus. He urged parents to cease their efforts to cleanse children's ears by the use of soap and water, twisted up corners of wet towels, handkerchiefs, etc. One especially valuable hint to mothers, as well as to those who are to advise them, is that concerning the rearing of young children, whose noses are usually allowed to take care of themselves. Every child should be taught to blow its nose. If it has not been or cannot be taught to free the nostrils of mucus, its chances for retaining hearing power in case of acute or subacute disease of the middle ear, are much poorer than in the case of one who has learned to blow its nose. Handicapped by being unable thus to free its nostrils, a child cannot possibly inflate the tympanum or middle ear, and clear the Eustachian tubes, so that the dread exanthema must as a rule mean deafness. Forcible dilation, by Politzer's method, is generally sufficient in the case of adults, but will not answer for children, who only become demoralized and terrified by the presence of any one who has been so injudicious as to attempt its use. For children he recommends one nozzle of an ordinary auscultation tube, protected by a perforated "lead pencil rubber cap," slipped upside down over it. This is called the nose-piece, and can be held firmly, as it plugs one nostril, and acts as a point of support upon which to close the other. As the child cries lustily or else blows out, (as if to blow out a light) the surgeon having the nozzle at the other end of the tube, in his mouth, blows a quick, short blast which invariably inflates both ears. Once assured that the procedure does not cause them pain, children enter into the spirit of it, and blow with a will.

The great secret in the treatment of all discharges from the ears, is dependent upon the fact that fermentation and putrefaction soon occur in the moist auditory meatus. So long as a discharge is not allowed to ferment it will not become fetid, seldom even purulent.

Eczema (otitis externa eczematosa) of the auricle, and external auditory meatus, whether in a child or in an adult, is generally a disease of neglect or injudicious interference. In children it is apt to be the former cause, in adults the latter, but it is usually induced by the use of soap; in adults it is generally caused by meddlesome attempts at ablution. In children eczema readily yields to treatment, providing soap and water be left out of the question, while in adults it is more persistent and stubborn, recurring monthly, perhaps, for several years. Mild cases yield to the constant application of a weak mercurial ointment, while chronic

cases require the application of a saturated solution of nitrate of silver.

Boric acid, if properly used, still holds its own as a specific for chronic otorrhœa, but not for acute otorrhœa (except when the discharge is fetid). This latter class of cases calls for an "aqueous boracic acid solution."

In the treatment of "tinnitus aurium" the different preparations of the erythroxylon coca are to be especially lauded, not only because of their direct local effect on the throat and rhinopharynx, but also for their anæsthetic effect on the mucous membranes generally. In this connection, hydrobromic acid in conjunction with bromide of sodium is not to be forgotten, especially in cases of tinnitus due to disorders of cerebral circulation dependent upon nervous irritation.

Dr. Turnbull called especial attention to a disease (not unlike boiler-maker's deafness) which he styles "mill-operative's deafness." This is a disease of the auditory nerve, caused by a prolonged succession of concussions (erschütterung) and irritation from the rattle and din of machinery, the first grave and characteristic symptom of which is the power of being able to hear distinctly only when in a noise.

DR. EDWARD JACKSON, of Philadelphia, read a paper on the

DIAGNOSIS OF INCIPIENT CATARACT.

Cataract, though perfectly amenable to treatment, is still one of the most dreaded diseases of the eye. This is mainly because it is blamed for the effects of other lesions. This would be largely avoided if practitioners of medicine were generally more skilful in its diagnosis. Subjective symptoms are of little importance except as they point to other affections complicating cataract. In this connection it should always be borne in mind that the uncomplicated advance of cataract is absolutely painless. The results of examination of the pupil by oblique illumination are often inconclusive or unreliable. The best way to detect partial opacity of the crystalline is to throw into the eye the light from an ophthalmoscope mirror, and then to look at the general red glare obtained from the back part of the eye. In doing this, the surgeon looks through the suspected lens, and all opaque portions become noticeable as black spots, lines, or patches in the red circle of the pupil. For such an examination no costly ophthalmoscope is needed. Any piece of looking glass, with a hole scraped in the silvering for the observer to look through, suffices perfectly.

But when lens opacity has been recognized, the diagnosis of cataract is only just begun. The practical question is, Does the lens opacity cause the symptoms complained of? Incipient cataract may be present and cause no inconvenience whatever. On the other hand, when cataract exists other lesions of the eye—nerve atrophy, choroiditis, or ametropia—are very apt to be present. The complete diagnosis of cataract demands ability to recognize all conditions that may impair vision, with the judgment and information necessary to assign to each its proper share in the causation of the patient's symptoms. The best measure of the extent to which lens opacity interferes with a patient's seeing is the extent to which it interferes with the surgeon's inspection of the optic disk and retinal vessels of the affected eye.

DR. PETER KEYSER, of Philadelphia, read a communication from a Committee of the Lackawanna County Medical Society relative to the case of a man in Scranton, who had registered a diploma from the Western Reserve College endorsed by the Dean of the Homœopathic College of Philadelphia. He then offered a resolution condemning the endorsement of such diplomas.

DR. BISHOP replied that the men who will endorse diplomas of no value, would pay no respect to the wishes of this Society.

Upon motion of Dr. Bishop, the resolution was laid over until to-morrow morning.

Adjourned.

THURSDAY, MAY 28TH.—SECOND DAY.

MORNING SESSION.

DR. EDWARD JACKSON, of Chester Co., read the report of the Committee on

MEDICAL EDUCATION,

appointed to prevent downward competition in the granting of a State license; to relieve medical schools of the degrading influence such competition exerts; to regulate the licensing of those obtaining the medical degree from institutions outside the State; to guard by publicity and direct control against abuse of the licensing power, and to insure the efficient administration of laws looking to these ends. The report recommends that this Society endorse and advocate before the people of Pennsylvania and their representatives in the State Legislature the following propositions:

First. The sole power of granting license to practise medicine in Pennsylvania should be vested in a single board.

Second. This board should have no connection with any corporation engaged in medical teaching.

Third. The doings of this board, including the determination of the fitness of applicants for the license to practise, should be public and matters of record, and the records open to public inspection.

Fourth. To secure the efficiency of the board against incompetent membership, and the undue pressure of partisian politics, the medical profession or its representatives, should nominate to the Governor a list of persons qualified to perform its duties, from which list the board should be appointed.

It is also recommended that a committee be appointed to prepare, in accordance with the views of this Society, a form of bill suitable for presentation to the next biennial session of the Legislature, and report the same to the next annual meeting.

DR. H. H. SMITH, of Philadelphia, moved that the resolutions of the Committee be taken up seriatim. Carried.

DR. SOLIS COHEN, of Philadelphia, offered, as an amendment, to insert the word "regular" in the first resolution, so as to make the resolution read, "The sole power of granting license to practise regular medicine," etc. He said this will prevent the practice of anything else, otherwise we have to associate with homœopaths, eclectics, etc., with whom we do not affiliate.

DR. R. S. SUTTON, of Pittsburg, could not see how the amendment would improve affairs. He did not believe that the Legislature of this State would pass any such law as the amendment proposed.

Dr. E. A. Wood, of Pittsburg, said that no law ever became beneficial which was not from the people, and he thought this Society ought simply to ask for legislation for our own school which will control our own ranks, and wait for the voice of the people for more.

Dr. Jackson, of Chester, said that to ask for legislation for ourselves only would be impertinence on our part. The question is for the good of the community. On *à priori* grounds the original resolution is better than the amendment. In California and Kansas there is a mixed board. Should we adopt the amendment we would defeat our own object. The medical laws of Canada allow a mixed board.

Prof. Osler, of Philadelphia, upon request, briefly related the effect of the laws in Canada. In Ontario a mixed board of regulars, homœopaths and eclectics, was instituted twenty years ago. The basis of the board was its being appointed by the profession. The examinations are of threefold nature: 1st, a preliminary examination on preliminary branches; 2d, examination on branches common to all schools; 3d, one on therapeutics and practice by each school. This has worked admirably, the eclectics have been abolished, and the homœopaths have been decreased, for the reason that it requires a four years' preliminary education. In Quebec, the population being chiefly composed of French-Canadians, the people are all very rugged, and the homœopathic medicines are of no avail in treatment, hence there are but very few homœopaths there. Concerning an inquiry by Dr. Smith as to whether the difference in the Government of Canada and the United States would not make a difference, he said none whatever, because the board is wholly under the control of the profession.

Dr. Traill Green said he thought the Society should not be in a hurry to act on these resolutions, but sleep over them three hundred and sixty-five nights, and appoint a committee to draft a form of bill to be discussed at the next meeting.

Dr. John B. Roberts, of Philadelphia, spoke against the amendment, saying, if we cannot take care of ourselves without the Legislature and the Governor he did not wish to practise. He placed it on higher grounds, and would advocate a proposition for the protection of life and health. We must have a board to do this, and he did not think that the association with members of irregular schools would have any bad effect. There are but two unmixed boards in the United States (Virginia and West Virginia).

Dr. Tyson, of Philadelphia, also spoke in favor of a board which should be entirely independent of the colleges.

On motion, the amendment was laid on the table.

Dr. W. D. Kearns, of Pittsburg, moved to postpone the further consideration of the report until next year. Lost.

The first resolution was then taken up and carried.

The other resolutions were then adopted seriatim.

The Secretary stated that at the last meeting of the American Medical Association an act for the establishment of a

STATE BOARDS OF EXAMINERS

was prepared for submission to each State Society for their views upon it. He read a draft of the same.

On motion it was referred to a special committe. of five. The Chair appointed the following: Drs. Shakespeare, of Philadelphia, Orth, of Harrisburg, Everhart, of Scranton, Breinig, of Bethlehem, and Price, of West Chester.

On motion, the Committee on Medical Education was continued for another year.

Dr. Taylor, of Wilkesbarre, then read a paper on *The Plymouth Epidemic*.

Dr. French, of Philadelphia, followed with a paper prepared by Dr. Shakespeare and himself on the same subject.

AFTERNOON SESSION.

The report of the Nominating Committee was read, and on its adoption the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—E. A. Wood, M.D., of Allegheny County.

Vice-Presidents.—Hiram McGowen, M.D., of Dauphin County; E. J. Russ, M.D., of Elk County; A. H. Sheaffer, M.D., of Mifflin County; and C. C. Halsey, M.D., of Susquehanna County.

Permanent Secretary.—W. B. Atkinson, M.D., of Philadelphia.

Recording Secretary.—G. D. Nutt, M.D., of Lycoming County.

Corresponding Secretary.—J. H. Musser, M.D., of Philadelphia.

Treasurer.—Benjamin Lee, M.D., of Philadelphia.

Members of the Judicial Council.—J. L. Stewart, M.D., of Erie County; S. S. Schultz, M.D., of Montour County; and Henry H. Smith, M.D., of Philadelphia.

Chairman of Committee of Arrangements for next Meeting.—T. H. Helsby, M.D., of Williamsport.

The next meeting will be held on the first Wednesday of June, 1886, at 9 A.M., in Williamsport.

THE ADDRESS IN MEDICINE.

was then read by Dr. E. T. Bruen, of Philadelphia.

In tubercular disease, he said, it has been established that a microörganism, the bacillus of tuberculosis, is constantly present. The inoculability of the tubercular material from pure cultures is also proven, and its causal importance is claimed by an increasing number of clinicians and pathologists. It is, however, a fact that healthy tissue can resist the inroads of the microbe, and constitutional predisposition or acquired ill-health is a constant source of menace if the new etiology should prevail. But there also exist cases of abdominal tuberculosis without pulmonary lesion, and even cases of cheesy degeneration in the lungs, in which the bacillus is not present, however careful the search. These cases radiate foci of infection through the lymphatic channels, and in this manner differ from a case of tubercular matter in which a bacillus exists, for in the latter case the entire system may be involved. There also exist the forms of interstitial phthisis, known as pneumonokoniosis or artisan's phthisis, in which the appearances are often very similar to the admittedly tubercular forms, but which are minus the bacillus.

Some personal views were expressed as to the diagnosis of friction over the pericardium, viz.: (*a*) They were synchronous with the movements rather than the sounds of the heart. (*b*) They were superficial sounds often accompanied by a fremitus. (*c*) Change of pos-

ture induces an increase of murmur. (*d*) The alterations common to the walls of the heart in endocardial disease were absent. The above were usually noted, but especial importance was laid upon the location of maximum intensity of a murmur in pericarditis which does not correspond with a valve point. The pericardial murmurs also change their focus of maximum intensity very often.

In alluding to antipyrine, it was described as undoubtedly efficient as an agent to reduce temperature, which continued to fall for about six hours after the exhibition of one or two doses. The objection to its use is the profuse exhausting perspirations to which it gives rise, and it also produced a depressing effect upon the heart, though the latter is less than the depressant effect produced by others of the carbolic acid series. The usual dose employed by the speaker is ten grains, as the strength of antipyrine is about twice that of quinine. Nitro-glycerine had been found valuable in lessening albuminuria associated with increased arterial tension, but its use must be watched, since it is possible that the reduction of arterial tension may be so great as to impair the cardiac power so essential to perfect circulation in renal processes, and thus albuminuria from feeble circulation would occur. Nitro-glycerine was also considered as very useful in renal asthma. Caffeine was a safe cardiac stimulant and diuretic. The dose should range between eight to twelve grains daily. A peculiar fanciful delirium, like that produced by excessive amounts of belladonna, was described as an occasional symptom when caffeine had been used continuously; the mental equilibrium is speedily restored when the use of the drug is suspended.

DR. H. H. SMITH, of Philadelphia, read a paper on

THE NON-CONTAGIOUSNESS OF CHOLERA.

DR. SHAKESPEARE, of Philadelphia expressed himself as heartily in accord with the author except as to the question of non-contagion; strictly, that is right, as it is not directly contagious. He thought, however, that it is indirectly transmissible from person to person. The fact that persons working about cholera patients do not contract the disease merely proves that it is non-contagious through the air. Observations are overwhelming which prove that cholera has a virulent infectious agent, which enters the water or food and the body through them by the oral passages or stomach. The susceptibility lies in disorders of the digestive system, which explains why drunkards are so susceptible to it, as was demonstrated in Europe last year. As to the comma-bacilli, the profession must be able to distinguish the varieties. In the advocation of measures for the protection of the public, it is well to allay the fears of the people, but the only way to reach proper legislation on the matter is to create popular sentiment in favor of it. Neither Koch nor any one else would say that any disinfectant will reach the special organism of cholera when once in the body, and it is unfair to demand that of Koch.

DR. VARIAN, of Crawford, stated that his experience made him coincide with the non-contagionists, but he believed that the comma-bacilli from the excreta of patients of cholera acted upon by fermentation and brought in contact with the water or food will generate cholera. It matters but little how we get cholera, whether by immediate contact or through the food, our duty is to seek how to keep the contagium outside the body, and he thought this can be done by a proper mode of living, and by avoiding alarm and panic, with their influence upon the nervous system. The simple application of heat will destroy the cholera contagium.

DR. HEEBNER, of Scranton, called attention to the fact that the cholera germ is supposed by good authorities to be killed by putrefaction.

DR. W. F. WAUGH, of Philadelphia, read a paper on

A NEW TREATMENT OF THE ALCOHOL HABIT.

The treatment of acute alcoholism, he said, is generally successful; but, except in a very few cases, the patient relapses into inebriety, and finally dies a drunkard. The disease is not, however, essentially incurable; for cases *do* sometimes recover permanently. The causes of the relapses are:

1. Previously existing disease, which led to drink.
2. Overwork, especially when combined with illness.
3. Gastric catarrh, due to alcohol.
4. Catarrh of the mouth, due to the same cause. This is the form which is popularly cured by using liquor as a gargle, instead of drinking it.
5. The depression due to the withdrawal of the accustomed stimulus.

In the first and second classes, the recognition of the cause affords the indication for treatment.

In the third class, the remedies recommended are hot water with soda before meals, oxide of silver, oxide of zinc, or bismuth following, and minute doses of ipecacuanha to restore the secretion of the digestive glands.

In the fourth and fifth classes, the use of coca is recommended, in the form of a masticatory; to obtain the local effect on the mouth, as well as the constitutional effect, in relieving the depression. The object is to substitute for the alcohol habit the harmless habit of chewing coca. The food should be carefully regulated, and should at first consist of raw oysters or beef, with capsicum and vinegar, pickled tripe or pig's feet. If the patient has passed the point when he still desires to be cured, and is unwilling to make an effort, he should be put under restraint; preferably in an institution where he could be compelled to earn his livelihood, instead of spending the time in enervating idleness.

DR. SPENCER M. FREE, of Dagus Mines, read a paper on *Morphia in Cholera Infantum*.

DR. JOHN H. PACKARD, of Philadelphia, presented a paper on

A NEW TRACHEOTOMY TUBE,

and demonstrated the use of a new apparatus for keeping the opening patulous.

PROF. PANCOAST stated that for years he had given up the use of the tracheotomy tube. The trachea is an open tube, the rings are its skeleton, take away one-half those rings, and the trachea still maintains its conformity. To put a tube in a tube seemed to him absurd, and it is only a source of irritation. He splits one or two rings and keeps the opening patulous by wires about the neck, the ends simply drawing asunder the sides of the opening. Sometimes he cuts an oval opening in the trachea.

Dr. Packard thought that as all surgeons are not able dexterously to cut out an oval piece from the trachea, the best rule is to make a lineal incision, and he

thought his instrument better than the tube, if for no other reason, than because it has not to be taken out, and is easy of insertion.

DISCUSSION OF THE PLYMOUTH EPIDEMIC.

Dr. Shakespeare, of Philadelphia, thought that the Plymouth epidemic is a clinching argument in favor of the specific nature of typhoid fever, and that it requires the specific germ or poison to start it. This has a very important bearing. It specifies that the specific cause is elaborated in the gut, and passes from the bowel, and through carlessness in disinfection reaches various things which, in turn, infect the community. Again it shows the absolute importance of precautions to kill the poison. Efficient means will prevent the transmission of the typhoid germ. He thought that printed rules for disinfection should be distributed among the people. The water should be boiled, food thoroughly cooked, milk boiled, culinary utensils, etc., all should be boiled in water of a temperature over 212° Far., for at least half an hour. The profession should instruct the laity on these subjects. A few days ago in visiting Plymouth he found only limited means of disinfection being used. If all the above measures were carried out, he thought the epidemic would cease. The lesson which this epidemic has taught the profession is that no case of typhoid fever, no matter where it be found, should be allowed to run its course without every evacuation being disinfected.

In the evening Dr. Allen delivered *The Presidential Address*

Friday, May 29th.—Third Day.

Morning Session.

Dr. C. A. Rahter, of Harrisburg, not being present, his *Address on Obstetrics* was read by title.

Dr. W. D. Kearns, of Pittsburg, read a paper on

RETROFLEXED SPLINTS FOR FRACTURES OF THE FOREARM.

which, it was claimed, give greater ease to the patient and efficiency in causing the parts to knit and heal in proper shape. In his experience he has found that in many, if not most, cases of fracture of the forearm or wrist, the splint should be applied so that the metacarpal phalanges of the hand may be bent upward from the plane of the arm, at an angle of about 122°, and that it should be left as free to move as possible. This is about the natural inclination of the human hand, or that in which the posterior muscular tendons are most completely relaxed, and the continued maintenance of this relaxation of the several tendons, fasciæ, and ligaments is of paramount importance in the class of fractures above noted. It is the purpose of this splint to secure these points of advantage, and especially to effect a ready and comfortable maintenance of the required muscular relaxation of the extensors and flexors to their insertion along the phalanges, and of the muscles and fasciæ of the hand and thumb.

Dr. John H. Packard, of Philadelphia, said that in Colles's fracture the immediate bandage does no harm, neither does it do good. If reduction is thoroughly accomplished, it is very seldom that displacement will recur, and almost anything will hold the ends in place.

Dr. J. B. Roberts, of Philadelphia, thought that permanent disability after these fractures was much more common than Dr. Packard would have us think. He believed that Bond's splint was the cause of many deformities, and he coincided with the idea that a simple Colles's fracture once thoroughly reduced needs no splint.

The Special Committee, to which was referred the communication from the American Medical Association concerning

A STATE BOARD OF MEDICAL EXAMINERS,

reported the act back to the Society with the recommendation that it be referred to the Committee on Medical Education, with the request to take it into consideration when framing a bill.

Dr. Solis Cohen thought the American Medical Association should receive an answer from this Society to its communication.

After considerable discussion the following was adopted:

Resolved, That the Secretary of this Society report to the American Medical Association that the Medical Society of the State of Pennsylvania had adopted its recommendation.

On motion, the resolution passed last year, forbidding the

PUBLICATION OF PAPERS

read before this Society, was rescinded.

Dr. Chas. Meigs Wilson, of Philadelphia, read a paper on *Mechanical Dilatation of the Uterus.*

Dr. E. A. Wood, of Pittsburg, then read *The Address in Surgery.*

Dr. Hewson, of Philadelphia, then read a paper on *The Topical Uses of Earth*, and also gave a demonstration of the *Use of the Electric Light in Diagnosis.*

PUBLICATION OF THE PROCEEDINGS.

The following resolutions were then introduced:

Resolved, That the proceedings of this Society be published in some medical journal of the State.

Resolved, That the Publication Committee are hereby authorized to receive proposals and award the publication to the lowest bidder, and that the journal so selected shall be regarded as the official organ of this Society.

Laid over for one year.

TRAINING SCHOOLS FOR NURSES.

Dr. Musser, of Philadelphia, offered the following resolutions, which were adopted:

Whereas, The State Society of Pennsylvania, in session in Scranton, have learned of the efforts of the management of the Blockley Hospital to establish a training school for nurses, and, whereas, the establishment of a temporary hospital in the fever-stricken districts of Plymouth has been the first practical outcome of their efforts, therefore be it

Resolved, That this Society extend its thanks to the Board of Guardians for its timely and valuable assistance, and most cordially endorse its efforts to establish a training school.

REGISTRATION OF DIPLOMAS.

Dr. Keyser, of Philadelphia, offered the following:

Resolved, That it is the sense of this Society that all diplomas from medical schools in any other State or

country than this, on being registered in this State should be endorsed only by a school of the same system of study and practice as the school granting the diploma.

Resolved, That a copy of this resolution be sent to the prothonotary of every county and to all the medical schools in the State. Adopted.

AFTERNOON SESSION.

DR. H. R. WHARTON, of Philadelphia, read a paper on

OSTEOTOMY FOR CORRECTION OF DEFORMITIES IN LOWER EXTREMITIES.

Under the general remarks upon osteotomy, attention was directed to the two methods employed, the linear and cuneiform operations, and preference was given to the former where possible, as it consists in a simple section of the bone and practically constitutes a subcutaneous operation, whereas the cuneiform operation, in which a wedge of bone is removed, necessitates an open wound with its attending dangers. The use of the osteotome or the saw rests with the choice of individual operators. The importance of making a full correction at the time of operation was insisted upon, especially if a fixed dressing be afterwards employed.

Among the causes which produce deformities for which osteotomy may be required are those arising from rachitis, from coxalgia, from badly united fracture, or from unreduced dislocation, and of all these, the vast majority of cases requiring operation are due to the first-named cause.

For the correction of angular deformities at the hip-joint, resulting from coxalgia, Gant's modification of Adams's operation is preferred; that is, a section of the femur just below the lesser trochanter. This operation is preferred because a section of the bone at this point secures its division at a locality where its structure is comparatively healthy, whereas its division through the diseased structure of the neck if it still exists is capable of renewing an active inflammation in tissues which are most susceptible to inflammatory accidents following traumatisms. Also from the fact that the shaft of the femur can no longer be influenced by the action of the psoas magnus and iliacus muscles, the chances to recorrect deformity are less when the section is made at this situation.

Adams's saw has, in the author's experience, formed a most satisfactory instrument, although some operators speak with equal favor of the use of the osteotome in performing these sections.

The fact that no case has resulted fatally in a large number of cases in the author's experience, speaks well for the general safety of the operation. The results obtained as regards the correction of the deformity are most satisfactory. The various operations which have been devised for the correction of the deformity resulting from *genu valgum*, were considered, and preference was given to Mac Ewen's operation, which consists of a linear section of the femur made from the inner side of the thigh, with the osteotome, just above the epiphyseal line. The ease of its performance, the fact that the section is made at some distance above the knee-joint just above the epiphyseal line, so that the articular surfaces of the bone and the ligaments can sustain no injury, and the satisfactory results as regards the correction of the deformity, are all circumstances which recommend it over the various other operations.

The various osteotomies for the deformity resulting from ankylosis of the knee-joint were considered, and that devised by Mr. Barwell, a linear section of the femur just above the knee-joint combined with a section of the tibia through its tubercle, has been found most efficient in correcting the deformity.

In genu varum a linear section of the tibia, fibula, and femur, with an osteotome at the point of greatest curvature has been found a safe and efficient means of correcting the deformity.

In tibial curves, a linear osteotomy at the point of greatest curvature, or, in very aggravated cases, a number of linear osteotomies, or the removal of a wedge of bone, may be required to produce the requisite straightening.

The use of the plaster-of-Paris dressing to fix the parts after the operation is strongly recommended.

DR. BENJ. LEE, of Philadelphia, read a paper on

"NIL DESPERANDUM" IN SPINAL CARIES.

There are two points that can never be too strongly insisted on in reference to the treatment of spinal caries, or Pott's disease of the spine: First, that it is never too early to begin the employment of mechanical support of the most decided character; and, second, that it is *never too late*.

The wearing of an artificial support, properly contrived, for a few months, can do the patient no harm if the spine is not diseased, but neglect on the part of the physician to advise a resort to this means of treatment when such disease is present will lead to irreparable injury to the patient, and a loss of prestige to the physician himself. It is perfectly easy to recognize the disease long before any deformity shows itself. The principal signs are: sudden attacks of cramping pain in the abdomen or sides, great stiffness on waking in the morning, and inability to stoop forward and touch the floor. There is not generally pain or tenderness in the back, and it is a great mistake to pronounce that there is nothing the matter with the spine because that symptom is absent. If the patient is able to walk, he will turn in one or both toes, and hold his shoulders back and up rigidly. If an infant, it will scream on being moved and lifted. The disease often follows an attack of whooping cough, and can frequently be traced to a fall or other injury. It is *never too late* to begin with the use of mechanical supports. It is the greatest possible error to suppose that strength is needed on the part of the patient in order to bear the application of a surgical appliance. When the vital energies are slowly wasting away in consequence of a local source of irritation, the mechanical support is the plug which stops the leak. Without this, internal medication is as vain as the labors of the fifty daughters of King Danaus, condemned to expiate the awful crime of murdering their husbands on their nuptial night, by filling eternally with water a vessel full of holes.

After the adoption of the usual resolutions of thanks, the Society adjourned to meet at Williamsport on the first Wednesday in June, 1886.

CORRESPONDENCE.

A VISIT TO PROF. MIGUEL'S LABORATORY.

Your correspondent sailed from New York on the French steamer "La Normandie" on the 29th of April, and arrived at Havre on the morning of May 8th. At 1 o'clock on the same day the passengers of "La Normandie" were landed in Paris by a special train, which is dispatched upon the arrival of each transatlantic steamer. As my time in Paris was limited, and my principal object in remaining for two or three days in this city was to visit the laboratories of Pasteur and of Miguel, I hastened to put myself in communication with the last-named *savant*, who was known to me not only by reputation, but also through correspondence with our mutual friend, Dr. Maddox, of London, who, as Miguel expresses it, is the father of modern aëroscopy, and who has also been very successful in photographing bacteria, and is *au fait* in all that is being done in the different biological laboratories in various parts of the world, where bacteria are especially studied.

Dr. Miguel responded promptly to my letter and, by appointment, I visited his laboratory at the Observatory of Montsouris, on Monday morning, May 10th. He was kind enough to show me in detail his methods, and to give me a summary of the results thus far obtained in his studies of atmospheric organisms. These results have been given in full in the annual reports of the Observatory with which he is connected, and in his book published about a year ago. The results obtained are extremely interesting and of considerable scientific value, but it must be admitted that the painstaking researches thus far made by this very patient and conscientious observer, and by others who have preceded him in this line of study, have not yet been fruitful in practical results. *A priori* it would seem that the presence of disease germs should, by a carefully made research, be demonstrated in an "infected atmosphere." But, as a matter of fact, no disease germ has as yet been discovered by this method, and all exact knowledge of pathogenic organisms which we now possess has been obtained by seeking them in the tissues, fluids, and excretions of infected individuals.

The writer was very much influenced by this idea of finding disease germs in the air when he commenced his bacteriological studies at Havana, in 1879, and much time was spent in this way, which might have been more profitably employed in more direct researches. Atmospheric organisms were collected by various methods in the hospitals, in sewers, on ships, and wherever there was a suspicion that the atmosphere might be infected by the "germ" of yellow fever, but among the crowd of organisms, such as pollen grains, spores of fungi, starch granules, etc., nothing was encountered which seemed to have any special significance with reference to the question under investigation.

Again, in 1880, in New Orleans, I studied the organisms suspended in the atmosphere in the streets, the cemeteries, the hospitals, etc., with a view to making myself familiar with the flora of the atmosphere in the absence of any epidemic disease and thus, if possible, being prepared subsequently to recognize any foreign morbific germ which might be present during an epidemic. These studies simply served to convince me that this method of research was invested with so many technical difficulties, complications, and possibilities of error, that I would spend my time more profitably in seeking disease germs at their source, for, after all, so far as we know, they, as well as the other organisms present in the atmosphere, are simply there as the result of accident; that is to say, they do not find their normal habitat in the atmosphere and multiply there; but they are simple wafted about by the wind when the material containing them becomes desiccated, and is raised from the surface of the earth, or is shed from the surface of the body of infected individuals. In this respect they do not differ from the inorganic material known as "dust," with which they are associated, and the laws governing the distribution, seasonal or diurnal abundance of atmospheric bacteria cannot differ greatly from those which cause the amount of "dust" to vary according to the direction of the wind, the relative position of its source as regards the point of observation, etc. If the wind comes from the direction of a pine forest when the pollen is being shed, the aëroscope will show the presence of a multitude of peculiar shaped bodies, which are in fact the pollen of the pine tree; if it comes from the direction of a city street during the time when this is crowded with vehicles, it will be apt to contain a large amount of "street dust;" if it comes over the surface of a desiccated swamp it will contain encysted infusoria, unicellular algæ, bacteria, etc.

I would not have it understood that I underestimate the value of such researches as Miguel is engaged in. They have a value comparable with that of carefully made meteorological observations relating to temperature, pressure, direction of the wind, etc. But, in my opinion, altogether too much has been expected from studies of this kind by those who are especially interested in pathological and sanitary questions. Miguel admits that it is impossible by the use of the microscope alone to distinguish with certainty the germs of bacteria present in the atmosphere, from certain non-living particles associated with them, and that it is only by culture methods that they can be distinguished and enumerated with any degree of precision.

The method which, after extended experiments, he has found to be most satisfactory, requires a well-equipped laboratory, and the expenditure of an enormous amount of time and patience. By this method a skilled observer may make a complete biological analysis of the atmosphere of a given locality, and by analyzing samples collected at different hours of the day may determine the diurnal variations as to the number of living bacterial germs present, etc. The method, in brief, consists in aspirating a given quantity of air through a tube provided with a filter of sterilized cotton, in washing the germs from this filter with distilled water, and in adding this to a sterilized culture-medium, which is distributed in a large number of germ-proof receptacles. The number of germs in the quantity of air passed through the filter is determined by the number of these cultures which are fertilized. When only two or three tubes out of twenty, for example, break down, it is assumed that these have each been fertilized by a single germ, and this is taken as the basis of a calculation of the number of germs per cubic metre of the air examined. If, however, a majority of

the tubes break down, it may be that several germs have been introduced into each, and it will be necessary to repeat the experiment, and to distribute the germs trapped by the cotton filter in a larger amount of fluid, distributed in a greater number of separate receptacles.

The interesting and valuable series of experiments made by Miguel to determine the antiseptic value of various chemical agents was terminated some time ago, and the results are published in the annual report of the Observatory for 1884.

Miguel has recently been experimenting with a new material for surface cultures, which he considers to be superior to the agar-agar gelatine for his purpose, and which forms a jelly that does not liquefy even at a temperature of 50° C. The material employed in making this jelly is the *Fucus crispus*, or white lichen. This is digested three-quarters of an hour in bouillon, in the proportion of twenty-five grammes to the litre; it is then boiled for a short time, and filtered, *hot*, first through a wire gauze, and then through a filter of coarse linen. The sterilized jelly prepared in this way is quite transparent, and M. Miguel assures me that it furnishes an excellent culture medium for bacteria of various kinds.

Miguel is still a young man, about 35, and with his robust constitution, enthusiasm, mechanical skill, and indefatigable perseverance, he will, no doubt, do all that one man can do in a single locality for the advancement of that branch of science—Aëroscopy—which he has made his specialty, and in which he is at present beyond question the highest authority. This letter has already reached such a length, that, in justice to myself and to the readers of The News, I must postpone an account of my visit to Pasteur's laboratory for another communication.

Paris, May 12, 1885.

NEWS ITEMS.

Congenital Absence of the Radius and Pollex of both Arms.—Dr. C. A. Wilson, of Atlanta, Ga., writes us that there was brought before him, on the first of May, a child, four months of age, in whom there was congenital absence of radius and pollex of each arm. Through the contraction of the muscles of the forearm the hand was rotated inwards and drawn upwards on the inferior extremity of the ulna, and the ulna itself considerably curved in its lower half. There was almost no power of flexion and extension of the fingers, and anything offered the child was grasped between the index and middle fingers. Of course, the lacking radii precluded the hope of accomplishing much by any manner of treatment.

Medical School of Maine.—The graduating exercises of the class of 1885, took place on Wednesday, May 27, at 9 o'clock, A.M., in Memorial Hall, Brunswick. An address was delivered by Weston Thompson Esq., of Brunswick, and the parting address to the class by A. C. Gibson, of Bangor. After the parting ode the degree of Doctor of Medicine was conferred upon fourteen graduates, and the diplomas were presented by Prof. Alfred Mitchell.

At noon of the same day was held the second annual meeting and reunion of the Medical Alumni Association. The retiring President, Dr. F. C. Thayer, of Waterville, delivered a short address. The Alumni are determined that the school shall enjoy better clinical advantages, and insist upon its removal to Portland, as soon as necessary expenses can be met.

A committee of conference, appointed last year, to consult with the faculty and trustees was continued, and it is probable that steps will be at once taken to foumd an alumni fund.

The officers for the ensuing year are:

President.—S. Laughton, M.D., of Bangor.

Vice-Presidents.—R. D. Bibber, M.D., of Bath; C. A. Peaslee, M.D., of Wiscasset.

Secretary.—Charles D. Smith, M.D., of Portland.

Treasurer.—F. H. Gerrish, M.D., of Portland.

An Adirondack Sanitarium.—A charitable institution known as the Adirondack Cottages for the treatment of pulmonary diseases, was opened near Saranac Lake, New York, on May 15th. The aim of this undertaking is to offer to patients of limited means and attacked with incipient phthisis all the advantages to be derived from a change of climate, a quiet outdoor life, and proper medical treatment. It is not meant as an asylum for hopeless cases, and none but patients whose chances of recovery seem reasonable will be admitted. The cottage plan has been adopted, and nothing has been neglected to insure the best hygienic conditions possible. Each cottage is to shelter two patients only, their meals being served in the main building. The location is a most happy one, embodying beautiful scenery, a dry, well-drained soil with a sunny exposure, and moderatly high elevation about the surrounding country.

A charge of five dollars a week will be made to each patient, which will include everything, even washing. Dr. A. L. Loomis, of New York, is the examining physician, who will pass upon applications, making examinations free of charge. Should patients, however, find it impossible to see him personally, the application can be made by letter to Dr. E. L. Trudeau, Saranac Lake, Franklin Co., N.Y. It should contain a description of the applicant's case by his own physician, giving information on the following points; Family history, duration of disease, pulse, temperature, and respiration in P.M., weight in health at time of examination, amount of cough and expectoration, and some remarks upon the amount of dyspnœa on exertion, strength, and general condition of patient. Besides this the results in detail of a physical examination of chest should be given. No charges will be made at any time for medical treatment.

A Professorship of Sanitary Engineering.—The trustees of Columbia College, New York, at their meeting on June 1, decided to establish a chair of Sanitary Engineering in the School of Mines. The proposition has been talked of for several years, and in view of the growing practical importance of the subject it was decided best not to defer it longer. The new course will begin in October. Dr. J. S. Billings, Surgeon U. S. A., who has delivered several courses of lectures at the College, has been appointed to deliver the lectures on hygiene. He will be assisted by an expert in microscopic study, and in the study of microbes. The trustees appropriated the money for this purpose and for plans and drawings for the work.

INOCULATION FOR CHOLERA.—Dr Ferrán, having heard that Dr. Cameron, M.P. for Glasgow, had asked a question in the House of Commons about his investigation, has sent that gentleman a telegram giving the results of a great test experiment which is at present being conducted by him, under the eyes of several scientific Commissions, at Alcira, a town near Valencia, where an epidemic of cholera is raging. According to this telegram, the population of Alcira is 16,000, and since the first of the present month 5,432 of its inhabitants have been inoculated with his protective *virus*. That would leave the number of those not inoculated about 10,500; or accepting 16,000 as an exact figure, precisely 10,568. Of the 10,500 persons who are not inoculated, cholera has attacked 64, and proved fatal to 30. Of the 5,432 who have been inoculated, it has, according to Dr. Ferrán, attacked only 7, and proved fatal in no single case. In other words, since the commencement of the experiment on May 1, one person out of every 163 has been attacked among the uninoculated population, and one person in every 352 has died of cholera; while among the inoculated population only one person in 776 has been attacked, and not a single person in the entire 5,432 has died of the disease. In view of the very startling and important nature of these results, Dr. Cameron hopes that either Her Majesty's Government, or some of our great scientific and medical associations, may see their way to sending a Commission to verify them.

The Spanish Minister of the Interior, on being asked in the Cortes on Monday to give Dr. Ferrán a grant in order to enable him to continue his experiments on a larger scale, said he was unable to do so at present, but as soon as it lay in his power he would grant a sufficient sum, although, in his opinion, Dr. Ferrán's experiments had not yet reached a sufficient degree of certainty to prove a complete success. He added that a commission of medical men would be appointed to visit Valencia and other towns, in order to study the experiments that are being made.

A correspondent from Alcira informs a Spanish journal, the *Independencia Medica*, that he has no doubt about the nature of the epidemic, as he has recognized Koch's comma-bacillus in the dejections of a patient. He also states that when Dr. Ferrán first visited the town he "vaccinated" all the boys in an asylum there except two. Now these two have taken the disease, and none of the others. This circumstance has made a strong impression on the people, and their faith in Ferrán's inoculation, as prophylactic against cholera, is unbounded. The journal quoted purposes to reserve a special section in each number for the purpose of reporting Dr. Ferrán's doings.—*Medical Times and Gazette*, May 23, 1885.

INTERNATIONAL SANITARY CONFERENCE.—The International Sanitary Conference met for the first time in Rome on May 20th, and was welcomed by the Minister for Foreign Affairs, Signor Mancini, who said that the duty of the Conference would be to concert preventive measures, to be enforced in each country, to prevent the introduction of communicable diseases, or to stamp them out at their outbreak, and also to make arrangements to adopt a rational and practically useful method for protecting other countries from invasion. Signor Mancini having declined to be nominated president, Count Cadorna was elected. The Conference adopted the rules in force at the Vienna Conference, constituted its bureaus, and then adjourned until Monday next, May 25th. Dr. Sternberg, delegate of the United States, presented copies of the protocols of the Conference held at Washington in 1881. It has been generally understood that the Conference will sit for about a month at the present time, and that if the business before it is not then completed its sittings will probably be suspended during the hot weather. As we have previously announced, scientific theories and controversy as to the nature of contagion, will be, as far as possible, kept outside the deliberations, and, if the Conference really confines itself to the business before it, there is no reason why it should not finish its work within a month. It has, in fact, only to lay down general principles, already well recognized by all epidemiologists and administrators, and ratified by the Conference at Vienna in 1874.—*British Med. Journal*, May 23, 1885.

DEATH OF PROF. HENLE.—The death of Dr. Gustav Jakob Henle, on the 13th of May, at the advanced age of nearly seventy-six years, removes one of the most famous German scientists. All his life he was an earnest worker, and was the author of numerous volumes, the best known of which is his *Handbook of the Systematic Anatomy of Man*. His contribution to the knowledge of the structure of the kidney completed the work of Bowman and Müller. Early in his career he was an assistant of Rudolphi. Afterwards he taught anatomy and physiology in Zürich and Heidelberg, and in 1852 he was appointed Professor of Anatomy in the University of Göttingen, a position which he filled up to the time of his death.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 26 TO JUNE 1, 1885.

HARTSUFF, ALBERT, *Major and Surgeon.*—Ordered from the Department of Missouri to the Department of the East.—*S. O. 121, A. G. O.*, May 27, 1885.

BROWN, H. E., *Major and Surgeon.*—Ordered from the Department of the East to the Department of Missouri.—*S. O. 121, A. G. O.*, May 27, 1885.

BROWN, J. M., *Major and Surgeon.*—Assigned to duty as Post Surgeon at Fort Omaha, Nebraska.—*S. O. 49, Department of the Platte*, May 29, 1885.

BRECHEMIN, LOUIS, *Captain and Assistant Surgeon.*—Relieved from Fort Omaha, Nebraska, and assigned to duty as Post Surgeon at Fort D. A. Russell, Wyoming Territory.—*S. O. 49, Department of the Platte*, May 29, 1885.

AINSWORTH, F. C., *Captain and Assistant Surgeon.*—(Department of Texas.) Ordered for temporary duty in Department of Missouri.—*S. O. 58, Department of Texas*, May 25, 1885.

HELL, WM. A., *Captain and Assistant Surgeon.*—(David's Island, New York Harbor.) Ordered for temporary duty at Willets Point, N. Y., during absence of Post Surgeon.—*S. O. 121, A. G. O.*, May 27, 1885.

SPENCER, WM. G., *Captain and Assistant Surgeon.*—Ordered for duty at Fort Sisseton, Dakota Territory.—*S. O. 55, Department of Dakota*, May 20, 1885.

DAVIS, WM. B., *Captain and Assistant Surgeon.*—Granted leave of absence for one month from May 25, 1885.—*S. O. 122, A. G. O.*, May 28, 1885.

INJURIES OF THE MAIN BLOODVESSELS IN THE AXILLA CAUSED BY EFFORTS TO REDUCE DISLOCATIONS OF THE SHOULDER.[1]

BY LEWIS A STIMSON, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF THE CITY OF NEW YORK, ETC.

DISLOCATION of the shoulder, an injury, both relatively to the other dislocations and actually common, is, at least when recent, deemed one of minor gravity, the cure of which can be effected readily and without risk to the patient. But, from time to time, cases are reported in which the gravest consequences have followed reduction or the attempt to reduce, and such accidents have happened and continue to happen in the practice of even the most experienced surgeons, aided by anæsthetics and employing methods of manipulation rather than those of force. The importance of the general recognition of this possibility, the interest attaching to certain questions of diagnosis and treatment, and the discovery of certain errors current in the statistics of the subject, have led me to bring before you a question which, within the last few years, has been the theme of several writers, and with which all are reasonably familiar. Among these accidents, the most frequent and most important are those of injury to the main bloodvessels in the axilla.

Although the earliest recorded cases of this accident occurred at about the beginning of the eighteenth century, the subject did not receive the attention of systematic writers on surgery until after the publi cation, in 1827, of an article by Flaubert.[2] Malgaigne, in 1855, discussed the subject at length in his work on dislocations, mentioning sixteen cases of all kinds, certain and uncertain. Callender,[3] taking as a text his own fatal case, again collected and collated the known cases; and similar use was made of the material, and other cases added to the list by Le Fort,[4] Willard,[5] and Marchand.[6] In 1882 Körte[7] reported three personal cases, and wrote a very full and valuable paper on the subject containing forty-four supposed (actually thirty-eight; see note below) cases of dislocation of the shoulder, in which the vessels had been seriously injured during the act of dislocation or of reduction; and in 1884 Cras[1] reported a personal case of injury of the axillary artery, and added a few others to Körte's list. Strictly speaking, several of these cases should not be here considered, since in them the vessel was injured at the moment of dislocation and not during reduction, and in many others it remains uncertain whether the same objection might not be made to them. They are retained because they serve equally well with the others to further the study of most features of the subject.[2]

The trustworthy recorded cases of injury to the larger vessels of the axilla in dislocation or reduction of dislocation of the shoulder are forty-four in number. Of these, the axillary vein alone was ruptured in three (Froriep,[3] Price,[4] Hailey[5]), although I think the last one doubtful, and the artery and vein together in two (Platner,[6] Baum[7]). In most of the others the axilliary artery or one of its branches was injured, but in some the source of the hemorrhage remains uncertain. In thirty-two cases death or amputation of the arm furnished the opportunity to ex-

[2] Reference to the original accounts, so far as I have been able to obtain them, shows several errors in the lists given by the above-mentioned writers. Sir Astley Cooper's case must be excluded because it is the same as Gibson's first case, having been simply quoted by Cooper without acknowledgment.

Blackman's case must be excluded because it proved to be not a dislocation, but a fracture of the humerus. As it has been widely quoted and is, indeed, given in detail as a dislocation by Dr. Hamilton (*Fract. and Disloc.*), an explanation of the manner in which the error arose may be of service. Blackman reported it as a dislocation in the *Western Lancet*, August, 1856, p. 469, and an abstract of this report was given in the *Am. Journal of the Med. Sciences*, 1856, vol. xxxii. p. 571, and is quoted by most writers. But on page 508 of the same (August) number of the *Western Lancet* is a note by Blackman, which apparently had been overlooked by the maker of the abstract, giving the results of the autopsy and showing the error in the diagnosis. The fracture was at the surgical neck, and the end of the shaft had been displaced upward and lay in contact with the coracoid process; the head was still in the glenoid cavity, and had partly united with the shaft about an inch below its upper end.

In Segond's case not only does the artery appear to have been wounded by a piece of the dish the patient was carrying, but it is doubtful even if the limb was dislocated.

In Delpech's case it is recorded only that at the moment of reduction the patient grew pale, became unconscious, and died immediately, and there is nothing to show the cause of death.

In Fano's the artery may have been simply compressed. O'Reilly's is the same as Adams's. The latter admitted the case into hospital, the former operated upon it.

A case which Callender quotes, a man treated by a "bone-setter," does not deserve to be grouped with those treated by professional surgeons, although the force employed—traction by twelve or eighteen assistants—was not much in excess of that recorded in some of the other cases, or of what I have myself seen employed. Not only the artery, but also the muscles were torn and the humerus was broken.

Green's case (*Lancet*, vol. viii. pp. 189 and 283, 1825,) is quoted as one of recovery after ligature of the subclavian, but the reports end on the eighteenth day with the ligature still in place, and after a free hemorrhage on the thirteenth day.

amine the region and determine the character of the lesion; this, in some cases, was a complete or partial rupture of all the coats of the artery, or of the inner and middle coats alone, with subsequent formation of a circumscribed aneurism.[1] In other cases the vitality of the wall appears to have been diminished or destroyed by direct pressure, and this to have been followed, after the lapse of a few days, by rupture (Warren[2]), or, still later, by the formation of an aneurism. In Gibson's second case[3] an aneurism appears to have formed in consequence of the earlier attempts to reduce, and then itself to have been ruptured when Gibson effected reduction. Rupture appears always to have taken place quite high up, and usually at the point pressed upon by the head of the humerus. Callender found it necessary to divide the pectoralis minor to reach it. In the fatal cases of injury of the vein alone the vessel was torn completely, or almost completely, across. In Baum's case both artery and vein were partly torn by a broken piece of the new bony socket that had formed about the head of the humerus. The artery was tied above the origin of the long thoracic, and a second ligature was subsequently placed on it at the level of the lower border of the pectoralis major.

In five cases (Callender, Desprès,[4] and Körte's three) only a small (one-sixth of an inch) oval opening was found on the anterior wall of the artery, and was thought to have been produced by the tearing off of a branch, the subscapular or circumflex.

In Gärtner's[5] case the opening in the artery is described as funnel-shaped, but the tumor was small, formed slowly, and presented the common signs of aneurism, so that it seems probable that what he describes as the opening included also the neck of an aneurismal sac. In other cases the subscapular (Lefebvre[6]) or the circumflex artery (von Pitha[7]) was torn across at or near its origin. These last-named eight cases form a considerable portion of the whole number, and are of great importance because they explain the persistence of the radial pulse noted in several of the histories.

Of twenty-nine cases in which the age of the patients is given, in twenty they were more than forty years old. The youngest was twenty (Gärtner), the oldest eighty-six (Sands[8]). In very few of the cases is it noted that the arteries were atheromatous, although the advanced age of many of the patients makes it probable that the elasticity of the vessels was diminished.

In more than half the cases the dislocation was recent—less than three weeks. In not more than one-third of them is it reasonably certain that the lesion was caused during reduction; in three cases it was certainly caused by the dislocation; in the remainder the cause is obscure. To these latter belong those cases in which the reduction was promptly effected, and without the use of much force or of exaggerated positions of the arm.

In many of the others the attempt to make reduction was greatly prolonged or several times repeated, and the force used was very great or improperly applied. This last criticism is probably applicable to the earliest four cases (Verduc, Petit, Platner, Bell), about which nothing is known except that death was caused by hemorrhage. In one of them (Bell[1]) the use of the ambi is mentioned, and it is probable that it or the method of the door or ladder was employed in all.

In some the injury was evidently caused by excessive traction (Gibson, traction by five or six assistants in one case, by pulleys for nearly two hours in the other; Leudet, eight assistants); in others by faulty manœuvres, such as extreme abduction or elevation of the arm, rotation, and circumduction; in others again apparently by direct compression of the vessel against the underlying bone, as by the booted heel in the axilla (Warren, Rivington[2]), or possibly by the thumbs (Panas[3]).

Leaving aside the earlier cases in which faulty methods no longer in use were employed, and those old dislocations in which the relations and connections had been permanently changed by fibrous or bony tissue of new formation, it becomes evident that in dislocation of the shoulder the accident is most to be apprehended when the elbow is raised in abduction to the height of the shoulder, or is carried, as in Callender's case, across the chest and face in a wide movement of circumduction; and for this reason, that in these movements the dislocated head of the bone is turned downward into the axilla, and the vessels which lie upon its inner side are pressed down before it and forcibly put upon the stretch, while those branches which run almost directly outward, the subscapular and circumflex, and are fixed to the tissues amid which they branch, are directly and forcibly elongated. Even when the head of the humerus is in its socket the axillary vessels are put upon the stretch when the arm is widely abducted, as can be readily verified during an operation for the removal of the axillary glands, or, still more simply, by observing the arrest of the radial pulse when the arm is raised and carried backward; and there are several cases on record in which this movement alone has resulted in the formation of an axillary aneurism or in rupture of the axillary artery.[4] Although in dislocation inward the limb is shortened by being abducted, yet the artery is not thereby relaxed, but, on the contrary, it is still further stretched around the head of the bone. Jössel,[5] in a recent case in which death was caused by associated injuries, found the "nerves of the brachial plexus, especially the circumflex nerve and the subscapular artery, greatly stretched by the head of the humerus," and according to Körte (loc. cit., p. 640), he found in another

[1] It is possible that this rupture may be followed by obliteration of the artery at the wounded part. Scarpa held this opinion (Hogson, Dis. of Arteries, p. 488).

case of recent dislocation the subscapular artery torn.

In his remarks on the case at the Sheffield Infirmary[1] in which the artery was torn across during an unsuccessful attempt to reduce a dislocation of six weeks' standing, and an incision was made through which each end of the torn artery was tied, Mr. Jackson says: "One thing was noticed on cutting into the axilla: the extreme tension caused by the pressure of the head of the humerus on the vessels and nerves when the arm was raised above the shoulder." This patient died two days after the operation.

In some of the cases in which it is certain or probable that the injury to the vessel was inflicted at the moment of dislocation, it is noted that the latter was produced while the arm was widely abducted—that is, under circumstances in which the head of the humerus would be driven downward and inward.

If the dislocation is an old one, and especially if there has been much inflammatory reaction and the vessels have become firmly adherent to the bone or embedded in unyielding cicatricial tissue, the liability to rupture is increased because the loss of elasticity occasioned by the latter condition, and because of the limitation of the strain to a shorter segment of the vessel in the former. If, in addition, the distensibility of the vessel has been further reduced by atheroma, the danger is still greater; and this last predisposing cause may properly be deemed sufficient to lead to the rupture even when the traction is slight and the manœuvres are confined within a narrow range.

In Anger's[2] case, fracture of the head (?) of the humerus coexisted; in Mash's[3] two pieces had been chipped off the head of the humerus, and were lying in the glenoid cavity. In several others fracture of the greater tuberosity of the humerus or of the rim of the glenoid cavity is noted; the former of these two complications is common in inward dislocation of the humerus, and could have had no direct influence in causing the injury of the vessels: the latter, also, was probably without influence, since the vessels are pushed away from the scapula, and the fragment remains attached to it.

The *symptoms* at the beginning present two widely different forms; in one, the less common, a tumor presenting many of the signs of an encysted aneurism appears in the axilla a few days or weeks after the reduction, and increases in size rather rapidly; if not successfully treated, it soon involves the skin and ruptures externally. In the other form, the more common, a diffused fluctuating swelling, without bruit or pulsation, appears immediately, or within a few hours, in the axilla, raising the pectoral and deltoid muscles, or is, perhaps, most prominent posteriorly, and in most cases promptly reaches a large size, even that of the adult head (Lister[4]): the radial pulse sometimes persists. The only exception to rapid growth among the recorded fatal cases is Körte's third case (loc. cit., p. 636), in which the extravasated blood disappeared slowly, leaving a firm, non-pulsating lump, as large as a walnut, in the course of the axillary artery, which a surgeon supposed to be a lymphatic gland, and undertook to extirpate nearly five months after the accident. It proved to be an aneurism containing much stratified clot; the axillary artery was tied above and below, and the patient died.

In several cases the patients died promptly after the accident, sometimes after profound syncope, sometimes (Gibson's first case[1]) after a short period of apparent well-being, with symptoms of shock or acute anæmia. In two, which finally ended in recovery (Sands, Agnew[2]), the patients were at first greatly prostrated, and death by syncope threatened. In another (Mash's) emphysema developed in the arm, and the patient died forty hours after the reduction. In this case the inner and middle coats of the artery were torn across "just beyond the point of origin of the dorsal scapular branch." The radial pulse was at first perceptible, but had ceased the next morning.

In most of the others the swelling increased, and, in a longer or shorter time, ruptured spontaneously, or was threatening to rupture when operative interference (puncture, incision, or ligature of the subclavian) was resorted to. The longest period was in Bellamy's[3] case, six months after reduction, and even in this case the first hemorrhage occurred five weeks after reduction.

In the cases that recovered without operation (Agnew, Sands, Malgaigne,[1] Desault,[5] Anger, Nélaton's second case[6]) the swelling subsided, and the ecchymosis was slowly absorbed. Agnew's patient was discharged in ten days, Anger's and Desault's in a fortnight, Malgaigne's was well on the twenty-second day, and Sands's, a woman eighty-six years old, made a slow recovery. In three of them (Nélaton's, Anger's, Sands's[7]) the diagnosis of rupture of the axillary artery was made. Desault's diagnosis was "emphysema of the cellular tissue;" he had reduced by violent and prolonged traction a dislocation of six weeks' standing in a man sixty years old. At the moment of reduction a tumor formed suddenly under the pectoral muscle, and soon filled the axilla; the patient fainted, and the pulse was barely perceptible on the affected side; the tumor was well defined, elastic, not fluctuating, the overlying skin was not at first discolored, and percussion gave a sort of sound (*espèce de bruit*). On these symptoms rupture of the artery was excluded, and the diagnosis of emphysema made. Malgaigne and Agnew made the diagnosis of rupture of the axillary vein.

I think there is reason to doubt the correctness of

[7] Dr. Sands's patient died in May, 1885. The injury proved to have been of the axillary artery, which was occluded at a point a quarter of an inch above the origin of the posterior circumflex. The specimen was presented at the meeting of the New York Surgical Society, at which this paper was read, and a description of it will be found in the report of the proceedings.

the diagnosis in the last three cases, certainly in Desault's and Malgaigne's, for it was avowedly based on the persistence of the radial pulse, and although it is not so stated in the report of Dr. Agnew's case, it seems fair to assume that the same persistence of the pulse which is noted in the report was also the basis of his diagnosis. As has been already mentioned, rupture of the subscapular or circumflex artery has several times presented similar symptoms, and, as in Mash's case just quoted, the radial pulse may even persist after rupture of the inner and middle coats of the axillary artery itself. Pelletan[1] had a case similar to Desault's, made the same diagnosis, and incised the tumor; the patient died of hemorrhage, and the artery was found to have been ruptured.

In the two cases in which rupture of the vein alone was demonstrated post-mortem (Froriep, Price), the patients died promptly, in an hour and a half and on the following day, respectively. In the third case, Hailey's, in which this lesion is said to have been proved by the autopsy, the account of the examination is very unsatisfactory, and leaves it, I think, quite uncertain what the actual injury was. The patient was a man fifty-nine years old; the dislocation was caused by a fall from a wagon and was very easily reduced. The symptoms were, first, pain in the wrist, then, after a few days, swelling of the shoulder and œdema of the arm; at the end of two mouths a tumor appeared between the acromion and coracoid (*sic*), and death by exhaustion a few days later. The tumor was blood-clot, more than two pounds being removed from the axilla.

In De Morgan's case[2] "it was impossible to detect the source of the hemorrhage" at the autopsy, and it was attributed to the rupture of many small veins. This explanation also, I think, may well be questioned, for in this case too the radial pulse persisted, and at that time no cases had yet been reported in which similar symptoms had been shown to be caused by rupture or avulsion of a branch of the main artery. If, as seems probable from the account and in view of the ignorance of this fact, the examination was mainly directed to the condition of the veins, it is not unlikely that rupture of an arterial branch may have been overlooked, especially since the symptoms were not unlike those of some of the other cases in which this rupture was demonstrated (Després, Körte's second case). The symptoms and course of this case were, in brief, as following:

The patient was a man fifty-four years old, the dislocation subcoracoid, the reduction immediate, under chloroform, with the heel in the axilla. During the first week "there was nothing to be noticed but the ordinary swelling attending such a dislocation. This swelling, instead of subsiding, increased, and this somewhat rapidly towards the end of the first week. There was also some purple discoloration about the inner and posterior parts of the shoulder. Still, there were no appearances which might not attend an ordinary bruise or laceration about the part. But, in the course of the following week, enormous swelling had come on, extending from the elbow up the arm and over the chest to the level of the outer third of the clavicle, and over the scapula." The swelling was soft and fluctuating; the skin in places dark purple and thin; the radial pulse was natural. Fever, with slight shivering and one distinct chill. "About the third or fourth week an incision was made in the arm and the hand passed up into the cavity, which contained an enormous amount of blood, chiefly coagulated, extending under the pectoral muscles, down the side of the chest, and behind over a great part of the scapula, and communicating with the shoulder-joint. The subclavian and axillary arteries could be felt." The man died with symptoms of septicæmia.

In Körte's second case (loc. cit., p. 635) the patient was fifty-two years old, the dislocation forward and inward. Several unsuccessful attempts to reduce were made during the sixth month, and the last was followed by the gradual appearance of a non-pulsating swelling under the pectoral muscle, œdema of the arm, and sharp neuralgic pain. Radial pulse. The patient became feverish, the tumor softer, the skin thin, and at the end of six weeks it ruptured spontaneously. The hemorrhage was arrested with a tampon, and the patient died shortly afterward. The autopsy showed a large cavity occupying all the space under the pectoralis major, and filled with large blood-clots. On the outer and front side of the artery, 4 centimetres below the clavicle, was a transverse oval opening measuring 0.4 by 0.3 centimetre (one-sixth by one-eighth inch), thought (loc. cit., p. 650) to have been produced by the tearing off of an arterial branch.

In Desprès's case there was the same swelling, slowly increasing and becoming fluctuating, œdema of the arm, and persistence of the radial pulse. In addition, a bruit was audible after the tenth day, and the swelling subsequently pulsated at times. An operation for ligature of the subclavian was done on the forty-fifth day, and was followed by arrest of the pulsation; but, after the patient died, on the fifty-fourth day, it was found that the ligature had been placed upon a nerve immediately overlying the artery. The common trunk of the circumflex arteries was found to have been torn off at its origin.

On the other hand, in Körte's first case, in which the lesion proved, post-mortem, to be a similar opening upon the side of the axillary artery, and of almost exactly the same size, pulsation in the brachial and radial arteries was barely perceptible two months after the accident, when the patient first came under observation with an enormous pulsating swelling of the shoulder, filling the axilla and extending up to the clavicle.

These histories show, and many of the others might be quoted in confirmation, that, although the diagnosis, so far as the general nature of the accident, rupture of a bloodvessel, is concerned, does not long remain obscure; the identity of the injured vessel cannot always be determined. If the tumor pulsates, the diagnosis of rupture of an artery may be made; and if, in addition, the radial pulse is present, it is extremely probable that the injured vessel is not the main artery, but that one of its branches, probably the subscapular or circumflex,

[1] Clinique chirurgicale, vol. ii. p. 95. Quoted by Malgaigne.
[2] British Med. Journal, i. p. 5, 1872.

has been ruptured or torn off at its origin. Beyond this it does not seem at present possible to go with much certainty, although the great preponderance of arterial lesions in the known cases—26 out of 28, or, adding Hailey's and De Morgan's, out of 30, or, again, adding Platner's and Braun's, in which both artery and vein were torn, out of 32—makes it highly probable in any given case that an artery, and not the axillary vein, has been torn.

Of the remaining 12 cases, 6 recovered without operation (Desault, Malgaigne, Nélaton's second case,[1] Anger, Agnew, Sands), and have been already discussed. Nélaton, Anger, and Sands made the diagnosis of rupture of an artery. In the other 6—Warren, O'Reilly,[2] Green, Volkmann,[3] Létiévant,[4] Cras—the subclavian was tied; in 5 of them with success; in 1, Green's, the result is not known.

In the last 6, and in 3 of the first 6, it seems reasonably certain that an artery was injured, for pulsation of the swelling is noted in every account that is given in detail, and such was the opinion of the surgeons who treated them. The record, then, may be made as follows: Of 44 cases, an artery (the axillary or a large branch) was ruptured in 35, the artery and vein in 2, the vein alone in 2, in 2 dissection failed to reveal the source of the hemorrhage; and in 3, in which the patients recovered without operation, the symptoms do not justify a positive diagnosis.

The *terminations* were as follows: 12 recoveries, 31 deaths, and in 1 (Green's) the result is unknown; 20 received no operative treatment; of these, 6 recovered and 14 died.[5] In 14 the subclavian was tied, with 5 recoveries, 8 deaths, and 1 unknown result. In 6 an incision was made in the axilla, and the artery tied above and below the point of rupture; all died. In 4 the limb was disarticulated; 1 recovery, 3 deaths. The treatment in the cases that recovered without operation was simply compression of the swelling and immobilization of the arm, with the application of ice in Malgaigne's, and compression of the subclavian artery in Agnew's.

In drawing inferences from these results, it must be borne in mind that in many of the cases in which operations were undertaken non-operative treatment had previously been employed, and had resulted in a condition that made an operation necessary. Thus, using only those cases in which the record is sufficiently detailed, of the 14 cases of ligature of the subclavian, in 7 the operation was done after the lapse of several weeks or even months, in 1 on the third day, in 1 on the tenth day, and in 5 the length of the interval is not known. Of the 4 disarticulations, in 1 the operation was of a late date, in 1 five days after the accident, and in 2 unknown. Of the 6 treated by incision and double ligature of the axillary artery, the operation was done promptly in 2, and after a long interval in 4. Consequently the results of non-operative treatment may be tabulated as follows: Of 32 patients, 6 recovered, 14 died, and 12 (with 10 deaths) subsequently underwent operation, either because death by hemorrhage threatened, or because of the existence of a growing aneurism.[1] A fair inference is that conservative treatment may properly be tried at first, but should not be prolonged if the symptoms do not promptly yield; and, secondly, that, in case of resort to operation, ligature of the subclavian artery or disarticulation at the shoulder is to be preferred to incision of the sac and double ligature of the artery.

Experience with arteries wounded under other conditions has shown that they will sometimes quite readily heal, or the opening made into them will close, under pressure accurately made at the point of injury, and it would therefore be proper to attempt to treat this injury by direct, limited pressure. Whether or not it would be possible to recognize the wounded point and make efficient pressure directly upon it cannot be said, since the attempt does not appear to have been made. In default of such limited pressure, general compression of the swelling in the axilla seems to be the only other resource short of operation. The common treatment of ruptured artery,—incision, and double ligature of the vessel,—was immediately resorted to in only two of these cases, Lister's, and the one at the Sheffield Infirmary.[2] Both were promptly fatal.

An important question arises from these facts in connection with the treatment of dislocation of the shoulder: How far does the possibility of the occurrence of this accident affect the choice of a method of reduction? and also concerning the propriety of attempting reduction in cases that are not recent.

In the reduction of recent dislocations, these accidents show that abduction of the arm especially should be avoided, as also circumduction, violent traction, and rough pressure in the axilla. Kocher's method by manipulation appears well adapted to avoid the danger. It is also to be remembered that the injury to the vessel may be caused by the dislocation itself, and its symptoms may be masked by the swelling commonly present during the first few days.

In old dislocations the probability of the occurrence of the accident is increased by the more forcible measures usually necessary to break up the adhesions that bind the bones in their new relations; and, while it may be proper in many cases to make the attempt to restore the limb to usefulness, this possibility creates another reason for abstention when the patient is old, the duration of the dislocation long, and the adhesions firm. Even a dislocated arm may be very useful, and the fatality of this accident, more than 70 per cent. of deaths, may well cause the surgeon to hesitate to incur the risk merely for the sake of ameliorating a condition which does not endanger life and is quite compatible with activity and usefulness.

[1] After rupture of the tumor without hemorrhage, and suppuration of the sac and shoulder-joint. See Körte, loc. cit., p. 655.

44. Sands, *Med. Record*, 1880, p. 45; 84 years. Dislocation 7 weeks. Autopsy in the proceedings of the New York Surgical Society, May 26, 1885, in this number of The News.

DISINFECTANTS.

PRELIMINARY REPORTS OF THE COMMITTEE ON DISINFECTANTS OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

XI.

COMMERCIAL DISINFECTANTS No. 2.

BY GEORGE M. STERNBERG, M.D.,
SURGEON U. S. A.

The following named "disinfectants" have been tested, under my direction, by my efficient laboratory assistant Dr. A. C. Abbott, of Baltimore. The test in every case has been made upon "broken-down" beef tea by the method heretofore described in detail.

Several of the disinfectants which stand at the head of the list contain the potent germicide mercuric chloride, as shown by the simple test of introducing a polished piece of copper into the solution. A deposit of metallic mercury upon the surface of the copper shows at once the presence of a soluble salt of this metal. Those who have occasion to use disinfectants, the exact composition of which is not made public, will do well to bear this in mind, and to remember also that the germicide power of such solutions is neutralized by contact with lead, copper, or tin, and that lead pipes are injured by passing

through them solutions of corrosive sublimate in any considerable quantity.

	Per cent. in which active.	Per cent. in which failed
Dr. Martin's "Disinfectant No. 1" (contains mercuric chloride)	2	1
"Thymo-cresol," English preparation, name of proprietor not given	2	1
"Withers Antizymotic Solution" (contains mercuric chloride)	4	2
"Pasteur's Marvellous Disinfectant,"[1] Blackman Disinfectant Co., of New York (contains mercuric chloride)	4	2
"Purity," Egyptian Chemical Co., Boston	40	20
"King Disinfectant," Humiston Manufacturing Co., New Haven, Conn.		50
"Sanguantræ," P. W. Manning, Stoneham, Mass.		50
"Phenoline," Hance Brothers & White, Philadelphia		50
"Golden Purifier," Thomas & Thompson, Baltimore		50
"Smith's Odorless Disinfectant," The Louis Smith Co., N. Y.		50
"Disinfecting Powder," G. L. Kidwell, Georgetown, D. C.		50
"Thymo-cresol Powder," English preparation, name of proprietor not given.		50
"Chloridium," Chemical Vaporizer and Deodorizer Co., of New York		50
"Carbolcrystal Disinfectant," H. H. Childs, proprietor		50

Dr. Abbott has also tested for me the different preparations of chloride of lime, and of Labarraque's solution which we have been able to obtain in the Baltimore market, with the following result.

Chloride of Lime.	Per cent. of available chlorine.
Brookman Manufacturing Co., Chicago	33.50
Risley & Co., New York	28.40
Rock Hill Alkali Co., Liverpool	28.00
Clagett Bros	24.10
Labarraque's Solution (liquor sodæ chlorinatæ).	
Reed & Carnrick, New York	3.80
Parke, Davis & Co., Detroit, Mich.	2.75
Powers & Weightman, Philadelphia	2.62
Hance Bros. & White, Philadelphia	0.35
Alonzo L. Thompson, Baltimore	c.013

[1] A preparation bearing the same name, reported upon in previous report upon commercial disinfectants, did not contain mercuric chloride and failed at 20 per cent.

NOTES ON PROFESSOR UNNA'S DERMATOLOGICAL PREPARATIONS.

BY ROBERT B. MORISON, M.D.,
PROFESSOR OF DERMATOLOGY AND SYPHILIS IN THE BALTIMORE POLYCLINIC.

THE idea of dermatologists for a long time past has been to find a means of making applications to the skin, which while containing the proper ingredients, would be manufactured in a form most comfortable to the patient. The inventions of Prof. Unna are a great step forwards in this direction. What recommends them, is their ease of application, their cleanliness, their durability, the comfort they afford the patient, and their efficacy in effecting a cure. There are other remedies which will cure as well, but up to the present time nothing has been invented in the author's experience which so well answers their purpose as these elegant preparations.

Short notes of a few cases taken from many are given in this paper to illustrate how they may be used in almost every form of skin disease.

CASE I.—Mrs. R., æt 60, has had chronic eczema of face, legs, and arms for many years. After trying ung. salicyl. five per cent. for some time with benefit, a fifty per cent. plaster of ac. salicyl.[1] was applied to the arms. It began to burn so, it had to be removed in ten minutes. The lead plaster[2] (salbenmull) was used however with great relief, though the arms were not cured entirely until the ordinary rubber bandages were used upon them. In places where eczema appears in small patches the plasters are especially useful.

Having found the action of the fifty per cent. plaster so intense I wrote to Mr. Beiersdorf to send me some five per cent. and ten per cent. salicylic acid plasters. They proved to be gently stimulating, sticking firmly to the skin, and soothing to the itching.

CASE II.—Mrs. M. showed two spots of eczema on back of neck which were about three centimetres in diameter. They had lasted four years, and had been treated with almost all known salves as well as with Prof. Pick's salicylic gelatine five per cent. The latter acted very well, but was so uncomfortable to the patient by catching in the dress and pulling upon the hair it had to be given up. The plasters were then resorted to. First, the spots were covered with a fifty per cent. salicyl plaster which was kept on for twenty-four hours. Upon its removal the spots were much irritated, were quite painful, but the itching had disappeared and their scaly appearance changed to a bright red color. The ten per cent. plaster was then applied, and while it has soothed the itching it has hastened the cure. The case is progressing most favorably.

CASE III.—A young man from the country with psoriasis orbicularis et punctata universalis, which had lasted one year, increasing from a few spots on his arms so as to cover the greater part of his body. Treatment was begun with Pick's chrysophanic acid gelatine ten per cent. It acted very well, but owing to the intense heat prevailing at the time, and the profuse perspiration of the patient which either softened or melted the gelatine, it was discontinued. Chrysophanic acid eighteen per cent. plasters were then applied, the pieces being cut just large enough to cover each spot. The patient applied the plaster himself to all places excepting his back, which part was kindly attended to by my assistant, Dr. Keyser. It is hardly necessary to say that the scales covering the spots were of course first scraped or washed off. There were over two hundred spots to cover, but after the first application much time was not required, since a renewal was only needed when a piece fell off. The patient spent two weeks in a private hospital in the city enjoying himself visiting his

[1] These plasters are made in Hamburg, and consist of a thin layer of India-rubber spread upon muslin, and upon the rubber the medicine is spread. They come all prepared for application and may be cut into any size.

[2] These plasters differ from the others in having no India-rubber, but consist of the common ointments, such as lead, zinc, white precipitate, etc., spread upon muslin. They come in rolls, can be cut into any sized piece, and they keep indefinitely.

friends, going to the theatre, and conducting himself as if he were not peppered over with medicated plasters. At the end of that time he returned home cured, with a package of plaster in his valise and a grateful heart in his body.

Case IV.—Female child, eighteen months old, had eczema of cheeks with scattered spots on the arms and legs since birth. In this case the salicyl gelatine, five per cent., acted for a time very well, but its application becoming distasteful to the child the parents asked me to stop it. The lead and vaseline muslin plaster was ordered, and proved satisfactory. The child is entirely well.

Case V.—Mr. ——, æt, 70. Chronic eczema of the left palm for seven years. Has tried every known salve and wash. Thinking it useless to go through the list again, I first softened the skin with a ten per cent. salicylic ointment and then applied ten per cent. salicyl gelatine. The gelatine proved an uncomfortable application for such a surface and was consequently given up. A piece of salicyl plaster, fifty per cent., was then applied and left on forty-eight hours, with the result of removing the whole of the upper surface of the skin. A ten per cent. plaster was then ordered and the patient's hand was more comfortable than it had been for many years. This treatment, viz., the application of the strong and then the mild plaster has been repeated several times, the hand being in a fair way to recover ultimately.

Case VI.—Mrs. S., æt. 50, has suffered with eczema of the fingers for five years. The same treatment as in Case V. was repeated, the fingers being wrapped first in the strong plaster, and then in the mild. The result was still better, for there was a complete cure in six or seven weeks.

Case VII.—Mrs. D., æt. 45. Tylosis of the hands and feet of three years standing. The epidermis was tough, thick, and unhealthy looking, the extremities cold. The patient was of a very nervous temperament, and disliked applications of any kind. She was persuaded to try the plasters, and although benefited for a time would not persist with them. The most satisfactory part of this case was the disappearance of a large and painful corn between the little and next toe of the left foot by the application of the fifty per cent. salicyl plaster for forty-eight hours. The corn was easily removed after the plaster. This result coincides with my experience in other cases of corn, in which the plaster has been used with most satisfactory result. The first effect of the plaster under such circumstances is to make the part rather tender, but the second effect after the removal of the corn is a feeling of great relief which lasts longer than when the corn is extracted or shaved off immediately. In one case the corn has given no trouble for six months and still lies dormant. It is well known that salicylic acid enters into many patent corn solvents, but none seem so beneficial as the above-mentioned plaster.

Case VIII.—Mr. R., æt. 23, has had a chronic eczema of the third finger of the right hand every winter for fourteen consecutive winters. The plasters of salicylic acid were applied as above and a cure effected in three weeks which has been lasting.

Case IX.—Mr. S., æt 38. Has had chronic eczema of the scrotum and inside the thigh for many months. Oxide of zinc muslin plaster was ordered and kept upon the parts for two weeks with marked improvement. Lead and vaseline muslin plaster was then used for a week and the disease appeared cured. After a few weeks, however, the patient fearing return of the trouble on account of the itching consulted me again. A ten per cent. salicyl plaster was applied during forty-eight hours. It caused some soreness, which was however immediately relieved by the use of the lead muslin plaster, and the patient is now entirely well. The ten per cent. salicyl plaster was stimulating enough for such tender parts, especially as the man was compelled to be walking all day long.

Case X.—Miss P., æt. 16, has had a disfiguring, dry chronic eczema of the cheeks for several years. Has used all kinds of ointments. I ordered for her lead and vaseline muslin plaster for the face, to be applied only at night, as she had to go to school every day. She had also a chronic eczema of both legs as far up as the knees. An ointment of salicylic acid, five per cent., in vaseline, was prescribed for it. She returned in a week very much improved, and was not to return again unless the disease became worse. It has been two months since she has been seen personally, but friends of the patient have reported most favorably.

Case XI.—Mr. S., has had psoriasis orbicularis of right elbow for a year with psoriasis punctata of head and palms. Chrysophanic acid plaster, eighteen per cent., was ordered for the elbow and palms. The disease has disappeared from the elbow in two weeks, but the hands on account of their being in constant use were not well covered with the plaster and consequently are still diseased. Several small spots on the wrists where the plaster did stick have disappeared. A pomade of white precipitate ointment was used for the head with much benefit.

These are some of the cases from private practice in which the various plasters have been used.

Unfortunately their cost is so great that when they reach this country they cannot be used extensively in dispensary practice. A piece of plaster which costs fifty cents in Hamburg, must bring more than twice that amount to pay the extortionate duties which our government demands, besides the express and profit to the importer.

The plasters have been found useful however in several cases at the Polyclinic Dispensary, and their use would have been more general if their cost had corresponded to cheaper applications. In some cases patients have been willing to buy them rather than return to the ordinary remedies.

One case of lupus vulgaris in a girl æt. 14, has been greatly benefited by the forty-five per cent. pyrogallic acid plaster. The disease extends over both cheeks, the upper lip and nose. The septum nasi was perforated when she first came to the dispensary, and the whole face was a mass of ugly scabs and ulcerations. At present the face is covered with healthy looking epidermis, although there are underneath it many lupus nodules still remaining. As the patient lives in the country and cannot come

often to town the treatment must necessarily be of long duration.

Among the others a case of ainhum was interesting. The patient, a negro æt. 42, had lost the little toe of the right foot from this disease two years before. He came to the dispensary to have the little toe of the left foot removed because it was very painful and an operation on the right little toe had relieved him previously. The toe presented the usual appearance of ainhum—a deep constriction with an enlarged toe beyond. It was so sensitive it could not be touched without intense agony, the pain running far up the leg, while the man in walking suffered with every step. Having noticed the anæsthetic action of salicylic acid in the treatment of corns, and not wishing to remove the toe immediately, I put a strip of the fifty per cent. salicyl plaster round the constriction, gave the patient a ten per cent. salicyl acid ointment, which he was to apply if the plaster came off, and I told him to return in two days. To the surprise of everyone, when he did return he said his toe was all right and he would not take off his shoe until solemn promises were made that I would not cut it off. When his foot was bare he took hold of the diseased toe himself and moved it all about without pain. I also moved it in all directions without any evidence from the patient that he felt it. The constriction was still there, and altogether the appearance of the toe had not changed in the slightest. Amputation was advised but the man would not hear of it. He did not care if the toe did drop off of itself, all he wanted was relief from the pain, and this he got from the plaster and salve. He was given more of each, promising to return if the toe got painful. He has not been seen for four months. As he is a sailor by occupation, and goes from port to port, it is doubtful whether the final result will be known, but that the temporary relief was very great can be well understood, since the man, although he had before, suffered so much from the toe was sufficiently well satisfied with the plaster and salve to trust to their virtues rather than to undergo an operation which promised absolute removal of the cause, an operation which from past experience with the little toe of the other foot he knew would give him permanent relief.

These cases are sufficient to call the attention of the profession to Prof. Unna's plasters, which are indeed worthy of the highest praise for their neatness and ease of application.

MEDICAL PROGRESS.

Pathogeny of Fetid Abscess of the Limbs.—Dr. G. Nepveu proposes the following explanation as to the cause of fetid abscess of the limbs:

1. Fetid abscesses of the limbs are very rare, and are presented under various conditions:

a. In consequence of rupture of vessels which in certain pathological conditions contain bacilli, and by direct inoculation of the contaminated blood into the tissues, constituting anto-inoculation.

b. In consequence of entrance into the tissues of bacteria, originating externally (from wounds, etc.). Under this head may be included their direct incarceration in the tissues, which is brought about by means of a granulating membrane.

2. The persistence of bacteria, or their origin from incarceration, is indubitable; in cases under the author's observation, they have been seen at the end of fourteen and of ten years.

3. Traumatism may have the effect of producing serious septic (bacterian) inflammation, viz., phlegmon and fetid abscess by a veritable inoculation of the peripheral tissues.

4. Long incarceration confirms the opinion that the bacteria are the real and only cause of the extreme fetor which is characteristic of these abscesses.—*Gazette Médicale de Paris*, April 25, 1885.

The Actual Cautery, in Ocular Therapeutics.—Dr. Turazza, in the *Gazzeta degli Ospitali*, of May 6, 1885, after discussing the indications for the use of the actual cautery in ocular therapeutics, cites the conclusions of Lavallée upon the same subject:

1. Cauterization is an excellent method for the cure of benign ulcer of the cornea which has become indolent, and also against rodent ulcer.

2. It is non-efficient in the serpiginous ulcer of hypopyon.

3. It may be used in suppurative or phlyctenular keratitis with threatened corneal ulceration, in partial opaque staphyloma, and in simple hernia of the iris.

4. Its use has not been sufficiently studied in vascular parenchymatous keratitis, in leucoma, ciliary blepharitis, and in granular conjunctivitis.

5. It arrests the accidents consecutive to septic infection from a wound of the cornea made under treatment.

6. It produces favorable results in entropion and lachrymal fistula, and gives encouraging results in non-cicatricial ectropion.

6, It combats efficiently the return of pterygium and of cicatricial fleshy growths.

8. It is well tolerated by the conjunctiva and eyelids, and gives good results in chalazion. It replaces, for the most part, cutting instruments in the removal of tumors of the conjunctiva and eyelids.

9. It does not cause serious reaction, is not painful, is limited in its action, destroys septic elements, produces an irritation favorable to cicatrization, and causes rapid cessation of pain in ulcers, abscesses, and phlyctenulæ of the cornea.

10. The galvanocautery, modified by Abadie, combines the best conditions for the application of the new method.

To obtain the best results by cauterization a reddish-brown color is recommended to be maintained in the cautery; moreover, the degree of incandescence should be proportioned to the moisture of the part.

Divulsion of the Cardia.—Professor Loreta, on the 21st of March, 1885, performed double digital divulsion upon a girl, aged 19 years. The patient was brought to Prof. Loreta sufferring from cardiac stenosis, for which he intended to practise dilatation, but, the abdomen having been opened, he discovered that the constriction extended to the pyloric orifice of the stomach, which necessitated the operation of

divulsion. The condition of the patient at the conclusion of the operation and for some time after, was exceedingly precarious, but at the present time a favorable result is anticipated. The other two patients upon whom the operation was performed are entirely cured.—*Gazzetta degli Ospitali*, May 26, 1885.

Strangulated Inguinal Hernia not Treated; Stercoraceous Fistula; Enterorrhaphy; Cure.—M. Sévier, at a meeting of the Société de Chirurgie de Paris, held March 18, 1885, gave the history of the following case:

A man, twenty-four years of age, had had from the time he was three years of age a left inguinal hernia, for which he had worn a bandage until he was fourteen. Since that time the hernia had remained only partially reducible, in the condition of a bubonocele. After a fit of indigestion the hernia became increased in volume, and showed all the ordinary signs of strangulation. Purgatives were administered. For two months, according to the patient's statement, there was no intestinal movement, and no passage of flatus. His diet consisted entirely of soups, which were vomited with other matter of disgusting taste. At the end of two months a fistula was spontaneously established, and three months later fecal matter again commenced to pass per rectum in gradually increasing quantity, although the fistula still persisted and continued to discharge fecal matter of varying consistency. The general condition of the patient was good. Enemata were immediately discharged by the fistula, and digital examination rendered it probable that the fistula communicated with the sigmoid flexure. After having tried without success to close the fistula by a skin operation, M. Sévier made an inguinal incision, circumscribing the lesion, mobilized the intestine without opening the peritoneum, and introduced sutures of silk into the mucous surface, after the method of Lembert. A second row of sutures united the edges of the fistula, comprising also the separated fibrous tissues. Corrosive sublimate dressing was applied. Flatus passed the same day per anum, and by the eighth day union was sufficiently advanced to permit the dressing to be dispensed with.

The patient at present is entirely well, requiring only a bandage to support a small hernia situated at the superior part of the cicatrix.

The mildness of the symptoms produced subsequent to the strangulation of the bowel, is phenomenal, and can only be explained by the location of the portion of the intestine involved, the sigmoid flexure of the ileum.—*Revue de Chirurgie*, April, 1885.

Treatment of Pneumonia by Cold Baths.—M. Charnier, after extended observation upon the effect of cold baths in the treatment of pneumonia, gives the following summary of his opinion as to their efficacy:

1. Cold baths are never dangerous in pneumonia at whatever period they may be employed.

2. They diminish the temperature, slow the heart, cause the bruits produced by the fever to disappear, ameliorate the dyspnœa, and allay thirst, thus permitting more abundant alimentation.

3. Having experimented only with cases which might have been cured without treatment, M. Charnier does not decide whether by their use the mortality of the disease is diminished; nevertheless, he inclines to the opinion that such is the case.

4. With adults, to obtain lasting relief, the baths should be given every two or three hours.—*Journal de Médecine de Paris*.

Hydro-pneumo-pericarditis Produced by an Ulcer of the Stomach.—At a recent meeting of the Société des Hôpitaux, M. Moizard gave the history of a case of hydro-pneumo-pericarditis caused by ulceration of the stomach.

He referred to the history of the pathognomonic symptom of the lesion, the *bruit de moulin* or windmill bruit, referred to originally by Laennec, and since his time by various French authors. Two varieties of the *bruit de moulin* are to be recognized. The first is consecutive upon certain traumatisms of the præcordial region, and is characterized by the disappearance of the bruit when a sitting posture is assumed; its prognosis is benign, and cure is the rule.

The second confirms the presence of gas and of liquids in the pericardial cavity, and does not disappear when the patient sits down; in this condition death is the rule.

The patient, whose history Dr. Moizard reported, was a woman 56 years of age, who entered the hospital with violent epigastric pain, and presented a cachectic appearance so marked that cancer of the stomach was suspected. Nothing abnormal was heard on auscultation of the heart. Some time subsequently a metallic bruit was noticed, the patient, however, showing no signs of palpitation or dyspnœa. The day following there existed a typical *bruit de moulin*, perceptible over the whole anterior thoracic region and not disappearing when the patient was placed in a sitting posture. The præcordial region was tympanitic in resonance. There was no dyspnœa, but in a short time the pulse began to increase in frequency and nausea supervened followed by cold sweats and collapse and death.

At the autopsy a perforation of the stomach was found situated at the region of the greater curvature, and whose edges were closely adherent to the diaphragm. The ulcer measured three inches in diameter, and free communication existed through the perforation between the stomach and pericardial cavity. The pericardium was also adherent to the diaphragm.

The only cause of the perforation of the stomach was the ulcer, there being no evidence of cancerous degeneration.—*L'Union Médicale*, May 12, 1885.

Ammoniacal Disks as Vesicatories.—Dr. Guido Turazza, in recommending ammoniacal disks for vesication, claims the following advantages:

1. Ease of application, moderate cost, and a duration of pain much shorter than that produced by actual blisters.

2. They produce in a short time the remedial effect of blisters, and may be used in cases where a speedy result is desirable, thus possessing an advantage over blisters and being far superior to sinapisms and cupping glasses.

3. They may be used in cases in which blisters are contraindicated on account of the danger of toxic effects.—*Gazzetta degli Ospitali*, May 3, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 13, 1885.

THE PREALBUMINURIC STAGE OF CHRONIC BRIGHT'S DISEASE.

IT has long been known that in the form of chronic Bright's disease known as interstitial nephritis, not only is the albumen as a rule small in quantity, but even at times altogether absent. In like manner, casts are scanty and sometimes totally wanting; so, too, it has long been recognized that this disease may exist for some time undiscovered, even until the convulsions or apoplexy, which are such frequent modes of its termination, usher in the end.

Recently, however, increased attention has been called to the fact of the insidious presence of this disease in a large number of cases, a long time before albumen is discovered, and even where pains are taken to look for it, and that the disease may run its course from beginning to end without the presence of albumen.

This being the case, increased effort has also recently been made to point out symptoms by which the presence of contracted kidney may be recognized independently of albuminuria. Conspicuous among writers attempting this has been the late DR. MAHOMED, of London, and recently DR. CHARLES W. PURDY, of Chicago, read an excellent paper on this subject before the Chicago Medical Society.

Seeking for such symptoms, Dr. Purdy first points out the fact that renal cirrhosis is most frequently developed after middle age, the largest number of cases occurring between 41 and 50 years, and the next between 51 and 60.

Second, it is found most often in persons who live generously, eating largely of highly seasoned and flavored meat food, and drinking freely wines and other alcoholic liquors.

Third, as to the cutaneous system, he calls attention to a peculiar pallor of the skin characterized by Dickinson as the *pallor luteus*, an appearance somewhat anæmic, though a sort of sunburnt tinge obscures the pallor. Deficient perspiration is also named as a common accompaniment of early cirrhotic disease, producing a dry, harsh skin. Erythema and acne rosacea may occur, but generally later.

Fourth, is diminished muscular power, manifested by weakness and indisposition to exertion characteristic of the disease in its more advanced stages. Emaciation is also occasionally present.

Fifth, dyspepsia, especially of the flatulent kind, is said to be one of the most constant of the symptoms of this form of renal disease in the absence of albuminuria. Loss of appetite and nausea, especially in the morning, are also frequent.

Sixth, of pulmonary symptoms, dyspnœa, so constant in advanced stages of contracted kidney, is also included by Dr. Purdy among those which precede albuminuria, as is also bronchial catarrh.

But the most invariable of these prealbuminuric symptoms are those connected with the vascular system. They are hypertrophy of the left ventricle and high vascular tension. We will not stop to discuss the rationale of their production. The former is recognized by its violent action and heaving impulse, and the latter by its hard, unyielding character; but it is best recognized by the sphygmograph, which has one of its most important practical applications in the recognition of this condition. The peculiarity of the high tension of renal cirrhosis is found in the fact that if a line be drawn from the apex of the up-stroke to the bottom of the aortic notch it intersects the descending stroke; whereas in the normal pulse no part of the tracing rises above this line. The aortic notch itself is higher than usual, and the length of that part of the basal line which indicates the duration of systole is also greater.

Retinal changes also precede the albuminuria of contracted kidneys, the most frequent being the white spots and patches due to degeneration. The changes in the arteries of the retina pointed out by Gowers, a narrowing of the lumen, independently of other evidence of retinal disease, may also be present.

Finally, polyuria, in which the urine at first has a higher specific gravity than normal—1020 to 1035—the urine of advanced contracted kidney is well known to have its specific gravity diminished—may precede albuminuria. Such urine is also apt to contain crystals of urea and oxalate of lime, and may strike the blue hæmoglobin reaction with peroxide of hydrogen solution and tincture of guaiacum.

It is evident, however, that there are very few of

the above symptoms which may not be present in the economy quite independently of any renal disease, and therefore, they are of uncertain value in diagnosis. The most important of these are the symptoms connected with the vascular system and the retinal changes, together with the habits of living. The remainder are, indeed, more frequently due to other causes, and retinal or vascular changes do not coexist.

We still hold that a certain diagnosis without albuminuria is impossible. Indeed, it seems scarcely justifiable to consider some of the symptoms referred to as characteristic, as, for instance, the pallor. We are quite certain that, in the cases of contracted kidney which have been under our observation, even when albuminuria has been established, the large majority have exhibited a ruddiness of complexion and color which are the very opposite of anæmia.

The importance, however, of a full knowledge of this subject cannot be overrated, and we are especially indebted to Dr. Purdy for calling attention to the symptoms of the prealbuminuric stage in a systematic manner.

RUPTURE OF THE VAGINA FROM COITUS.

The subject of tears of the vagina in coition derives special interest from some recently published cases of this accident. That the vagina can be thus torn has been denied by some, while others have expressed doubt as to whether a serious hemorrhage could be thereby caused. For example, Breisky, in Billroth's *Handbuch*, observes that the fact of brutally performed coition causing fatal injury is doubtful. He quotes Hoffman, who questions whether, even in raped children, the vaginal tears are to be attributed to coition, but rather to rough manipulation. A similar doubt is also expressed by v. Preuschen, *Real Encylopädie der Gesammten Heilkunde.*

The older authors reported cases of the accident where death occurred, rejected indeed by Breisky, but which are indirectly confirmed by recent observations. Even the remarkable case given by Demerbroc does not seem impossible. A bride after the first coitus had such a violent hemorrhage that Diemerbroc says: "ut intra tres horas una cum virginitate etiam vitam amiserit."

The Centralblatt für Gynäkologie, of February 21, 1885, contains the report of a dangerous hemorrhage from a rent of the hymen in coition, and one of rupture of the vaginal vault from the same cause; these cases are given by Dr. Zeiss, of Erfurt. In the first, Dr. Zeiss did not see the patient until 4 P.M., the day succeeding the night of the accident. He found her pulseless, pale, bathed in a cold sweat, and a pool of blood about the thighs, sides of the pelvis, and back. After the removal of the blood he found two rents of the hymen, one on each side, and from the left which extended to the vaginal attachment of the hymen, a continuous stream of blood was pouring from a torn artery. The suture was used to arrest the hemorrhage, and by stimulants reaction was accomplished. The suture was removed on the third day, and there was no recurrence of the bleeding.

The second case was one where a married woman who had borne a child a few weeks before, had her vagina ruptured by coition, which was *a la vache.* In this woman the uterus was strongly retroflexed, and the cervix hard and fixed at the right side, and upon this side of the vault there was a tear large enough for the finger to enter readily.

Dr Chadwick, in the *Boston Medical and Surgical Journal,* April 30, narrates a case of vaginal rupture occurring in a woman forty-eight years of age, who had been married six years to a sailor, and cohabitation had occurred freely without difficulty or pain. Her husband returning after four months absence, intercourse took place causing a rupture an inch long, in the upper third of the vagina, opening into the connective tissue. In the same journal for May 14, Dr. Mundé reports two cases of dangerous hemorrhage from rupture of the vagina in coitus; these cases had been previously reported, and their repetition was suggested by Dr. Chadwick's paper. Both of Dr. Mundé's patients had been married the previous day; in one the rent was an inch long, and began at the hymen; in the other it was on the left side of the vagina, fully two and a half inches in length, half an inch deep, and extended from about an inch above the hymen nearly to the vaginal vault. The length of the vagina in the second patient was extraordinary, its side measuring apparently not less than four inches. The hemorrhage in each case was arrested by tamponing.

The London Medical Times and Gazette, vol. i., 1860, contains the record of a case operated on at the Samaritan Hospital, by Sir Spencer Wells, where rupture of the recto-vaginal wall occurred at the consummation of marriage.

Dr. Ross reports in the *Canada Medical and Surgical Journal,* 1877, the case of a patient in the Montreal General Hospital sixty years of age, with rupture of the vagina; her husband, seventy years old, had been absent nine years, and returning insisted upon coitus, which caused violent pain, and an exhausting hemorrhage that came from a rent an inch long in the upper part of the vagina, just behind the cervix.

Kleinwächter, in the *Wien. med. Presse,* 1880, reports a case of rupture of the vagina occurring from violence during sexual intercourse. The subject, twenty-two years of age, was brought to the clinic in an unconscious condition, underclothes, abdomen, and legs covered with blood, and bleeding from the vagina. Upon examination, the labia majora and

minora were found œdematous, the perineum greatly swollen and discolored; the posterior wall of the vagina had a triangular tear, the base of the triangle being below, the length of the wound from above down was two inches. In this case it is believed the injury resulted from the use of the fingers or hand.

The Indian Medical Gazette for 1872 contains the report of a case in which a native drugged his wife, who had not yet reached puberty, and then had intercourse with her. She died of hemorrhage, and a post-mortem showed a rent one inch and a half long in the posterior wall of the vagina and the perineum torn to the anal sphincter, and a second rent in the anterior wall close to the cervix.

The Gazette of the same year also contains the report of a case where an English officer had intercourse with a girl between eleven and twelve years of age. She died from loss of blood, and a rent in the vagina, including the fourchette and extending two inches in a longitudinal direction, was found.

It will be seen from some of these cases that there may be a fatal hemorrhage even from coition, in others at least a dangerous bleeding, while in one probably the injury to the vagina was done, as suggested by Breisky and Hoffman, by the hands.

A WORD OF WARNING.

JUST about this time multitudes of people are laying their plans for the summer vacation, and are casting about for a spot for a brief sojourn away from home. To such, a word of caution with regard to the importance of investigating the sanitary arrangements of their proposed summer resting-place, before making a selection, will not be out of place.

Before choosing a summer home it is usual to inquire particularly about the situation of the house, the eligibleness of the rooms, the character of the service, the quality of board, and the class of guests entertained, and very properly so; but none too frequently is a question asked or an inquiry made with regard to the water-supply or the drainage arrangements, both subjects of paramount importance to health. Fortunately, the proprietors of public houses are being forced to realize their responsibility to the public, and are now giving more attention than ever to matters connected with the health of their patrons. If the public patronized no house which is not provided with pure water and a perfect system of drainage, these essential features of a healthy habitation would soon be supplied.

The results of the summer vacation are often most disastrous. For the want of exercise of common prudence and foresight, many a one, who has left home in search of health or recreation, has been overtaken by preventable disease, or has returned with the seeds of some malady already implanted in his system. Beauty of location, salubriousness of climate, comforts and conveniences, and pleasant society are not to be undervalued, but they count for naught if the air and water-supply are poisoned through defects in the drainage system. Without perfect drainage and wholesome water, the safety of no locality can be insured, however attractive it may be in other respects. It is, therefore, the duty of every one seeking a summer resort for his family, to make diligent inquiry on both these points, and to satisfy himself that there is nothing wrong about either of them, before coming to a decision. If this is not done, the responsibility of having exposed the health of his loved ones to serious risk will rest largely upon his own shoulders.

A word of advice should also be directed to the keepers of seaside watering-places, and country and mountain resorts. Now is the time for them to correct defects and supply deficiencies. In a short time they may expect to be questioned shrewdly as to the sanitary advantages of their houses. If they have been negligent in providing everything necessary for the health of their guests, they may expect to lose patronage, and deservedly so. The business of a season and the reputation of a house have been destroyed by the occurrence of sickness due to inattention to these important matters. But a higher motive should actuate them to comply with the requirements of sanitary law. The dictates of humanity and honesty forbid that advantage should be taken of their patrons by offering accommodations professedly safe, when no effort has been made to guard them from dangers which lie concealed from view, and of which they have had no means of gaining a knowledge.

MILK DIET IN THE ALBUMINURIA OF PREGNANCY.

TARNIER'S treatment of the albuminuria of pregnancy by an exclusive milk diet has counted in his hands, as well as in those of others, many successes, and it has received a very strong endorsement from Charpentier, among recent obstetric writers. Under this treatment it is usual to see the albumen lessen, in some cases disappear, and the symptoms which threaten eclampsia, such as headache, dimness of vision, indisposition to exertion, and drowsiness, cease, or become much mitigated. In some cases, however, it is important to conjoin with milk diet a hot bath once in three or four days. The temperature of the bath should be from 98° to 100°, and while in the bath or immediately after it, the patient should drink a tumbler of hot milk. A profuse perspiration usually follows, and the relief is prompt and positive. In one case, however, now under our observation, a primigravida now in the eighth month, who has had albuminuria for at least four months, and who derives marked benefit from the hot bath, has also a very serious discomfort following it. There is unusual and violent activity of the fœtus

always occurring after the bath, so that she is for some hours unable to sleep,—a very serious inconvenience, as the usual and most favorable time for the bath is just before retiring.

Valuable as most practitioners regard the milk treatment of the albuminuria of pregnancy, some entirely reject it. Pajot, for example, in a recent discussion held at the Paris Obstetrical and Gynecological Society, and reported in the *Journal d'Accouchements*, May 5th, refers to it as a bitter pleasantry. One of his arguments against the milk treatment is that infants from six months to the end of the first year, are peculiarly liable to eclampsia, and yet they are then on milk diet. Guéniot very well answered this argument by saying that these infants that have eclampsia are not albuminuric, and the milk diet in albuminuric pregnant women does not act upon the eclampsia, but upon the albuminuria; it is only indirectly by curing the albuminuria that it renders eclampsia much rarer. It is impossible to attribute infantile and puerperal eclampsia to the same cause.

DIAGNOSIS OF GONORRHŒA IN THE FEMALE.

MARTINEAU, at a recent meeting of the Paris Obstetrical and Gynecological Society, stated a most important fact by which specific can be distinguished from simple vaginitis. It depends upon this that in the specific form of the disease the pus is always acid, while in the simple it is alkaline. It is very easy, therefore, to decide by a piece of litmus paper as to whether a woman is or is not suffering from gonorrhœal inflammation.

This sign will prove of value, too, in determining, when rape has been committed, whether the person committing the crime was affected with gonorrhœa, for then the vulvitis would be characterized by an acid discharge, while in the simple form of the disease the discharge is alkaline.

SOCIETY PROCEEDINGS.

OHIO STATE MEDICAL SOCIETY.

Fortieth Annual Meeting, held at Dayton, June 3, 4, and 5, 1885.

(Specially reported for THE MEDICAL NEWS.)

THE Society convened in Association Hall, and was called to order at 2 P.M. by THE PRESIDENT, DR. J. C. REEVE, of Dayton.

DR. W. J. CONKLIN, President of the Montgomery County Medical Society, in a few appropriate words, tendered the members a hearty welcome to Dayton.

DR. WEAVER, Chairman of the Committee on Arrangements, made a detailed report of the arrangements already made for this meeting, the order of exercises, receptions, and extended formal invitations to the members to visit the various charitable institutions located in and about the city.

DR. COLLAMORE, of Toledo, read

THE SECRETARY'S ANNUAL REPORT,

showing the following facts. In 1882 the membership of this Society was given as 540, of whom 13 were non-resident. Since then it has been increased by 79 new members, admitted at last meeting, and the restoration to membership of 4 old members, in all 83, while it has been diminished by 47 forfeited memberships, 8 deaths, and 1 expulsion—56 in all—showing a net gain of 27 members. The present enrollment is 567, of which 13 are non-resident members. It appears that during the past year seven of the auxiliary societies abandoned their organizations. It is a deplorable fact that there are at least 18 counties of the State in which there is no local medical organization.

DR. JONES, of Columbus, presented

THE TREASURER'S REPORT,

showing a balance of $477.82 in the treasury.

The Special Committee appointed last year to secure the passage of a bill by the Legislature creating a

STATE BOARD OF MEDICAL EXAMINERS,

reported at length, through Dr. Weaver, of Dayton. In order to secure the opinion of the profession throughout the State, the Committee sent copies of the bill, already endorsed by this Society, to every prominent physician, accompanied by a circular letter requesting a written opinion. The responses were very numerous and favorable. All of the local societies in the State, with one exception, endorsed the proposed legislation. The Committee worked energetically, but when the bill was put upon its passage it was defeated, and, singular to state, its defeat was due to the petty jealousies and opposition of the ten medical members of the Legislature, nearly all of whom had some bill of their own creation for which to work. After considerable discussion at various times during the session, it was finally agreed to continue the same Committee for another year, and to authorize them to draw from the treasury a sum not to exceed $500, with which to defray their necessary expenses.

DR. BALDWIN, of Columbus, reported that he had recently secured for the Society from Dr. J. B. Thompson, of Columbus, a

COMPLETE SET OF THE SOCIETY'S TRANSACTIONS,

believed to be the only complete one in the State. Dr. Thompson, whose death has occurred since making the gift, was a charter member of the State Society, and was its Treasurer for many years. It was subsequently agreed, upon recommendation of the Finance Committee, to whom the matter had been referred, that this set of *Transactions* be accepted, and, in accordance with the request of the donor, be placed in the State Library at Columbus.

The Secretary was instructed to place annually a copy of the *Transactions* in the same library, so the file may be kept complete.

THE ANNUAL ASSESSMENT

upon members for the ensuing year was fixed at one dollar.

DR. GILL, of Cleveland, Chairman of the Committee on

GENERAL COLLECTIVE INVESTIGATION OF DISEASE,

made a verbal report. The Committee had not matured a plan of action. After a long discussion, it was resolved to continue the same Committee for another year, and to authorize it to appoint an additional member from each county in the State to assist in the work.

DR. C. A. L. REED, of Hamilton, read a paper on

PELVIC HÆMATOCELE.

He took advanced views in its treatment. In view of the protracted nature of these cases, and the fact that absorption of the effused blood takes place slowly, if at all, and especially in view of the protracted and hazardous invalidism which generally ensues upon these extravasations, the position was taken that something should be done to control the initial hemorrhage. A case was given illustrating the dangers of too conservative treatment. Abdominal section and the ligaturing of both extremities of the broad ligament, so as to include all of the underlying vessels, was suggested as a possible expedient in desperate cases. The evacuation of the sac after the arrest of hemorrhage, and either before or after suppuration, is best accomplished by making an incision along the upper margin of Poupart's ligament, and elevating the peritoneum in cases in which the extravasation occurs beneath the fold of the broad ligament. A case was given in which the operation had been made with success.

DR. C. D. PALMER, of Cincinnati, followed with a paper on

A RARE COMPLICATION AFTER OVARIOTOMY.

The complication was the appearance of a *fecal fistula* twelve days after the operation. The fistula opened in the median line, midway between the umbilicus and the pubis, and seemed to be connected with the lower small intestine. The discharge, at first, amounted to about one ounce per day. The literature of this rare complication was exhaustively given by the author. The query was raised as to whether these fistulæ should be closed by operation or left to nature. The author advocated the latter course. Fatal results have followed the operation, and a very large majority of these fistulous openings close spontaneously within a year.

DR. MILLER, of Cleveland, and DR. DUNLAP, of Springfield, reported cases in which fecal fistulæ following ovariotomy have closed without an operation.

In the evening the members and their wives were pleasantly entertained at the Southern Ohio Insane Hospital by the trustees and officers.

THURSDAY, JUNE 4TH.—SECOND DAY.

MORNING SESSION.

THE COMMITTEE ON ADMISSIONS AND MEDICAL SOCIETIES

reported favorably on the applications of the Hempstead Academy of Medicine, of Scioto County, and the Lake County Medical Society, and the Columbus Medical Club, to become auxiliary societies. The application of the Midland Medical Society, of Fayette County, was rejected on the ground that the Code of Ethics of the American Medical Association is not specifically endorsed in its Constitution and By-laws. After considerable discussion an amendment to the Constitution was defeated, by which membership in the State Society could be acquired without first becoming a member of the local society.

DR. REED, of Mansfield, then read a paper on

VITILIGO,

in which he stated that Dr. McCall Anderson had only met with this disease four times in eleven thousand consecutive cases of skin disease. It is caused by a lack of the proper action of the nerves controlling the supply and distribution of the pigment. On examination under the microscope, it will be found that in some instances an increase of pigment takes place in the parts adjacent to the white spots, which gives rise to the peculiar mottled appearance of these patients. The author reported the histories of five cases which had occurred under his personal observation. He considered the disease incurable, but spoke favorably of the use of electricity.

DR. DAN. MILLIKIN, of Hamilton, presented a valuable paper on

EMPYEMA AND ITS TREATMENT BY DAILY ASPIRATION THROUGH A DRAINAGE-TUBE.

On theoretical grounds, he advocated the introduction of a small tube into the affected side of the chest, through which fluid should be aspirated and injected. He laid stress on the importance of keeping the opening air-tight, in order that there might be produced each day a partial vacuum in the chest; that vacuum to be maintained for upwards of an hour and thus solicit the expansion of the lung. The views propounded were illustrated with the brief histories of two cases in which it had been successfully carried out, though the reader stated that he merely approached the subject as a theorist, seeking for that which is not to be found in any accepted treatment, viz., some means of preventing the lung from going to destruction by reason of its own elasticity.

DR. P. S. CONNER, of Cincinnati, presented a paper on

VESICAL EXPLORATION.

He spoke of the frequent difficulty of diagnosticating correctly conditions of the bladder. Endoscopic examination, of some value in females, is almost useless as a means of interrogating the male bladder.

After considering the various modes of examination and emphasizing the fact that they are all unsatisfactory in certain cases, he urged a resort to perineal section in these cases. The danger is slight, and the great advantage which results from digital examination of the bladder is certainly evident. The operation and exploration are easy and satisfactory in thin subjects. Some French surgeons advocate the suprapubic method of exploration rather than that by perineal section. The author gave the preference to the latter method both on account of the safety of the operation and the greater ease with which the exploration can be made.

DR. S. C. AYRES, of Cincinnati, read a paper on

DIABETES,

giving two cases with interesting eye complications. In the first, there was an attack of amblyopia which lasted

about one month, during which time the patient suffered severely with headache. The optic disks were blanched, but vision in the right eye was good, while that of the left was considerably impaired. The urine was loaded with sugar. In the second case, there was acute papillitis of both eyes, with marked impairment of vision. There was also occasional attacks of pain in the head with vertigo, followed by nausea and vomiting. He was under the care of Dr. Sharp, of London, who put him on the arsenite of bromine, under which rapid improvement took place. The patient was present and was examined by many of the members. Ophthalmoscopic examination showed atrophy of the optic nerve—his vision was greatly impaired.

Afternoon Session.

THE PRESIDENT'S ADDRESS.

Dr. Reeve dealt with medical history and questions of medical politics. The subject was *The Latest Systems in Medicine*. These were the systems of Brown, of Broussais, of Rasori, and of Hahnemann. Each was briefly sketched in its leading features. Then was considered the influence exerted by each on therapeutics. A potent factor in causing the acceptance of homœopathy was held to be the abuse of bloodletting by the profession, and a sketch was given of this sad page in the history of medicine. The claim of homœopathists that the entire reaction was against this abuse, and the institution of a milder form of treatment was then considered and refuted. All progress was in that direction, and the names of Graves, Louis, Laennec, Marshal Hall, and Forbes, with Minor, and Tully, and Bigelow were mentioned in this connection. The changes introduced into the practice of homœopathy since Hahnemann's time, were then briefly alluded to, and by quotations from writers of that school it was shown that there were the widest differences of opinion among them upon leading points of their creed. So varied are these opinions, that to say a man is a homœopath, does not define him with any accuracy.

The speaker gave three classes: 1. A few who are pure Hahnemannians. 2. A class of honest believers in the law of similars, who are not rigid as to the dose, who believe in educated medical men, and who sustain medical legislation. These are dropping their distinctive title and are on their way back to the regular profession. No obstacles should be placed in their way. 3. The largest class, who pursue sectarianism in the spirit of trade, who traduce the regular profession, misrepresent it, and live by keeping alive in the public mind prejudices against its practice.

The bearing of this diversity of opinion upon the question of consultation with this class of practitioners was also considered. Time did not permit a pursuit of the subject into the future. But were there to be other symptoms in medicine? Was pathology to be based on microörganisms, and was therapeutics to consist in the administration of germicides? A warning was given against the error of the system-makers generalizing from too few facts.

The Society then proceeded to the

Election of Officers,

which resulted as follows:

President.—W. Morrow Beach, M.D., of London.

Vice-Presidents.—H. C. Gill, M.D., of Cleveland; H. R. Kelly, M.D., of Galion; T. McEbright, M.D., of Akron; and I. D. Robinson, M.D., of Wooster.

Treasurer and Librarian.—T. W. Jones, M.D., of Columbus.

Secretary.—G. A. Collamore, M.D., of Toledo.

Assistant Secretary.—E. C. Brush, M.D., of Zanesville.

Akron was chosen as the *place of meeting* in 1886, and the *time*, the first Wednesday in June.

Dr. Himes, of Cleveland, presented a very interesting essay on *Cases Connected with Life Insurance Examinations, with Remarks.*

Dr. G. W. Ryan, of Cincinnati, read a report on the

Influence of Spinal Irritation as an Orthopædic Factor.

The influence of spinal irritation in the production of various deformities was carefully pointed out and numerous cases cited in proof of the author's statements. An interesting case of spasmodic clubfoot was related, which was readily relieved by treatment directed to the spine. Two other cases, who had been unable to walk for years because of this condition, were cured within a comparatively short time. The essayist placed little reliance upon the remedies ordinarily recommended. He had seen no good effect from the use of phosphorus, strychnia, or ergot. He had no experience in the use of opium. The proper and efficacious treatment is by means of blisters or the actual cautery applied along the spine. Spinal support is of benefit. Faradism and massage were valuable adjuvants to treatment.

Dr. Zenner, of Cincinnati, next read a paper on

Diseases of the Spinal Cord.

After commenting upon the frequency and gravity of these diseases, he proceeded to relate several cases in which erroneous diagnoses had been made, in some instances by prominent physicians.

Case I. was a typical case of locomotor ataxia which had been diagnosed as rheumatic pains. There was no excuse for an error in a case so well marked as this, but even in the early periods of the disease, the absence of the patellar tendon reflex, lightning pains, and certain ocular troubles, especially a narrow pupil which does not respond to light, will often enable us to make a diagnosis.

Case II. was one of lateral sclerosis which had been mistaken for locomotor ataxia. The danger of placing too much dependence upon the patient's inability to stand firmly with closed eyes was pointed out.

Case III. was one of progressive muscular atrophy, unusual in the adult. The diagnosis was based upon the paralysis and atrophy of the muscles and altered electrical reactions.

The author spoke lastly of the diagnosis of functional diseases of the spinal cord, which was only to be made after a careful examination had failed to reveal any evidence of organic disease.

Dr. Corlett, of Cleveland, followed with a paper entitled

Diseases of the Skin of Reflex Nervous Causation,

and gave two distinct varieties of *neuroses cutanea*; one a senso-neurosis in which the characteristic feature is a

disturbance of cutaneous sensation unaccompanied by any lesion, the other a tropho-neurosis characterized by anomalies of nutrition.

Neuroses of the skin are met with in neurasthenic persons, either when they are suffering from pathological changes in the viscera or when the viscera are undergoing physiological evolution, as pregnancy, etc. The most marked neuroses within the author's observation have closely simulated eczema. Senso-neuroses are more frequently associated with mild conditions, nerve irritations, etc., while the tropho-neuroses more frequently follow pathological conditions of a graver import—*e. g.*, nerve lesions.

Dr. Ransohoff, of Cincinnati, read a

REPORT ON URETHRAL CALCULI.

He presented two specimens which he had removed from a man aged thirty-seven years. The patient had frequently suffered from retention of urine, necessitating the use of the catheter. When the patient came under the writer's care a large abscess was found behind the peno-scrotal angle. The abscess was opened, but no stone detected until an instrument was passed. The median operation was performed, and two calculi removed; one smooth, weighed 265 grains; the other, very irregular, weighed but 5 grains. The small calculus had doubtless produced the abscess; the larger one had probably been in the urethra for sixteen years.

In the evening a promenade concert and banquet were given by the Montgomery County Medical Society.

Friday, June 5th.—Third Day.

Morning Session.

Dr. Landis, of Columbus, presented a paper on

OCCIPITO-POSTERIOR POSITIONS,

in which the diagnosis, methods of rotation, and the use of the forceps were thoroughly discussed. A series of illustrative cases were given.

Dr. N. P. Dandridge, of Cincinnati, read

SOME CLINICAL NOTES ON OSTEOTOMY, WITH CASES.

After short quotations from recent authorities, showing that osteotomy, in experienced hands, was capable of dealing with otherwise irremediable deformities, and that the accidents following were few in number, and the percentage of mortality slight, the author gave his personal experience. In two cases the femur had been divided below the trochanters (Gant's operation); the first being a case of bony ankylosis at a right angle in an adult after hip-joint disease. The operation resulted in leaving a limb only an inch and a half shorter than its fellow. The second was a case of spontaneous dislocation in a child with necrosis of the opposite tibia, and here the result was again satisfactory.

The treatment of bowlegs was illustrated by two cases occurring in sisters, respectively fifteen and seventeen years of age. The first was successful, but the second operation terminated fatally from septicæmia. These cases were fully illustrated by diagrams. In conclusion, the author advocated strongly the advantages of osteotomy, but at the same time enforced the necessity of every care to avoid the accidents which may ensue.

Dr. Hall, of Chillicothe, next read an interesting paper on

ABDOMINAL SECTION,

in which he gave much information as to the modes and successes of the operators on the other side of the water, gleaned from personal observation.

Dr. Von Klein, of Dayton, followed with an essay on

VOICE.

After detailing some points in physiology, he passed on to a brief history of music and the famous singers of the world. He combated the popular idea that the world's greatest singers were born under Italy's blue sky. He referred at length to the climatic influences on the cultivation of the voice, and claimed that America had produced the sweetest voices and best singers of all times.

The last paper of the session was by Dr. Herrick, of Cleveland, on *Dietetics of Typhoid Fever*.

Dr. Beach, the President-elect, was introduced to the Society, and in a short but appropriate speech returned thanks for the honor conferred upon him.

After passing the usual complimentary resolutions, the Society adjourned to meet in Akron on the first Wednesday of June, 1886.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 26, 1885.

The Vice-President, Charles McBurney, M.D., in the Chair.

PRIMARY EXCISION OF WRIST-JOINT.

Dr. McBurney presented a patient who received an unusual injury three months ago, when his hand was caught between the coupling of an engine and a car, and all the bones of the carpus with the exception of the scaphoid and pisiform were crushed. The metacarpal bones and also the radius and ulna entirely escaped injury. A large wound was produced along the inner side of the hand, lifting up about six inches of the skin, but the tendons were not torn. The comminution was so great as to require removal of all the bones of the carpus except the scaphoid and the pisiform. The operation was performed under bichloride irrigation, and a firm permanent antiseptic dressing applied with iodoform gauze and plaster of Paris, which was kept in place eighteen days, after which the dressing was changed occasionally. There was no rise of temperature at any time during the progress of the case. The man now has some motion at the wrist in every direction, even some lateral motion, and the motion of the fingers is steadily increasing. The result was very much more satisfactory than Dr. McBurney had expected. He did not know of a case where the bones of the wrist were so extensively crushed without injury to adjacent bones.

PERSISTENT PRIAPISM.

Dr. L. A. Stimson presented a man forty-eight years of age, who came under his care about a week ago, having a good family history, a doubtful history of syphilis, and who had been married twenty-five years. The first thing the patient noticed was recently that after having sexual intercourse his erection was slow to

subside, and nearly three months ago without previous trouble except rheumatic pains simulating sciatica, he noticed upon the glans penis two raised deep-colored spots, one on either side, and these were immediately followed by priapism, which has continued until the present time. The penis has remained as it is now without change in size and coloration. It was first treated by elastic pressure, which resulted in slight superficial sloughs upon the glans. The organ measures six inches in circumference, six inches in length upon the dorsal surface, and ten inches and a half from the bulb to the glans. The bulb shares in the erection, as do also the two cura, although the right is somewhat less involved than the left. There is a slight dorsal incurvation and a slight concavity towards the right. The only noticeable feature in the general appearance of the patient was a peculiar livid color of the lips, and there was exaggeration of his reflexes, most marked upon the right side. There were no symptoms of locomotor ataxia. The blood had been examined and showed no excess of the white blood-corpuscles, although there was a distinct enlargement of the spleen and liver, and also some consolidation at the apex of the right lung, and some pleuritic friction sounds upon the left side of the chest. There was but slight sexual appetite. The patient's principal suffering was from an aching pain in the perineum. The stream of urine was small, but there was no pain on micturition.

DR. MARKOE referred to a case of priapism occurring in a patient in whom there were symptoms of leucocythæmia. The peculiarity of the case, however, was in the fact that the erections seemed to be confined to the corpora cavernosa. The glans penis was almost entirely flaccid, as well as the entire corpus spongiosum.

DR. POST had had a case under his care in a man somewhat older than Dr. Stimson's patient, who had priapism equal to this which had continued about three months. Otherwise he was apparently a healthy man.

DR. MCBURNEY thought that the suddenness with which the condition developed would seem to dispose of pressure on bloodvessels as the cause, unless it was from extravasation of blood, and it would also seem to dispose of leucocythæmia as a cause. The history of the case would lead one to think of some neurosis, perhaps some disturbance of the sympathetic system.

DR. STIMSON said he regarded the case as of central origin.

DR. L. A. STIMSON then read a paper entitled

INJURIES OF THE BLOODVESSELS IN THE REDUCTION OF DISLOCATION OF THE SHOULDER.

(See page 653.)

DR. STIMSON presented, in connection with his paper, a specimen removed *post-mortem* from the patient whose case Dr. Sands reported to the Society in December, 1879, a woman 86 years old with dislocation of the shoulder of seven weeks standing. Ether was given, slight movements made to break up adhesions, and then slight traction upward and outward. Immediately a swelling appeared in the axilla, the radial pulse ceased in the affected side, and the patient was extremely prostrated, death by syncope appearing to be imminent. The condition was relieved by hypodermics of brandy, and the arm bandaged to the side. For several days the patient remained in a critical condition, attacks of syncope occurring every night, but she gradually recovered. She died in May, 1885, five and a half years after the accident.

The specimen consists of the upper part of the humerus, the adjoining portions of the scapula and clavicle, the artery, and some of the nerves. The head of the humerus has torn through the subscapularis muscle and lies below to the inner side of the coracoid process. It is slightly rotated outward; the greater tuberosity has been torn off and occupies the glenoid cavity, but has reunited with the humerus. The subscapularis lies between the humerus and the head of the scapula, and is firmly united to both.

The artery and median nerve lie at the inner border of the anterior aspect of the head of the humerus and are adherent to it. The artery is most firmly fixed at the lower part of the head, and there presents a marked narrowing and a change in direction of about 30°, the angle being open externally. The posterior circumflex artery, very much larger than usual, is given off a quarter of an inch below the narrowed point. When the specimen was fresh, liquid injected into the upper end of the artery flowed freely from its lower end; but in cutting it open longitudinally on each side of the constriction, it was impossible to detect a channel through the latter, and it is probable that the liquid made its way through the dilated circumflex. The subscapular artery could not be found.

The artery for an inch and a half above the occluded point was occupied by decolorized clot adherent to its posterior wall and terminating just below the origin of the acromio-thoracic. The artery is not atheromatous.

The injury appears to have been either a rupture of part of the wall of the artery, or possibly the avulsion of the subscapular branch; and the arrest of the hemorrhage was probably aided by the pressure upon the vessel of the head of the humerus and by the syncope.

DR. POST said that these cases formed an extremely small proportion of the cases of old dislocation which were reduced, and he would like to ask whether the danger of rupturing an artery was sufficient to deter one from undertaking to reduce such dislocations. He had had a number of cases of this character, and had succeeded in several instances in reducing the dislocation at the end of five or six months without doing injury, although he had not resorted to a very great amount of force or violent movement. It had seemed to him to be legitimate to resort to surgical manipulations for the purpose of reducing the dislocation, and he would like to know if he had been wrong in that view.

DR. MCBURNEY thought that when dislocation occurred in a moderately young individual, and the parts had not been manipulated very much, and the history showed that the first injury was not followed by very much swelling or inflammatory action, it might properly be the subject of an attempt at reduction even at a considerable time after the occurrence of the original injury. But where other conditions were present and the case occurred in an old person, the results were not very satisfactory even when the dislocation was reduced, and it might be questionable whether the effort should be made; at least such cases were worthy of caution.

So far as statistics went, Dr. Stimson's collection did not pretend to include a number of other accidents,

such as fracture of the humerus, which occurred rather frequently.

Dr. Stimson said that he had not directed attention to other accidents, although he had known of three cases of fracture of the humerus as a result of efforts to reduce old dislocations occurring in one surgical service within six months.

Dr. Hall asked if it would not be a more scientific procedure to cut down and liberate the head of the bone.

Dr. Stimson remarked that this had been done with success.

EPITHELIOMA OF THE RECTUM.

Dr. A. C. Post presented a specimen of epithelioma of the rectum, which he removed that afternoon, at St. Luke's Hospital, from a man fifty-three years of age, of good general health and constitution, and who had been subjected to hemorrhages from the rectum during the last two years, with more or less pain, but the disease had not advanced so far as to cause symptoms of obstruction. When Dr. Post first saw the patient he found that there was a morbid growth within the rectum not connected with the sphincter, at least three or four centimetres from the sphincter, and he was able to pass his finger above the diseased part, and on drawing upon it, the mass seemed to move freely upon the surrounding parts. He determined to excise the tumor and make an effort to save the sphincter, which he succeeded in doing. He began by making an incision through the posterior part of the anus down to the coccyx, and laying open the posterior part of the rectum, and then making a lateral incision on each side, at a distance of two or three centimetres from the anus. The lateral incisions were extended backward and curved inward, so as to meet the median posterior incision. These lateral incisions throughout their whole extent were on the outer sides of the rectum, and not involving its coats. As he approached the wall of the rectum he made the dissection with a blunt instrument and with the fingers, using the knife and scissors as little as possible. He succeeded in reaching as high up as the upper extremity of the tumor, and then divided it into the lateral portions, opening it before and behind, and cutting through the walls of the rectum above and below it. It was somewhat difficult at certain points to make these incisions, but he succeeded finally, after a protracted dissection. There was only a moderate amount of hemorrhage, and no oozing of blood at the close of the operation. He applied a solution of chloride of zinc, two scruples to the ounce, to the surface, irrigated the wound with mercuric bichloride solution, 1 to 1000, drew the parts down, and connected the mucous membrane above the excised parts to the parts below, and made a continuous canal on all sides. He then dusted the parts with iodoform, introduced a tent of iodoform gauze into the rectum, applied iodoform gauze over the surface with absorbent cotton and a T-bandage.

The case was an unusually favorable one for operation, because of the fact that the sphincter was not involved and the disease was almost entirely confined to the mucous membrane and the parts immediately adjacent to it.

Dr. George A. Peters said that the case seemed to him to be a very favorable one for operation, and that Dr. Post was able to get good coaptation throughout the entire circumference of the bowel.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifth District Branch.

Scientific Meeting held at Poughkeepsie, May 19, 1885.

(Specially reported for The Medical News.)

In the absence of the President, Dr. J. C. Hutchison, of Brooklyn, Dr. J. G. Porteous, of Poughkeepsie, was called to the Chair.

Dr. J. D. Bryant, of New York, reported

THREE CASES OF LIGATION OF THE EXTERNAL CAROTID: IN TWO, BOTH VESSELS WERE TIED SIMULTANEOUSLY.

Having given an early history of the operation and stated the objections which had been urged against it, some of which he said are still held valid, he proceeded to narrate his own cases. The operation in the first case was for the relief of a large and rapidly increasing aneurismal tumor resulting from a blow with a bottle in front of the left ear, and involving the trunk of the temporal artery and its terminal branches, together with the occipital. Dr. Bryant ligated the external carotid, under antiseptic precautions, in August, with the effect of reducing the tumor one-third. Ten days after the operation, however, there was noticed a slight returning pulsation. This afterwards increased, and the bruit also returned. Both the pulsation and bruit, it was found, could be checked by making pressure on the external carotid on the opposite side (the right). About seven months afterwards he operated on the tumor itself. Among the lessons which this case seemed to teach were, that the ligation of the external carotid in such cases is but a temporary expedient, and that the division and ligation of all the vessels leading to the growth, except just at the flap, are required. Six other similar cases had been reported, and in only two of them was a cure effected by ligation of the external carotid. The ligation of this artery, therefore, can only be regarded as a palliative measure and not curative, except in connection with other procedures. He did not think it justifiable to ligate the common carotid, since the rate of mortality is equal to the number of recoveries.

Dr. Bryant's other two cases of ligation of the external carotid, in both of which both vessels were tied simultaneously, were for the relief of malignant disease. In the first, excision had been repeatedly followed by rapid recurrence, and the knife was no longer available. Death occurred eleven days after the operation from hemorrhage of the facial artery at a point of sloughing, and he attributed the fatal result in the first place to an anomalous arrangement of the external carotid and its branches, which deceived him, and, secondly, to the carelessness of the attendant who did not discover the hemorrhage until the patient had lost so much blood that it was impossible to restore him, although transfusion with a saline solution was resorted to. This was the only case which had been reported in which death resulted from hemorrhage at the seat of disease.

In the second case the operation was also performed for the starvation of a malignant growth. At the present time, nearly four weeks afterwards, the disease, which at the time the two external carotids were ligated was progressing rapidly, is in a quiescent state. While he does not expect to cure malignant disease by this pro-

cedure, he believes that it is a rational and effective means of treating malignant and other growths which are fed by the branches of the external carotid. Exclusive of the two cases now presented, the operation has been reported in six cases, in four for the relief of malignant disease, in one for a vascular tumor of the face (in which no benefit was derived from it), and in one for a pulsating tumor at the back of the neck, with the same unsatisfactory result.

Dr. Bryant's general deductions were as follows:

1st. That ligation of the external carotid artery, with independent ligation of its branches arising from the first inch of its trunk, is a safe and commendable operation.

2d. That when the facial and lingual arteries do not arise singly or by a common trunk from the first inch of its course, the branches arising at the bifurcation should be tied.

3d. That a simultaneous ligation of the external carotids is a rational preparatory measure to operations involving the parts supplied by their branches when dangerous hemorrhage is feared.

4th. That simultaneous ligation is advisable to diminish the rapidity of the development of extensive malignant growths when nourished by the branches of the external carotid.

5th. That the ligation of one or both external carotids for the cure of aneurismal formation of the branches of the same is not warranted as an independent measure.

6th. That ligation of the common carotid should not be done for the cure or for the arrest of morbid conditions involving the external carotid with its branches, except as a final resort.

The paper was discussed by Drs. Wieber, of Brooklyn, and Hinton and Gouley, of New York, and the discussion brought to a close by Dr. Bryant.

Dr. S. J. Murray, of Brooklyn, read a paper on

DIPHTHERIA, AND ITS TREATMENT BY CALOMEL.

Having given a brief sketch of the history of the disease, he said, in regard to the epidemic, and occasionally endemic nature of diphtheria, the evidence was plain; but it was still an open question as to how far it possesses contagious and infectious properties. That it is transmitted directly by contact with the morbid products generated by the local disorder, he did not himself doubt. Its prevalence, and especially its virulence, is favored by defective drainage and contaminated air, and by the drinking of impure water. It is certain, however, that occasionally diphtheria appears in a sporadic form, and that isolated cases sometimes occur which can be attributed to no known cause whatever.

The large rate of mortality, sometimes running as high as fifty per cent., in this disease would seem to show that we have not adopted the best plan of treatment for it. The entrance of the diphtheritic poison, he believed, is effected in some way long before the disease is recognized by its local manifestations, and it destroys life, not by its local, but by its constitutional effects. In prescribing a drug intelligently, it is necessary to have some accurate knowledge of its effects on the system, and he therefore referred briefly to the action of calomel, which is the remedy which he employs in diphtheria. This drug, on entering the stomach, is supposed to escape unchanged into the intestines. It is then decomposed by the alkaline juices, and a portion of it immediately absorbed, passing into the bloodvessels. He was aware that it had already been employed to some extent in diphtheria, but it had been pretty generally condemned as a dangerous remedy. It was not the legitimate use, but the abuse of it, he believed, which had been followed by unpleasant after-effects. Dr. Wallon, in his able paper read before the Kings County Medical Society, in which he advocated the bichloride of mercury treatment, said that when the patient's bowels were constipated, he gave the mild chloride. We might infer from this, he said, that his success was in part due to the latter.

While others had used calomel for diphtheria, he knew of none who had used it in the same quantities that he had done. He did not adopt this plan of giving calomel in large doses until he had exhausted nearly or quite all of the remedies prescribed by various authors, and when he commenced with it he resolved that he would give it a thorough trial. The two following cases were the first in which he employed it: On Nov. 27, 1879, he was called to a house, where he found the whole surroundings in a most filthy condition. The parents had just returned from the funeral of one of their children who had died of diphtheria. On entering, he found a girl of ten and a boy of eight who were ill with the disease. The boy had been sick three or four days. His temperature was 103° and his pulse 115, and he was thin and anæmic. The pharynx was covered with a dirty, grayish membrane, foul-smelling, and strongly adherent. The girl's throat presented much the same appearance, while her temperature was 101° and the pulse 96. He immediately ordered the house to be disinfected, and gave the girl ten grains of calomel, and the boy eight; these doses to be repeated every four hours until he returned the following day. He also had the throat lightly swabbed with a mixture of carbolic acid and glycerine, and ordered stimulants and proper nourishment to be given at stated periods. When he called the next morning, the patients had each taken four doses of calomel, of ten and eight grains, respectively. The temperature of the girl had fallen one degree and she seemed a little better; but the condition of the boy, with the exception that the temperature had fallen half a degree, was not at all improved. The treatment was ordered to be continued. On his third visit the girl was doing very nicely, and a portion of the membrane was gone. She had taken ninety grains of calomel, and he now ordered the ten grain doses to be given only night and morning. The boy's temperature had fallen to 101°; but the appearance of the throat was about the same as before. The calomel was continued at the same intervals, but in five grain instead of eight grain doses, and in addition he ordered five grains of quinine every six hours, with an increase in his stimulants and amount of nourishment. On the following day the membrane was found to have entirely disappeared from the girl's throat, and the calomel was consequently discontinued. She was placed upon quinine in tonic doses, and made an excellent recovery. The boy's condition was also found to be more favorable; the pulse and temperature being nearly normal, and the membrane being partially detached around the edges. He had now taken about 100

grains of calomel, and it was discontinued, though the quinine stimulants and nourishment were maintained. He made a slow, but good, recovery. Having related a number of other cases with favorable results under the calomel treatment, Dr. Murray said, in conclusion, that he always gave the remedy dry, since when thus administered, more or less of it lodges upon and around the membrane, acting as a solvent and preventing its extension. He had never seen hemorrhage after the removal of the membrane, or the formation of a second membrane. Although the calomel acted as a sedative, it did not produce mercurialization or leave any unpleasant after-effects.

DR. ALFRED L. CARROLL, Secretary of the New York Board of Health, said that unquestionably the cases reported in the paper recovered after the administration of calomel; but in listening to it a doubt had arisen in his mind as to whether the calomel was, in reality, the efficient agent in their cure. In the first cases described the sanitary condition of the premises was very bad, and the first thing that the doctor did was to remedy this. Now, diphtheria is generally recognized as a filth disease, and it is a fact that a large number of cases recover without any medicinal treatment whatever, if they are placed under good hygienic surroundings. Again, with the calomel, stimulants, and nourishment were very freely given, and he had personally seen cases which recovered very rapidly under the use of stimulants and nourishment alone, without anything more, in the way of drugs than an occasional dose of quinine. Fresh air, stimulants, and plenty of food are very potent factors in the successful treatment of diphtheria; and when these are all made use of, it is not quite clear how far the calomel aids in securing the great results noted.

There are two things which he has especially noticed in regard to diphtheria. The first is, that the amount of exudation has no positive relation to the severity of the disease; and the second, that, in his own experience, at all events, the most rapidly fatal cases are those in which the temperature never rises above the normal, or if it does soon becomes reduced.

DR. GREENE, of Buffalo, who was a delegate from the Fourth District Branch of the Association, said that he had had a large experience in the treatment of diphtheria, and that he had become convinced that the chlorides are the most important agents for internal administration in it; though for himself he prefers others to either the bichloride or the mild chloride of mercury. He had, however, used the bichloride with good effect in combination with tincture of the chloride of iron. He believes alcohol is essential in diphtheria, considering it an excellent germicide, and said that he always commenced the treatment of every case with alcohol, unless the fever was very high. He also believed in plenty of quinine and a nourishing milk diet. During the last two or three years he had seen some very severe and malignant forms of the disease; but, except in the case of infants, he always felt assured that if the parents would carefully carry out his directions, there would be no doubt of recovery.

As a local application, he preferred to all others a saturated solution of persulphate of iron (a drachm to about four or five ounces of water). He believed there is nothing like it, and said he had saved five cases out of eight of membranous croup in which he had used it. He employed it by means of an atomizer which gave a continuous spray, and during its application he had seen some patients throw out whole casts of the upper part of the trachea. There was one case of special interest which he would relate: He was called late at night to see a young child who was cyanotic and choking to death. He at once gave it as much brandy as he could get down it, and commenced the use of the persulphate spray. Presently a violent paroxysm of coughing was induced and it threw up a large mass of membrane, with immediate relief.

DR. E. R. SQUIBB said that Dr. Greene, was mistaken in supposing that his solution of the subsulphate of iron is a saturated one. The Monsell solution contains a far larger proportion of the salt than his so-called solution, but the latter is a safer one to use, and more efficient for the purpose required than a stronger solution. He approved of Dr. Murray's method of giving calomel dry, as this had long been urged as the best way to administer it, and as an albuminate of mercury is thus formed, which is soluble by the fluids of the mouth, it has been proposed to use an albuminate of the drug which was made artificially outside the body.

DR. R. C. VAN WYCK, of Dutchess County, read a paper on the

TREATMENT OF CEREBRAL HEMORRHAGE AND EMBOLISM BY THE INTERNAL USE OF CARBONATE OF AMMONIA.

Having related in minute detail two cases occurring in his practice, he stated that the advantages which he claimed for the treatment were the following:

1. As a diffusible stimulant to the general circulation, relieving the anæmia which is present in the brain, increasing the cutaneous circulation, and inducing perspiration—relieving in this way intracranial pressure.

2. By its direct action in dissolving the clots. The only agents which possess this property are the alkalies, and the most efficient of these is ammonia.

3. In the œdema and congestion of the lungs so often seen in apoplexy, the used of this salt will frequently relieve the condition, partly by its stimulating action on the terminal capillaries, and also by its expectorant action on the bronchial mucous membrane.

4. By keeping up the alkalinity of the blood, and preventing further thrombosis.

Remarking that he did not claim for this drug a specific action, but only that it acted as an efficient auxiliary to the use of other measures, he said that in the treatment of cerebral hemorrhage the following would seem to be the proper order of procedure:

1. To endeavor to control prodromal symptoms, which threaten an attack of apoplexy, by prompt venesection and catharsis.

2. To relieve the period of reaction after paralysis has taken place by arterial sedatives, preferably aconite.

3. To remove the exudation, relieve cerebral anæmia and pulmonary congestion, and prevent further thrombosis by the free use of carbonate of ammonia.

4. To support the system by nourishing, yet unstimulating diet, and by the use of remedies which specially

nourish the brain tissue, such as lactophosphate of lime, cod-liver oil, and the phosphate of zinc.

5. To increase the muscular development by massage, friction, electricity, and strychnia.

The carbonate of ammonia should never be given in cerebral hemorrhage, he said, until the period of reaction has fully set in—say, from ten days to two weeks. It should then be given continuously for at least a month, or until the retrograde changes in the clot are accomplished. In thrombosis and embolism, if the diagnosis can be clearly made, it should be given at once. The dose employed by him is five grains three or four times a day, and it is given in half an ounce of liquor ammoniæ acetatis. He said there is one class of cases in which the carbonate of ammonia had not acted well in his hands, viz., cases of cerebral hemorrhage associated with interstitial nephritis and hepatitis. Here he had had good results from the use of sodium phosphate, in doses of from twenty to thirty grains, given in the infusion of dandelion, three times a day after meals, and of bichloride of mercury in doses of one-twenty-fourth of a grain, given (sometimes combined in a pill with digitalis and squill) before meals. In conclusion, Dr. Van Wyck read a letter which he had received from Prof. Roberts Bartholow, in regard to the utility of the carbonate of ammonia plan of treatment. There is one class of cases, Dr. Bartholow wrote, in which he had seen most admirable results, viz., the cases of thrombosis of cerebral vessels due to chronic arteritis. Embolism of the brain, secondary to lesions of the cardiac valves, is another condition in which the same treatment is very effective.

Dr. J. G. Porteous read a paper on

HYPERTROPHY OF THE PROSTATE GLAND.

He briefly mentioned the symptoms, and said that the diagnosis is not difficult. From thirty to fifty per cent. of men over fifty years of age are troubled with this condition, and the suffering caused by it is often extreme. The administration of drugs has no effect in reducing the size of the enlarged prostate. Personally, he had had but little experience, except with the senile variety of the trouble, which is by far the most common. The best treatment, he believed, is the early use of the soft catheter; the instrument to be passed every three or four days. By this means it is possible to avert or greatly postpone the distressing symptoms of the condition; but if a case is left too long without treatment, there will almost inevitably be great difficulty in its management. There is one important lesson that he had learned in connection with this affection, and that is, that it is extremely dangerous to empty the bladder completely. Formerly he had done this, but the results had more than once been so disastrous that now he is content to adopt the plan of gradual evacuation. When this is practised, there is seldom any blood, and the quantity of pus is much less; while the patient lives longer and gets along with less suffering. In conclusion, he would, therefore, say, empty the bladder in these cases with great caution, and always use a soft catheter. When there is very great irritation present, it is advisable to resort to the aspirator until this has been sufficiently allayed to permit of the use of the catheter. While this is not necessary in ordinary cases, he believes that the aspirator will in the future be more often used in connection with hypertrophied prostate than it is at present.

Dr. J. W. S. Gouley, of New York, said he was much gratified to hear of the wise course which Dr. Porteous had adopted in cases of retention of urine from enlarged prostate. The idea of gradual evacuation of the bladder in these cases had been first suggested by Sir Benjamin Brodie, and Dr. Porteous by careful clinical observation had arrived at the same conclusions as that great master. Young practitioners are always anxious to see the last drop of urine, and he said he could relate a dozen cases in which death had resulted from the complete emptying of the bladder. Caution in this regard was the principal practical point that was impressed by the paper just read.

Another point to which he should like to call attention was the existence of incontinence of urine in connection with enlarged prostate. Hypertrophy of the prostate is not a single entity, but consists of a number of entities. At the present day we can determine what form of hypertrophy is present, and this knowledge guides us in the selection of the proper instrument to be used. He said he agreed with Dr. Porteous that, as a rule, the vulcanized India-rubber catheters are the safest, particularly for patients to pass themselves; but cases are met with from time to time in which it is not possible to enter the bladder with them, viz., those with intraurethral hypertrophy, with a zigzag course of the urethra, and, perhaps, a bar at the neck of the bladder. Then the metallic flexible elbow catheter of Mercier is required. When there is a false route, Mercier's invaginated catheter is invaluable. With this instrument Dr. Gouley said he had never failed to get into the bladder, and since he had been in possession of it he had thrown the aspirator entirely aside. Every man who has enlarged prostate, he went on to say, does not have retention. On the other hand, the patient may have incontinency, which is not to be confounded with the dripping of an overflowing bladder. In conclusion, he spoke of the importance of the surgeon's being on his guard against the possible stoppage of the catheter by a blood-clot filling up its lumen, so that no urine could pass through it.

Dr. Robert Newman, of New York, having, in the course of some remarks on the paper, recommended the use of cocaine in cases where the parts are so sensitive that instruments cannot be tolerated, Dr. Gouley expressed the opinion that this is bad practice. It is highly desirable, he thought, that we should have the sensations of the patient to guide us—otherwise there is a liability of making a false passage—and the skilful catheterist, having made a careful diagnosis and selected the proper instruments, will not be at all likely to give pain.

Dr. C. S. Wood, of New York, read a paper entitled

REPORT OF A CASE OF SO-CALLED METASTASIS OF ACUTE RHEUMATISM FROM THE SHOULDER AND ARM TO THE MENINGES OF THE BRAIN, RESULTING FATALLY.

The patient was thirty-eight years of age, and inherited a strong rheumatic tendency. The rheumatic attack referred to was treated first with salicylate of soda, and afterwards with alkalies in full doses, morphia being also used as occasion required. Eight days from the commencement of the illness the metastasis

took place, and the fatal result rapidly ensued, the temperature rising to 106° just before death. No autopsy could be obtained. During his professional career, Dr. Wood had met with a number of such cases, though the most of them occurred while he was serving as a surgeon in the army. In conclusion, he quoted the opinion of various standard authorities upon this subject.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 4, 1885.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. RICHARD H. DERBY read a report on

CONTAGIOUS OPHTHALMIA IN SOME OF THE ORPHAN ASYLUMS AND RESIDENTIAL SCHOOLS OF NEW YORK CITY.

A child in these institutions, he said, is far more liable to lose its sight from contagious ophthalmia than to lose its life from scarlet fever or other infectious diseases, over which such careful surveillance is kept by the Board of Health. Having stated that he had made an examination of 7440 children in 24 orphan asylums and residential schools, he gave a brief description of the disease referred to in his report, as blenorrhœal conjunctivitis, and its complications. He then said that it often exists among the children in these institutions without any medicinal treatment whatever; or if these affections are treated, it is merely as a simple catarrh.

The disease is most frequently communicated by means of towels, and by the water in which children wash together. Fourteen years' experience as an officer in one of the largest ophthalmic hospitals in this country, has convinced Dr. Derby of the great prevalence of the trouble; and his inquiries have demonstrated the fact that the ophthalmia is almost invariably contracted in the institutions spoken of, the eyes of children, as a rule, being perfectly healthy when they are committed to them.

In the asylum which he first visited, out of 326 boys, he found 96 suffering from contagious ophthalmia; and out of 331 girls, 65; a total percentage of 24.5. Separate towels were used for each child, and the general sanitary condition of the institution was good. In this respect there was a great improvement over the state of affairs which he had found on the occasion of a former visit, in company with the late Mr. Theodore Roosevelt, and it was in consequence of suggestions then made to the managers that the system of separate towels and other reforms had been adopted.

In the second institution visited, out of 1586 children, there were 488 cases, or a percentage of 30.7. In the third, there were 782 children, and 111 cases, or 14.2 per cent. In the fourth, 188 children, and 93 cases, or 49.4 per cent. In the fifth, 740 children, and 71 cases, or 9.5 per cent. In the sixth, 96 children, and 26 cases, or nearly 37 per cent. In the seventh, 282 children, and 15 cases, or 5.7 per cent. In the eighth, 455 children, and 74 cases, or 16.2 per cent. In the ninth, 155 children, and 5 cases, or 3.2 per cent. In the tenth, 240 children, and 15 cases, or 6 per cent. In the eleventh, 21 children, and no cases. In the twelfth, 451 children, and 204 cases, or 45 per cent. In this institution there was great overcrowding, and the general condition of the inmates was bad; no attempt was made at isolation. In the thirteenth, the percentage of cases was 5.7. In the fourteenth, the percentage was 17.3. In the fifteenth, there were 151 children, and only one case of contagious ophthalmia. This was an institution in which the cottage plan was adopted. In the sixteenth, on the same plan, there were 122 children, with one case. In the seventeenth there were 399 children, and 7 cases, or 1.9 per cent. In the eighteenth there were 245 children, and 40 cases, or 16 per cent. In the nineteenth there were 98 children, with 2 per cent. of cases. In the twentieth there were 124 children, and 6 cases, or 4.8 per cent. In the twenty-first there were 132 children, and 21 cases, or 15.9 per cent. In the twenty-second there were 18 children, and no cases of the disease. In the twenty-third there were 19 children, and no cases; and in the twenty-fourth, 82 children, and 8 cases, or 10 per cent.

It was not the purpose of the paper, Dr. Derby continued, to discuss the causes of contagious ophthalmia, such as imperfect quarantine, bad hygienic conditions, etc. This object would be gained if he could succeed in drawing renewed attention to the fact that in the orphan asylums and other similar institutions of the city the disease exists to an alarming extent, while attracting but little attention from the attendants. The statistics obtained from his investigations showed that among 7440 children, 1428, or 19.19 per cent., were suffering from communicable eye disease.

When the disease prevails to an unusual extent in any of these institutions, it is the common practice to move the worst cases to their homes, which is in every respect objectionable. The children are apt to be neglected, or if they are taken to an eye infirmary three times a week, as would be demanded in such cases, it imposes an enormous burden upon the already overtaxed parent; to say nothing of the fact that the affected children constitute fresh centres of contagion. Too often the want of proper care results in irreparable damage to the eyes. One great source of the trouble is the overcrowding of children in asylums, since the most of these institutions received additional pecuniary support for each child committed to them.

Dr. Derby, in conclusion, made a number of suggestions, among which were the following:

That all institutions for the case of children should be compelled by law to comply with certain specified requirements for the prevention of the spread of eye disease among their inmates.

That each asylum should be required to present at certain stated intervals a report of the cases of contagious ophthalmia among its inmates.

That complete separation of all affected children from the others should be insisted on.

That adequate treatment, not merely local, but hygienic and general, should be enforced in every case.

That the same precautions should be taken in regard to the spread of the disease as are now employed in the case of scarlet fever and other contagious diseases.

That prompt and systematic action for relief from this pressing evil is required, and that a special hospital is needed for the successful treatment of the disease.

It is time, he thought, that the Academy of Medicine should protest against the present inhuman state of affairs in these institutions for children.

DR. H. KNAPP said that he would in no way underrate the statements of the author of the paper. The institutions referred to, he believed, are at times the direct foci by means of which contagious ophthalmia is spread, and sometimes the outbreaks of the disease are so serious that the authorities controlling them are obliged to close the institutions temporarily and farm the children out. It is too often the case, however, that the children thus sent out are the means of spreading the disease through the community. Some of these institutions take the most active measures to stamp out the disease; but the truth is, that when they once become invaded, a certain number of cases are almost sure to remain all the time. Consequently, he doubted whether the disease is altogether preventable.

He felt sure, however, that those in charge of some of the institutions did what they could to keep it under control. Two of them, one a Roman Catholic institution, and the other a Hebrew orphan asylum, invariably sent candidates for admission to him (Dr. Knapp) to examine the condition of the child's eyes before it was permitted to enter. Very recently he had made an examination of the eyes of all the children in the second of these institutions, which is situated in a most healthful location at One Hundred and Thirty-eighth Street, and in which the children are cared for very much in the way that they would be in private families. The result showed that out of 400 inmates, he found only two with sore eyes, and neither of these was affected with contagious ophthalmia. He thought that Dr. Derby's suggestion, that a certain supervision over the eyes of the children in all these institutions should be maintained, an excellent one; and if from time to time rigid inspections are made by competent physicians, and the reports of the results of the same transmitted to the proper authorities, he believed that large epidemics, at least of contagious ophthalmia, would be avoided. He knew of nothing that would be more philanthropic than the maintenance of such a supervision.

DR. D. B. ST. JOHN ROOSA said that by a curious coincidence, only this afternoon he had been called upon, at the request of the attending physician, to examine the eyes of 242 children in a certain institution. Out of these he found 67 who were affected with conjunctivitis; but it was for the most part of a very mild type. It was probably follicular in character, and he considered it perfectly curable under appropriate treatment and with as good care as could be had without isolation. Two years ago he had seen an outbreak which was much more dangerous in a school which was greatly overcrowded, and in which the treatment adopted had not been very intelligent. He did not consider the authorities of these institutions altogether to blame for the existing state of affairs, but thought that the Board of Health was responsible to a large extent. The institutions are often forced to take children when they did not want them.

In 1834 contagious ophthalmia prevailed among the Belgian army, and when the soldiers were let loose, they carried the disease all over Belgium. In this city the public interest that had been excited in this matter of eye disease in the institutions for children had, he believed, already borne considerable fruit. One interesting fact had struck him in the examination which he had made, and that was, that some of the most delicate and badly nourished children had the best eyes; being entirely free from all trace of the conjunctivitis. For his part, he believed the disease is purely local, and has no special connection with struma.

The remedy is at hand, and to be obtained with perfect ease. The taxpayers of the city should be made to pay for the establishment and support of such a special hospital as Dr. Derby had suggested. The cost to the State of a man with poor eyes, or altogether blind, is a very serious matter, and the reduction of the pauper class is certainly important enough to engage the attention of the political philanthropist. The Board of Health, he thought, should at once take measures for the establishment of such a hospital.

DR. OLTMAN, of Nyack, spoke of his experience in connection with an institution for the care of children committed by the courts. Over one hundred had been admitted during the past winter, and with the exception of two, who were affected with trachoma, all had healthy eyes when they entered. In the winter, however, mild catarrhal disease developed, and went on until the spring. Forty-four children had catarrhal disease, which was probably contagious, seven had acute granular disease, and one had purulent ophthalmia.

DR. C. R. AGNEW said that his interest in this subject began nearly thirty years ago in Ireland, where, in connection with the famine, the disease developed in the poorhouses and other public institutions. At that time he saw an immense number of lids there, and from this stock, he said, the United States had been receiving fresh importations ever since. He had hoped that in the State of New York he would never be called upon to observe such scenes as he had unfortunately witnessed in some of our institutions. In regard to one of these institutions he made a report three years ago, which was afterwards embodied in the annual report of the State Board of Health, and it illustrated very well the manner in which an outbreak of contagious ophthalmia augments and gets headway.

Dr. Agnew then gave an account of an effort to develop an orphan asylum in a neighboring county, when the available funds were totally inadequate for the purpose. In a building which was entirely unfit for this use nearly three hundred children were packed, a much larger number than it could properly accommodate. The hygienic conditions were thus very poor, and contagious ophthalmia soon broke out. The children all washed in a trough sixteen feet long, and by this means the disease was communicated to eight-tenths of those who came in from outside. What made the disease all the worse was the fact that in the infirmary the children had to sleep two or three in a bed. There was a gentleman present at the Academy to-night who had taken charge of the children at that time, and who had brought about a complete revolution. He turned all the children out of doors into two large circus tents, and instead of keeping them upon ten or fifteen quarts of milk a day, as had previously been done, he allowed them to have four hundred quarts. The change produced was indeed marvellous. This was a fair type of a considerable number of institutions which are all the time taking in children for whom they are altogether unable to provide; and he thought, therefore, that there should be much more and better inspection than is now ordinarily seen. It

is not every general practitioner whose opinion as to the condition of eyes can be safely trusted.

He did not like the idea of entrusting such a matter to the State; but there is a limit to individualism and the power of voluntary efforts. It seemed evident to him, therefore, that there is need of some legislation. He believed in agitation of a subject, and it is his opinion that by judicious efforts on the part of those specially interested in the matter, the public mind can soon be brought to realize the necessity for the adoption of active measures for repressing the existing evil. A few years ago the vile condition of the vessels bringing immigrants to our shores was such that ship fever was of the most constant occurrence, the passengers being subjected to as much overcrowding and bad treatment generally as the negroes in the slave ships. This state of affairs continued until public opinion became roused to a sufficient extent to cause the adoption and enforcement of those wise and beneficial rules which now invariably regulate the carrying of steerage passengers. He thought that before an institution for the care of children should be allowed to exist, it should place on file a certificate to the effect that it had ample provision for the accommodation of a certain definite number of inmates, with specified statements of its capacity and arrangements, and that it should be prohibited by law from being permitted ever to receive any more children than the number designated in such certificate. The State Board of Charities, he believed, ought to take some action in regard to this important matter. The managers of these institutions are almost without exception disposed to do what is right. They are perfectly willing to act for the best interests of the children under their charge, but are ignorant of the proper methods to pursue. It is certainly horrifying to think of making six or seven hundred paupers in the residential schools of this city, and it is high time that something should be done to prevent the continuance of the present state of affairs. It is his opinion that the vast majority of children who contract chronic conjunctivitis in these institutions never recover from it, and in after-life they constitute an immense body of drifting and despairing sufferers, in many instances endlessly wandering about from one dispensary to another. A few years ago it used to be the boast of Fourth of July orators that there were no indigenous paupers in this country; but all this is changed, and there is unquestionally a large amount of indigenous pauperism here now.

THE PRESIDENT thought that this disease could never be eradicated as long as an institution in which an outbreak of it occurred remained in the same spot and the children remained in it. All these institutions are, no doubt, designed and expected to do good, but in reality they accomplish much harm. Outbreaks of ophthalmia are liable to occur, notwithstanding all the means adopted to prevent them, just as scarlet fever or measles is liable to break out among the children in them; and these diseases are often of a very malignant turn under the circumstances. Measles, as it generally appears in the community, is a mild disease; but in public institutions it is often very fatal. He believed it would be very much better if children were left in the tenement houses than entrusted to the care of institutions. These institutions are always overcrowded, and whenever a disease like measles or whooping-cough breaks out among the inmates the results are apt to be very serious. Whooping-cough, like measles, is not, under ordinary circumstances, a very grave affection, but among children thus crowded together it often proves fatal; and when this is not the case is likely to be followed by disastrous consequences. Very frequently phthisis, for instance, is the result of whooping-cough or measles contracted in early life in these institutions.

If, therefore, the object contemplated by some of the speakers was simply to add another to our already numerous hospitals, he did not think much good would be accomplished by the present agitation. In such an institution for the treatment of contagious eye diseases he could not doubt that many cases which are mild when admitted would assume a severe type, and that the danger would be increased, instead of diminished, by placing children in it. The question must come up here, as it had already done all over Europe, whether these institutions for children ought to be multiplied at all; and for his part he felt convinced that it would be a benefit to the community if these public institutions were done away with altogether. If the same money now expended for the erection and maintenance of splendid buildings, and the same care now bestowed upon their management, were given to the farming out of the children, he believed that we would be much better off. There would be more children alive, and fewer blind ones than we have at present.

DR. N. T. MITTENDORF said that there are two points which the public do not understand. The first one is, the very contagious nature of the disease in question, and the second, the fact that when it once makes its appearance in an institution it cannot be eradicated. He agreed with the President as to the evils associated with public institutions. In the country branches of the Nursery and Child's Hospital, and of the New York Infant Asylum, the plan had been adopted of placing a few children in separate cottages, and the results had been much better than when a large number of them were crowded together. The best plan at present seems, therefore, to have a number of small buildings and to place as few children as possible in each one. When contagious ophthalmia breaks out in an institution he thought that the patients should be kept in it, but strictly isolated. It is inadvisable to send them to a general eye hospital, for the reason that the disease is likely to spread to other patients, and in an institution where delicate operations are constantly being performed this would be followed by the most serious consequences.

DR. AGNEW then presented

RESOLUTIONS

to the effect that it is necessary and expedient that steps should be taken to prevent the occurrence of contagious eye disease in the schools and asylums of this city, and that the Council of the New York Academy of Medicine should be requested to unite with the author of the paper, the State Board of Charities, the Board of Health, and the Society for the Prevention of Cruelty to Children, in adopting such action as would be most likely to secure this result.

DR. ROOSA seconded the resolutions, and in doing so

said he could take the opportunity of saying a word further in regard to the hospital plan, in favor of which he had spoken. It is necessary to take things as they are, and not as they might be under a Utopian order of affairs. In his opinion, the disease could be successfully stamped out, and his idea would be, not to make the proposed hospital a permanent institution, but simply to resort to it as a temporary expedient.

Dr. R. P. Lincoln then exhibited

A NEW ELASTIC LARYNGOSCOPE AND OTOSCOPE,

together with an electric mouth lamp, lantern, and illuminator for the urethra and other cavities, invented by E. T. Starr, of Philadelphia, and also a convenient primary and storage battery.

CORRESPONDENCE.

A VISIT TO PROF. PASTEUR'S LABORATORY.

My visit to Pasteur's laboratory was made on the morning of May 12th, and the same evening I took the express train for Rome, to be in time for the International Sanitary Conference, which, according to the invitation first issued by the Italian Government, was to be on the 15th, but which was subsequently postponed to the 20th.

At the request of Dr. Koch, the delegate from Germany, I was invited last evening to meet the delegates from Germany at the house of Dr. Moleschott, one of the delegates from Italy, for an informal talk with reference to the questions which are to be submitted for the consideration of the Sanitary Conference. Dr. Koch expressed his views very freely, and it is evident that he has very positive convictions with reference to his "comma-bacillus" and to the proper measures to be taken to restrict the spread of cholera. It would be premature, however, to state these views at the present time.

While in Paris, armed with a letter of introduction from Miguel to Dr. Roux, one of Pasteur's most able assistants, I made my way to the laboratory, which is quite near the Pantheon—45 *Rue d' Ulm*.

Dr. Roux hastened to introduce me to Pasteur, who kindly conducted me through the laboratory and the adjacent buildings in which the experimental and *commercial* work connected with, or resulting from, his biological investigations is conducted. Dr. Roux, himself, seemed to be chiefly occupied in the microscopical part of the work, and in cultivating various pathogenic bacteria. He is entirely familiar with Koch's method of cultivation upon a solid medium, and showed me pure cultures of the microbe of *rouget*, or swine plague, upon the surface of agar-agar gelatine. While appreciating the value of this method, it is not considered by Pasteur and his assistants as a substitute for the older method of cultivation in fluid media, which has so long been practised in this laboratory, but simply as an additional resource, which is especially useful for certain purposes.

I had brought with me from home a pure culture of the micrococcus which Dr. Salmon has described as the cause of swine-plague as it exists in the United States, and was curious to know whether it was identical with the microbe which Pasteur has under cultivation, and which he has proved to be constantly present in the blood of swine attacked with that form of disease known in France as *rouget*, and to reproduce the disease when inoculated, in pure cultures, into healthy animals. This disease has been supposed to be identical with "swine-plague" or "hog-cholera" as it exists in the United States, and if so, it must be admitted that two different organisms can give rise to the same symptoms, or that one of the investigators named has failed to obtain the veritable germ of this disease, for Pasteur's microbe does not correspond at all with that of Salmon, which is a micrococcus, while Pasteur's is, in fact, an extremely minute bacillus. It will be remembered that Klein, in an elaborate memoir, published some years since, described quite a different organism from either of these, viz., a large bacillus with spores.

The minute bacillus which Pasteur finds to be the cause of *rouget* resembles, as stated to me last evening in conversation, by Dr. Koch himself, the minutest bacillus which produces that form of septicæmia in the mouse, which the German investigator named has so well studed. Dr. Koch admits that this bacilli is the veritable cause of the form of swine-plague which Pasteur has studied, but says that he is familiar with at least two different organisms which bear an etiological relation to other forms of swine-plague which prevail in certain parts of Germany. It seems probable, therefore, that the disease studied by Pasteur is absolutely identical with that which Salmon has had under observation for several years and which he finds to be due to a micrococcus. I have myself obtained a pure culture of the micrococcus described by Salmon, from the blood of a pig suffering from "hog cholera," which was killed for the purpose, and collected with precautions which made it certain that the micrococcus which multiplied abundantly in my culture-fluids came from the blood of the animal, and not from any accidental source.

Pasteur has not only demonstrated the etiological relation of his microbe to the disease *rouget*, but has succeeded in producing an attenuated virus which is now offered by sale by an agent whose place of business is in the immediate vicinity, and who obtains his stock in trade from the laboratory of the famous chemist. The assortment of "attenuated virus" now offered for sale at this establishment is limited to three diseases, anthrax, fowl cholera, and swine-plague (*rouget*).

The price of the anthrax vaccine, sent free in tubes, stated in a circular handed to me by the agent, is as follows:

Tube for 25 oxen or 50 sheep, first vaccine, 2½ francs; second vaccine, 2½ francs; total 5 francs, or $1.

The demand for this vaccine is constantly increasing, and, according to Pasteur, the mortality from anthrax in centre sections has been reduced from ten to twenty per cent. to less than one per thousand. The number of sheep vaccinated during the year 1884, in France alone, was 316,553; the number of cattle 33,906. During the month of April of the present year the orders received have been for a quantity sufficient to vaccinate 108,448 sheep. In that part of the laboratory devoted to the manufacture of vaccine I found two boys engaged in filling little tubes with the *premièr vaccin* and the *deuxième vaccin of charbon*, and in the warm chamber adjoining were numerous flasks containing cultures of the "attenuated" anthrax bacillus, which in due time would be distributed among the farmers of France and

other portions of Europe in which protective inoculations are how being practised.

Pasteur is still engaged in his studies relating to hydrophobia. His experimental inoculations are made upon the extended scale so desirable in researches of this nature, and which the liberal policy of the French government enables him to follow. His arrangements for keeping animals for experimental purposes are admirable, and he showed me with pride the well-made iron cases for dogs, the patches for rabbits, and the yards for fowls, all kept in perfect order and well stocked with animals. Having succeeded in transmitting hydrophobia by inoculations upon the surface of the brain by trephining with virus from the nervous centres of an animal recently dead of the disease, and in obtaining an attenuated virus which produces a non-fatal form of the disease, by which the animal is protected from subsequent attacks, Pasteur's next object is to ascertain whether protective inoculation may be successfully practised after an animal has been bitten by a rabid dog. His experiments lead him to believe that this is practicable, and the test is being made at the present time. The curious thing about these experiments relating to hydrophobia is, that while the nervous tissue has been proved to contain the virus, which by inoculation gives rise to the disease, the exact nature of this virus has not been determined. No microbe has yet been discovered in the virulent material by means of the microscope, and all attempts to obtain cultures of the germ, which Pasteur assumes must be present in this material, have thus far failed. In reply to a question, Pasteur informed me that microscopically he had not been able to recognize any difference between healthy brain substance, for example, and that which, coming from an animal recently dead of hydrophobia, is capable of reproducing the disease.

It will be remembered that some time since an item passed the rounds of the newspapers and medical journals, to the effect that Pasteur was about to visit Brazil for the purpose of investigating yellow fever, and especially of verifying the reliability of the claims of Dr. Domingo Freire to have discovered the germ of this disease and a method of practising protective inoculations against it. I inquired whether there was any truth in this report, and was informed by M. Pasteur that he had not entertained the idea of undertaking such an investigation, although invited by the Emperor of Brazil to do so. He has very little confidence in the alleged discoveries of Dr. Freire, and stated that the Emperor of Brazil, himself, was very incredulous as to their scientific value. I may say that in a letter from Dr. Koch, which I received two or three months since, a similar want of confidence was expressed. My own views with reference to Dr. Freire's methods and reputed discoveries are in conformity with those of the high authorities above named, and have been on record for more than a year.

Pasteur is a vigorous and well-preserved man, notwithstanding his sixty years (?) and the attack of hemiplegia from which he suffered eighteen months since. There is still some paralysis of the muscles of the left leg, and he is obliged to go up and down stairs with caution, but did not show any indications of fatigue from the extended trip which we made together through the laboratory, and the yards in which his animals are kept, which are two or three squares distant from it.

Rome, May 20, 1885. G. M. S.

NEWS ITEMS.

The American Medical Association and the International Congress.—The London *Lancet* (May 30, 1885), in commenting on the recent action of the Association in reference to the organization of the Washington Session of the International Medical Congress, says: At its meeting, in 1884, the American Medical Association appointed a committee of seven gentlemen to present an invitation to the International Medical Congress at Copenhagen to hold its next meeting in Washington in 1887. As our readers are aware, this invitation was accepted; and the committee, desiring to advance all the arrangements for the meeting, and, believing itself to be empowered to do so, proceeded to nominate the chief officers and to conduct the preliminary negotiations. Unfortunately, it seems that in so doing they have excited certain local jealousies; and at the late meeting of the Association in New Orleans their action was discussed and condemned, and a resolution was passed electing a committee, consisting of the seven gentlemen previously appointed and thirty-eight others, "one from each State and territory," who should "proceed at once to review, alter, and amend the action of the present committee as it may deem best." From the reports of the discussion we gather that some members of the Association consider that the appointments to the Congress should be filled up on a geographical basis, each State being considered as a distinct entity to be represented. We trust, however, that the new committee will take a wider and more enlightened view than that, and will make the appointments solely in reference to the merits of the various nominees, and the degree to which they possess the confidence of the profession in the United States, as a whole, and in Europe. We may be permitted to assure our American brethren that visitors from Europe will in a large measure judge of the position and character of the profession in the States by the scientific eminence of those whom they choose as their prominent representatives. We trust that all difficulties such as we have hinted at will be wisely and amicably surmounted, and that the meeting of the Congress in Washington will be as signal in its success as a scientific gathering, and in its display of true cosmopolitan brotherliness, as any previous one.

Inoculation for Cholera.—The following is an abstract of a report made by a committee of the Madrid Academy of Medicine, consisting of Señor Carreras and four others, to the Academia de Medecina y Cirugía, of Barcelona, on this subject.

The report commences with a brief account of Dr. Ferrán's original memoir, in which he states his agreement with Koch's conclusions, and his belief in identity of the microörganism with which he worked and Koch's comma-bacillus. The investigation was conducted with the aid of Dr. Ferrán in the performance of the experiments, or of many of them, and with his full recognition.

The work of the Committee was arranged under the following heads:

1. The investigation of the *morphology* of the micro-organism, the manner of its cultivation, and the changes effected in it by various reagents.

2. The *pathogenic action* of the cultivated organism, especially before attenuation.

3. The *preventive action* of the cultivated organism when ejected after attenuation, both in quantity and quality.

1. *Morphology.*—A full account is given of the precautions taken to secure purity of the apparatus, of the air of the laboratory, etc., and then the mode of preparation of the tubes of sterilized gelatine, and of the flasks of sterilized broth, ready for the cultivation of the microbes, is described. These media were inoculated with (1) the microbe of Van Ermengen, procured from Brussels; (2) the microbe of Ferrán; and (3) the microbe of Finckler and Prior, as obtained from cases of sporadic (non-Asiatic) cholera. The results, summarized, are to the following effect: 1. The micro-organism of Finckler and Prior found in sporadic cholera is distinct from the comma-bacillus of Koch. 2. The organisms described by Koch, by Van Ermengen, and by Ferrán, are the same, and are found in Asiatic cholera. 3. The comma-bacillus (of Koch) represents only one stage of this organism. 4. It has been shown by Ferrán, and confirmed by the Committee, that this organism passes through the following stages: *a*, a spiral filament; *b*, production of spores in fins; *c*, separation of the spores; *d*, growth of the free spores; *e*, change of the spores into a mulberry-shaped mass (*cuerpo muriforme*); *f*, which becomes diffluent protoplasm; *g*, from which, by condensation, a very fine filament is again formed. 5. Bodies, other than this microörganism in its various stages, are also found in the cultivation-fluids. It having been stated by Ferrán that alkaloids which had a toxic action upon animal life generally, had no such action upon the microbe, the effect of the addition to the cultivation of several of these was tried, such as aconitine, morphine, codeine, camphor, digitaline, ergotine, eserine, strychnine, and several others. The result was to confirm the statement as to their inaction, save in the case of eserine, which appeared to favor the development of the spores. The Committee, however, do not enter into any explanation, or speculate further upon this exception. Following the example of Ferrán, in his memoir, the committee do not discuss the question of the classification of the microbe.

2. *Pathogenic Action.*—A. *Experiments on Animals.* These were exclusively performed upon guinea-pigs, by means of hypodermic injection. Von Ermengen's and Ferrán's cultivations were used indifferently, the results being the same in each case. As a preliminary precaution, some of the cultivation-fluid was sterilized by heat, filtered, and injected into a guinea-pig. There was no injury to health, nor were any new organisms found in the blood. The same and similar cultivations, unsterilized, were then injected in various doses (from one to eight cubic centimetres). The severity of the symptoms produced varied directly with the dose. These symptoms were, briefly, at first, discomfort and restlessness, with refusal of food; then rapidly increasing prostration, followed by seemingly painful convulsions, spasms similar to the actions of vomiting, marked cyanosis, terminating generally in death within a period of from six to thirty-six hours, the time varying with the dose. On post-mortem examination, the principal changes were found in the blood, and in the lymph exuding from the neighborhood of the hypodermic injection. The corpuscles were disintegrated or reduced in size, and numerous micrococci, spirilla, and commas were present. In no case was any indication present of septicæmia or pyæmia, nor of the presence of the *coccidia oviformis*. Injection of a very small quantity of the cultivation-fluid into the duodenum, as has been performed by Nicati and Rietsch, of Marseilles, and also by Von Ermengen, was tried with negative results; but, in these experiments, the animals had not been starved. B. *Experiments on Man.* The same cultivation-fluids were similarly injected hypodermically into eleven human beings (one of the first being a member of the Investigating Committee), for the purpose of studying the pathological results. These are described at length, but the chief points are these: Within a few hours, the site of injection (the back of the arm) became hot and swollen to a limited extent; this was followed by malaise, muscular fatigue, and a sense of exhaustion, nausea, and slight shiverings, followed by febrile action, and a temperature ranging from 100° F. to 101.5° F. The blood, examined during the febrile stage, showed changes similar to those observed in the guinea-pig, but less marked. In all the cases, vomiting and looseness of the bowels were produced, but the vomit and dejecta were not preserved for examination. The dose employed for human beings was half a cubic centimetre, as compared with six cubic centimetres in the case of guinea-pigs.

3. *Preventive Action.*—The general results obtained by Ferrán are stated by the Committee to be absolutely confirmed by them. With regard to the guinea-pigs, it was found that, if those which survived a first injection were afterwards reinoculated, even with doses invariably fatal if employed on the first occasion, *without exception*, no ill results followed beyond a very slight constitutional disturbance. Further, those persons who, having been once inoculated, submitted themselves to reinoculation, experienced only a slight local irritation upon the second occasion. There appears to have been four of these cases, the clinical details of which, together with those of the seven others who were inoculated once only, are given in an appendix to the report.

Lastly, it is mentioned that Dr. Ferrán himself, having suffered one morning with a looseness of the bowels, causing two unusual evacuations, found in the second true specimens of the comma-bacillus, which he used for a series of cultivations.

The report ends by saying that, in the opinion of the Committee, the identity of the microörganism of Ferrán with the comma-bacillus of Koch has been established, and that its pathogenic effects have been proved to be prevented by inoculation. Therefore, a means of averting cholera has been discovered.

The original report was illustrated by photographs, which are not reproduced in the printed copy.—*British Medical Journal*, May 30, 1885.

Society Meetings.—The New Hampshire State Medical Society holds its annual meeting on Wednesday and Thursday next, at Concord.

The American Neurological Association will hold its Eleventh Annual Meeting in the Hall of the Academy of Medicine, of New York, on the 17th, 18th, and 19th.

ORIGINAL ARTICLES.

AN EPIDEMIC OF TYPHOID FEVER AT PLYMOUTH, PA.

(*SECOND PAPER.*)

BY LEWIS H. TAYLOR, M.D.,
OF WILKESBARRE, PA.

FOLLOWING the writing of my first article on the subject of the Plymouth epidemic, on May 9, which was published in THE MEDICAL NEWS of May 16, Dr. J. L. Miner and myself continued the investigation of the subject thoroughly for several days, and these additional observations were embodied in a more extended essay which was read before the Luzerne County Medical Society, on May 21, and subsequently before the Pennsylvania State Medical Society at Scranton.

While finding many points of interest confirmative of the opinion expressed in my previous paper, I have found nothing which throws any doubt upon the conclusions reached at that time. It has seemed to me that an abstract of my completed paper, containing some additional facts and points of interest might be acceptable to readers of THE NEWS, especially since a few gentlemen of our profession have seemed to doubt the possibility of the epidemic arising from water polluted by the excreta of a single typhoid patient.

The first post-mortem examination was secured by Drs. Davis and Beckwith only after urgent solicitation, the people being singularly averse to any such examinations, notwithstanding that many cases had already died. This autopsy was conducted by Dr. E. O. Shakespeare, of Philadelphia, on May 10, in the presence of several physicians from Wilkesbarre and Plymouth. Two other examinations were made on the following day by Drs. Shakespeare and French, and in every case the characteristic lesion of Peyer's glands was found. If doubt as to the diagnosis lingered in the minds of any, it was finally dissipated when these autopsies showed the disease to be genuine typhoid fever.

Of the various causes suggested as productive of the epidemic, the filth theory soon fell to the ground, because,

1. Plymouth is not in worse sanitary condition than neighboring towns where the disease does not prevail.

2. Its sanitary condition was not worse at this particular time than on proceding years.

3. All parts of the town were affected, the clean as well as the filthy.

4. It is admitted by common consent that filth *per se* does not cause typhoid fever. The emanations therefrom may so prepare the system, or, figuratively speaking, so till the ground that when the proper seed is sown an abundant harvest may be the result.

Whether typhoid fever may be communicated directly through the air or not, is still a mooted question, but it is generally admitted that in a large majority of cases, at least, the poison is conveyed to the system by means of polluted food and drink taken directly into the stomach.

The inhabitants of Plymouth receive their drinking water either directly from private wells, or from hydrants under control of the Plymouth Water Company. Knowing the history of many epidemics of typhoid fever, and knowing the facility with which wells become contaminated from carelessly located privies, the thought of well-water contamination naturally presented itself to many. That this was not the case was clearly shown by some very interesting facts.

Near the extreme southern end of Plymouth, upon the banks of Coal Street Creek, a house was found in which hydrant water is used, and in this house two persons were sick with the disease, while in another, situated but sixty feet away and supplied with well water, all the inmates are and have been free from the disease. A little further to the north of these two houses there are found, on Temperance Hill, eleven families using well water, and no case of typhoid fever has yet appeared in any of these families.

On the upper side of Lee Street almost every family using hydrant water is affected, while those living on the lower side of the same street are all supplied with well water and none of them are sick. Upon Welsh Hill, a community of several hundred persons was found supplied exclusively with well water. There were upon the day of our investigation, but six persons sick on this hill, and these all were persons who had been working in Plymouth in the daytime and were accustomed, a part of the time, to drink water from the hydrants.

The same relative condition exists in other parts of the town, the investigation of numerous cases showing that persons who used well water in general and are suffering from the disease, are those who had been in the habit of drinking hydrant water while away from their homes, while those who use well water exclusively are not attacked. It is thus shown conclusively, we think, that well water as a factor in the causation of this epidemic must be excluded.

Inasmuch as the disease is found wherever hydrant water is used, and *only* there, the conclusion is irresistible that this was the chief and only cause of this most remarkable outbreak. The hydrants receive their supply from two sources. During the greater part of the year it is from a mountain stream of great purity, which is distributed through the various streets by pipes running from the lower or first of four successive reservoirs, formed by huge dams of

masonry across the stream. Occasionally, however, when the water in this stream is quite low, the pipes are supplied with water pumped directly into the mains from the Susquehanna River. This was the case from March 20th, at noon, to March 26th, in the evening, of the present year.

Here then are, apparently, two possible sources of contagion, and it is evident that the cause of the epidemic must be traced either to the water pumped from the Susquehanna, or to that supplied by the mountain stream.

Why not the river water? In considering this question we must not forget the exact time the river water was used, March 20th to March 26th, and the relation of this time to the outbreak of the epidemic. From replies to a circular sent to the physicians of Plymouth, I find that the outbreak occurred about April 10th to 12th, there being one case reported as early as April 9th. A large increase occurred after April 15th. The gentleman who saw his first case April 9th, saw but thirteen more in the next five days, while another who saw his first case April 14th, saw seventy-five new cases in the five succeeding days.

The length of the period of incubation in typhoid fever varies, but it is usually stated as being from ten to fourteen days. Dr. Stillé states fourteen days. Liebermeister says three weeks—*i. e.*, counting to the time the patient is thoroughly ill with the fever, though he says in many cases the period seems to be but seven days. Wilson, in his treatise on *Continued Fevers*, gives the average period as fourteen days, though he cites numerous cases to show that exceptionally it may be as short as five, three, or even two days, while very exceptionally it may be as long as four weeks. He mentions one particularly interesting epidemic in which a number of persons on a certain day visited a neighboring town, and while there drank from a well polluted with excreta from a typhoid fever patient. Of these, fourteen were attacked who drank from the same well at the same time, and their cases showed a range in the period of incubation from eight to eighteen days.

Dr. Thomas Watson cites the following interesting cases:

"In North Taunton, A. and B. lodged next door to a house in which typhoid fever existed. The two houses had a common privy. Both of these men took the disease, and becoming too ill to work, returned to their respective homes in the parish of Morchard, seven miles off. A. at once took to bed. Ten days after, his two children were laid up with the same disease, and had it severely. B., a single man, lodged with two aged persons. When at his worst a friend C., who called, was asked to assist in raising him in bed, and was overpowered by the smell. Ten days after, in another part of the city, C. was also down with the fever."

Trousseau cites cases to show that the period of incubation is eight days. All of the authorities that I have consulted admit that many cases, at least, may appear in ten days from the time of contagion, while others may require a much longer time.

But, suppose we admit from two to three weeks as a proper *average* period of incubation, instead of from ten to fourteen days, as is claimed by many, we should nevertheless, naturally expect *some* cases to arise in ten days from the time of infection. If then it be from drinking Susquehanna water, we should look for some cases of the fever as early as March 30, or ten days from the time the pumping of river water began; but no such cases appear, nor do they appear within ten days after the pumping ceased—*i.e.*, within ten days of March 26. Inasmuch as no outbreak occurred previous to April 10, we would infer that the poison was not taken previous to the last days of March or the first days of April; in other words, not until several days after the use of river water ceased.

Whether decomposing sewage in drinking water will produce typhoid fever without the dejecta of a typhoid patient being present is still an open question. Dr. Downs, reported in *The Lancet*, and quoted by Parkes, records six cases of typhoid as the result of the overflow of non-typhoid sewage into a well. On the other hand cases recorded by Allbut and Wohlrab, show that contaminated water may be used for a long time without causing typhoid fever, then persons affected with the fever enter the place, and their dejecta pass into the water causing an outbreak of typhoid fever.

In an admirable article read by Dr. E. G. Janeway, before the New York Medical Society, February 18, 1884, and in the discussion which followed, the prevalence of opinion seems to be that the disease does not arise *de novo*, but is spread only by contamination from previous cases of typhoid.

An extremely strong case is quoted by Ballard:

"Very polluted water had been used for years by the inhabitants of Muncy without causing fever, when a person with typhoid came from a distance to the village, and the excreta from this person were washed into the stream supplying the village. Between June and October, 1872, no less than 76 cases occurred out of a population of 832 persons. All of those attacked drank the stream water habitually or occasionally. All who used rain or well-water escaped except one family, who used the water of a well only four or five yards from the brook. The case seems quite clear: first, that the water caused the disease; and, secondly, that though the water polluted with excreta had been used for years, no enteric fever appeared until an imported case introduced the virus."

He further says:

"Positive evidence of this kind seems conclusive, and we may now safely assume that the presence of typhoid evacuations in the water is necessary. Common fecal matter may produce diarrhœa, which may be febrile, but for the production of enteric fever the specific agent must be present."

If this argument be true, then river water polluted with the sewage of a large city free from typhoid is less dangerous than a smaller amount of water containing the specific poison.

All of us, no doubt, have seen cases of this disease which defied all our efforts at discovering their source. I call to mind one special case under my care last autumn. The patient was a lad of fourteen years, in a house remarkable for neatness and cleanliness, nor did the most digilent search reveal any difficulty whatever with the water-pipes or the sewer discharges. No other member of the family, consisting of seven, was afflicted.

The sewers of Troy all empty into the Hudson, and Albany, which is six miles lower down, derives its water from the river after this sewage has been poured into it. The borough of Nanticoke, situated a few miles below Plymouth, receives all of its hydrant water from the Susquehanna, but at no time has it suffered from a serious outbreak of typhoid fever, notwithstanding the water there used must be contaminated by the sewage from populous towns and cities above. In fact, it is proven that Nanticoke had fewer cases of typhoid during March and April than in any other months of the past year. It is well known, however, that typhoid fever is frequently found in Wilkesbarre, three miles above Plymouth, and might not the Susquehanna become polluted with the specific poison at this place?

A careful report from thirty-one physicians in Wilkesbarre (I failed in my efforts to get reports from two of our physicians), shows that they had under their care between January 1 and April 1 of the present year, twenty six typhoid fever cases. Of all this number only two were in houses connected with the sewers, and thus in all this time there were the excreta of only two typhoid patients poured into the Susquehanna at Wilkesbarre, and in both of these cases disinfectants were used to neutralize the poison.

The flow of the Susquehanna at Wilkesbarre at low water mark, as taken from the Government survey, is 930 cubic feet per second, showing that the dilution of this poison would be, at least, at the rate of 602,604,000 gallons per day, and the danger from this source would thus be almost infinitesimal.

But there might be pollution nearer to Plymouth than the cases mentioned above. Dr. C. W. Spand, a medical friend, in answer to certain inquiries, gives me the following:

"In the summer of 1884, typhoid fever broke out in Whitewash Hollow, a small valley that runs from No. 2 to No. 4 breakers and up to the Boston slope just below Larksville. In nearly every house from No. 2 to No. 4 breaker, one or more members were down with it up to March of this year. The snow melted in that locality during the latter week of March very rapidly, filled the creek with running water, and as the people were indifferent as to what was done with the excreta, it was carried down said stream into the river below Boston Hill, just above Plymouth, and in my opinion the fever sprang from the germs that were carried down into the river from Whitewash Hollow."

Now, at first blush, this might seem a point for consideration; but that it could have had no effect whatever in causing this epidemic, may be shown from the following statements:

First, this stream joins the Susquehanna at the upper end of Plymouth, and any one taking the trouble to examine it will find that it remains a distinct stream flowing close to the right bank of the river for a long distance, and does not readily mingle with the general current. The Plymouth Water Company, however, took their supply two hundred and fifty feet from shore.

Second, there is but very little sewage carried by this stream at any time, as but few houses are situated directly upon its banks.

Third, whatever this stream might contain, it did not, by any possible chance, empty any surface water into the Susquehanna in March previous to the 26th, much less previous to the 20th, for the temperature during the greater part of March was far below the freezing point, thus preventing any thaw of any consequence at this time. As is well known, March was the coldest month of the past winter. On March 20th, the maximum temperature was 20° F.; March 21st, 20.1°; March 22d, 20.1°; March 23d, 23.2°; March 24th, 35.6°; March 25th, 34.8°; March 26th, 46.5°. So it will be seen that there was no day previous to March 26th, that it would be possible for any considerable thaw to take place.[1] If further confirmation of the opinion already expressed, that the river water had nothing whatever to do in causing this epidemic, be needed, it may be found in the statement of a few additional facts and in the history of some very interesting cases.

It must be borne in mind that the river water used between March 20th and 26th, was not pumped into the reservoir and thence distributed to the town, but was pumped directly into the pipes as already stated, and chiefly devoted to supplying the mines and that part of the town bordering on the river, *i. e.*, Main Street, and this part was thus supplied during the whole of the time of pumping; while the valves were all closed in the pipes leading from the Main Street pipe to the upper or back part of the town, and this latter part was thus supplied chiefly with water from the reservoirs. But should work at the mines be stopped during any of this time, it would be possible for some of the water pumped from the river to force its way into the bottom of the first reservoir and thus be distributed throughout the town, and it is without doubt true that the back streets were thus supplied with some river water for, at least, two days of this time. It is a notable fact, however, that typhoid fever is not more prevalent, but really less so, in the part supplied with river water during the whole of this time, than in the parts supplied chiefly with mountain water. But all river water in use, I am informed by the Superintendent, would pass out of the pipes in six hours after the pumping ceased, and it thus could not have been used later than March 27th. If, then, the pumping of river water ceased on the evening of March 26th, persons moving to Plymouth after the following day could not possibly have drunk such water from the hydrants.

The following cases seem to bear directly upon this point:

CASE I.—Mrs. J. K. came to Plymouth from Afton, Wisconsin, and arrived March 30th, four days after river water was in use. She was taken sick April 18th, though she had been feeling unwell for several days previously. She is now, May 21st, convalescent from a severe attack of typhoid fever.

CASE II.—Mr. M. F., patient of Dr. C. H. Wilson, had been working in Plymouth during the winter, but on April 1st moved his family from Ashley to Plymouth. Himself and two others of his

[1] For the above record of temperature I am indebted to the Rev. Dr. Hodge, of Wilkesbarre, who has charge of the Government meteorological observations at this place.

family, who had not been in Plymouth previous to April 1st, are now ill with the fever.

CASE III.—Miss McG., patient of Dr. F. L. McKee, moved to Plymouth from Sugar Notch, April 1st, and was taken sick with typhoid fever April 15th, though she had been complaining two or three days previously.

CASE IV.—Miss H., patient of Dr. Guthrie, went to Plymouth from Wilkesbarre on March 30th, and remained thirteen days. She returned to Wilkesbarre on April 12th feeling unwell, and was seriously ill with the disease by April 15th.

CASE V.—Miss A. came from New Jersey to Wilkesbarre in March. She visited Plymouth first on March 25th, remaining only from 10 A. M. to 3 P. M. She went again on March 27th, remaining about ten days; was taken sick on April 18th, and has been seriously ill ever since.

CASE VI.—Mrs. C , patient of Dr. Guthrie, visited Plymouth first from March 21st to March 24th. Again on March 31st, and April 1st. Again from April 17th to 21st. She was taken sick on April 22d. If she became infected between March 21st and 24th, the period of incubation would be one month, which all admit is highly improbable. If, however, she drank contaminated water on April 1st, the period of incubation in her case would be twenty-one days, or the time claimed by Liebermeister as necessary.

CASE VII.—R. B., patient of Dr. Spencer, of Dallas, visited Plymouth early in April about the 5th. He drank water at a barber shop, and also at a livery stable, was taken sick April 15th, and by April 18th had well-developed typhoid fever.

CASE VIII.—C. C., patient of Dr. Spencer, visited Plymouth about the last day of March to attend a funeral. He drank considerable water at a hotel, as he was very thirsty. He was ill with typhoid fever, and called the doctor on April 22, though he had been ailing nearly a week.

CASE IX.—Mr. S. moved his family to Plymouth on March 30th, though he had previously been working there. He was taken ill about April 13th, and died on April 30th. His wife was taken ill on April 18th, and died on May 20th. Frank S. visited this family about April 9th, and later. He, too, was taken sick and died early in May.

CASE X.—Miss L. went to Plymouth with Case II., to assist the family for a few days. She remained a week or ten days, returned to her home in Ashley, and was soon after seriously ill with typhoid fever.

CASE XI.—Dr W., resident physician at German Hospital, in Philadelphia, visited Plymouth on April 1st, and drank of the water until April 4th, when he returned to Philadelphia. In a few days after his return he began to feel languid, and this feeling progressed gradually. On April 16th, he had a chill, and also on the two following days. April 18th, he took to bed and was seriously ill with typhoid fever for some weeks. The temperature on the 10th day was 105°, and continued from 104° to 105° for several days.

These all drank water in Plymouth, but did not drink river water. No doubt other similar cases exist, but they were not brought to the attention of the writer of this article.

Is there anything further needed to convince the most sceptical that the Plymouth epidemic was not caused by using river water? If so, here it is. In pursuing our investigation,, we found at Ridge Row, a community of twenty families living in ten double houses, and at Broadway, a community of forty families in twenty double houses. These two places are in the upper end of Plymouth, and are entirely free from the fever. But all through the fall and winter, and even through the fatal month of March, they were supplied with water by the Delaware and Hudson Company, pumped directly from the deadly (?) Susquehanna, sixty feet from shore, and half a mile nearer to the Wilkesbarre sewers, than the point at which the pipes of the Plymouth Water Company enter the river. It is proper to state that at Broadway there are two wells, and at Ridge Row one spring and one well, and no doubt many, especially at Ridge Row, used spring water, but the majority of these sixty families used river water exclusively, and continued to do so until April, and, as above stated, no case of the fever has appeared among them.

The people of Plymouth have at various times used river water in previous years without causing outbreaks of typhoid fever. The pumps were used continuously in 1882, from October 27th to January 1st, a period of sixty-five days. Again from September 30, 1883, to February 1, 1884, 124 days, and again last autumn from July 30th to November 24th, a period of 118 days.

No such outbreak followed these pumpings. Can we be made to believe that the river water, which was comparatively innocuous to the people of Plymouth at one time for a period of 110 days, when typhoid fever was rife in the city just above, should in six days of the following March, cause an epidemic affecting more than one thousand people, and that at a time when it is proven that it was not contaminated by typhoid fever?

There remains then but one possible cause for this most serious and deplorable epidemic, and that is, contamination of the mountain stream supplying the Water Company's reservoirs.

The history of the case of typhoid fever upon the banks of this stream has already been given in my first paper and need not be dwelt upon in detail here. The dejecta passed at night were thrown out on the banks of the stream, while that passed during the day were emptied into a privy a little further back, the contents of which lie upon the surface of the ground. These dejecta were thrown out from time to time until the accumulation no doubt equalled the daily dejecta from many such patients. They remained innocuous upon the snow and frozen ground until some time between March 25 and April 1, when they were washed into the stream and into the third reservoir.

It should be remembered, that the maximum temperature on March 26 was 46.5°; March 27, 56°; March 28, 48°; March 29, 37°, increasing rapidly until April 4, when a temperature of 70° was reached. Also, that this house does not stand in a ravine or in a protected spot, but in the midst of an open clearing, which clearing would naturally feel the effects of the sun's rays, and part with its snow

and accumulated filth sooner than the more protected regions which also drain into this stream.

March 26, with a maximum temperature of 46.5°, is the first day upon which any considerable thaw could occur. Upon this evening the Superintendent of the Water Company visited the reservoirs to ascertain whether it would be allowable to discontinue the pumping of river water. He found the first and second reservoirs almost empty, while the third was filling rapidly, the short pipe which allows the water to discharge from the bottom of the third into the stream leading into the second reservoir being tightly frozen. He caused a fire to be built to melt the ice in this pipe and then stopped the river pumps. This water with the accumulated typhoid fever poison was discharged from the bottom of the third reservoir, ran down to the second, on to the first, and was thence distributed to the town, in all probability, between the 28th of March and the 4th or 5th of April.

When might we then expect the first cases from this cause to appear? Regarding the period of incubation as fourteen days, we would look for the first case to appear from April 10 to 15, with possibly a few exceptional cases somewhat earlier, while the majority would come somewhat later.

We do not presume to say that all of this poison passed out of the third reservoir in five days. No doubt some of it lingered and was operative in diminished strength for some time later, and this but explains more fully the lateness with which some cases of the disease appeared.

It seems to me that the simple statement of these facts as I have given them, without any warping or twisting to suit preconceived theories or desirable conclusions, is sufficient to explain fully the cause of this sad scene of desolation, and it points unmistakably to the polluted mountain stream as the chief and only cause of the present epidemic of typhoid fever in Plymouth.

As previously stated, our first investigation was made on May 6th; we examined carefully the whole length of the stream to some distance beyond the fourth reservoir, and reached unhesitatingly the conclusions already expressed in this paper. A few days later the same ground was gone over by Drs. Shakespeare and French, of Philadelphia, and in a preliminary report to the Philadelphia County Medical Society, on May 13th, they confirm *in toto* the report mentioned in my first article. Among other remarks they gave the following:

"During the period of pumping from the Susquehanna the water in that river was lower than it had been at any time for years, and the surface was frozen tight. The city of Wilkesbarre, containing 30,000 inhabitants, delivers its sewage directly into the Susquehanna, the mouth of the lower sewer emptying only two miles above the Plymouth pumping station, while the current is very rapid between the two towns. The water is further contaminated by refuse water from five or six mines, as well as by the garbage from the abattoirs at Wilkesbarre. Notwithstanding this unusually filthy condition of the Susquehanna water, it is beyond question entirely innocent of causing the epidemic, for the following and other reasons."

They then go on to state certain facts already presented in this paper, and conclude as follows: "No other conclusion can be arrived at than that this infective poison existed in the mountain water, and originated from the one case of fever in the house on the side of the stream."[1]

From some unaccountable reason this plain statement was misquoted in the morning papers, and it was made to appear that the gentlemen above mentioned had expressed themselves in favor of the river water theory. This called forth a denial from these gentlemen, and at the meeting of the Citizens' Committee, in Philadelphia, the next day, the following statement from Drs. French and Shakespeare was read:

"We observe that, in some reports of our opinion of the origin and spread of the epidemic at Plymouth, we are quoted as expressing the belief that the Susquehanna water, containing the sewage of Wilkesbarre, caused the disease. This is quite contradicted by the facts which we were able to collect, and is just the opposite to our belief, based upon our investigations. We are of the opinion that the Susquehanna water had nothing to do with the outbreak of the epidemic, but that, on the contrary, those portions of the town which were less supplied with mountain water, and more supplied with Susquehanna water, have suffered the least."

A few days later a third thorough investigation was made by Drs. Taylor and Edson, of the New York Health Department, and Chemist Martin of the Columbia School of Mines.

Their report[2] has not yet been published, but they expressed themselves as decidedly of the opinion that the epidemic was due to the polluted mountain water. They found one or two cases of the disease in families supplied with milk from neighboring families where the disease existed, but as these had also drunk the hydrant water it was impossible to tell from which source the infection came.

A fourth thorough investigation was made by a Committee from the Buffalo Board of Health, Dr. A. H. Briggs being Chairman. After a statement of the history of the epidemic, etc., they conclude as follows:

"From the above facts we drew the conclusion that this epidemic owes its origin to the solitary case in the Davis family. The excrement thrown on the slope un-

[1] Since writing the above, the report of Drs. Shakespeare and French has been published in full in pamphlet form, with an appendix containing valuable sanitary rules for the people, in relation to stamping out the epidemic.

[2] An abstract of the New York Committee's report appeared in the *New York Tribune* on May 28. They state the same facts as given in this paper, and reach the same conclusions. They also say: "The Water Company has four storage reservoirs in a ravine extending to the top of the Shawnee Mountain, overlooking the town. These reservoirs have a capacity of about 10,000,000 gallons. They are fed by mountain springs and an artesian well, 1950 feet in depth. In the extreme cold weather of last winter the people let the water run day and night to keep the pipes from freezing. All the water stored in the four reservoirs was exhausted on March 20, the springs in the mountain having dried up. For a week water was pumped from the river, but the people disliked to use it, believing that the river was contaminated by sewage from Wilkesbarre, three miles above. Water from the mountain reservoirs was used again on March 27. It is now believed that if the river water had been used a few weeks longer, the great epidemic would not have occurred."

doubtedly contaminated the water of the entire brook. It is a notable fact that those using water from springs and from the Susquehanna River have been largely exempt from the scourge."

In fact, the same conclusions have been reached by everybody who has made any investigation of the matter. The opposition has come from persons who have not visited the ground, but who have written from the privacy of their offices upon the supposed possible origin of epidemics. Now, it is not the province of this report to discuss the cause of possible epidemics, or of epidemics of typhoid fever in general, but to state as clearly as may be the cause of the present epidemic in Plymouth. It is true that polluted well water may cause sickness, but it did not cause this epidemic. It is true that polluted milk may cause sickness, but it did not cause this epidemic. It is true that polluted river water may cause sickness, but it did not cause this epidemic.

I trust I may not be misunderstood in this matter, nor be quoted in any way as favoring the use of river water for drinking purposes, especially of river water contaminated by sewage. The subject is not a pleasant one to contemplate, and it should ever be condemned by us, and ever severely condemned. The constantly increasing amount of sewage poured into the Susquehanna at Wilkesbarre and neighboring towns will ever render this a dangerous source of supply to the people of Plymouth. But even river water contaminated with sewage without the specific typhoid fever poison, is not so dangerous as reservoir water contaminated by such specific poison. I would say further, that the river water used in Plymouth from March 20 to March 26, in my opinion, had nothing whatever to do with the causation of the present epidemic, except, possibly, indirectly by rendering the system more susceptible to the poison that subsequently followed. Had river water alone been used at this time there would possibly have been the usual number of isolated cases that any year may show in Plymouth, but there would have been no serious epidemic had it not been for the excreta thus carelessly thrown out upon the ground, and later washed into the stream.

In considering the possibility of one patient poisoning a thousand in Plymouth, we must bear in mind all the attending circumstances.

1. The accumulation of weeks, equalling the dejecta of many patients.

2. The nearness to the stream.

3. The sudden thaw pouring the surface water into the empty reservoir.

4. The concentration of the poison in a small amount of water.

5. The short distance to the town, and finally the possible previous preparation of the soil for the reception of this seed, which sprang at once into vigorous growth, and ripened for an abundant harvest of death.

The condition of affairs in Plymouth, but a short time back, was sad in all its features, but it nevertheless contained many points of interest to medical men. We had in this epidemic all the features presented that were necessary to a complete study of typhoid fever. Here are the regular typical cases, together with the many varieties, or seemingly exceptional cases. Here are the three classes so graphically described in Reynolds's *System of Medicine*.

The *first class*, with its insidious, gradual approach, moist, tolerably clean tongue, cool, pallid skin without eruption, and later presenting the more serious typhoid symptoms, ending too often, when least expected, in death.

The *second class*, with its more sudden approach, moist, but furred tongue, high fever, etc.

The *third class*, with dry, glazed tongue, intense heat of head, acute delirium, frequent vomiting and purging, painful abdomen, etc. All these have been present.

This epidemic, as already mentioned, has been widespread, and, from careful inquiry, I find no occasion to change the statement made in THE MEDICAL NEWS, under date of May 9th, that in Plymouth and its immediate outskirts there have been rather more than one thousand cases. The death-roll thus far has reached nearly one hundred. It must not be supposed that everybody sick in Plymouth is down with typhoid fever. There are, undoubtedly, many ill with other diseases, and, undoubtedly, many ill with fever not distinctly typhoid. Many new cases will probably arise from secondary infection, as gross carelessness has existed among the people in regard to disposing of the dejecta, and even physicians themselves have not exercised that care which the urgency of the case demanded. Especially are the wells upon the hillsides liable to contamination from carelessly disposed excreta.

It is one of the most remarkable epidemics in the history of typhoid fever, and teaches us some important lessons at fearful cost. These have already been sketched in my previous paper, and need not be rehearsed in this.

Another lesson taught by this history comes more nearly home to us all. The water companies throughout our land should be taught that they must furnish us the water, for which we pay, from the best sources that the country affords. Not only should they avoid the use of river water contaminated by sewage, but they should be compelled to remove from the banks of their streams and reservoirs not only all probable, but all possible, sources of pollution.

Shall we, too, wait for a similar sad experience brought to our own doors to teach us the lesson; or shall we not rather, by being forewarned, be, also, forearmed?

In gathering material for this essay I have been especially indebted to my friend, Dr. J. L. Miner, who has been my associate throughout the investigation. Also to Mr. O. M. Lance, Superintendent of the Plymouth Water Company; to Mr. Delbert Barney, student of medicine, and to the physicians of Plymouth and elsewhere who have so kindly answered my inquiries and assisted in gathering facts relative to the epidemic.

WILKES-BARRE, June 13, 1885.

DISINFECTANTS.

PRELIMINARY REPORTS OF THE COMMITTEE ON DISINFECTANTS OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

XII.

EXPERIMENTS WITH SULPHUROUS ACID GAS.

BY J. H. RAYMOND, M.D.,
OF BROOKLYN, N. Y.

THE following experiment was made in Brooklyn, at the request of the Commissioner of Health, with the object of determining the germicide value of sulphurous acid gas, produced by the burning of sulphur in the manner recommended by boards of health generally. Dr. George M. Sternberg, U.S.A., kindly proffered his services, and conducted the inoculation with material prepared by him at the John Hopkins University. The methods employed were the same as he has employed in similar experiments, and which he has repeatedly described. Dr. W. E. Griffiths, of Brooklyn, and the reporter, assisted in the experiment.

The room selected was on the second floor of a private residence, and connected with it was a small clothes closet. Two doors opened out from it, one into the hall; the other into an adjoining room. The experimental room had a single window. All cracks and crevices, by which fumes could escape, were carefully closed by cotton. In the room were the following articles: A carpet on the floor; a wooden bedstead with springs, on which were two mattresses in close contact; a chair, over which was spread a bed-quilt; a sofa; an empty stand of drawers, on the top of which was placed a large book; the closet was empty. The room and closet together contained, as nearly as could be ascertained, 1850 cubic feet of air space, and were in free communication.

On the 18th of April, pieces of blanket, about four inches square, soaked with blood from a rabbit, killed while affected with septicæmia, and other similar pieces soaked with blood from another rabbit affected with anthrax, were exposed in different parts of the room, as hereafter described. Some of these pieces were folded double, with the blood inside the fold; others were left unfolded.

Piece No. 1, soaked with septicæmic blood, unfolded, was placed on the floor of the closet.

No. 2, septicæmic blood, unfolded, was pinned to the upper part of the window frame, eight feet from the floor.

No. 3, septicæmic blood, folded, was attached to frame of closet door, seven feet from floor.

No. 4, septicæmic blood, unfolded, was placed between the mattresses, which were in close contact.

No. 5, septicæmic blood, unfolded, pinned to the underside of the bed-quilt, which was spread over the chair.

No. 6, anthrax blood, unfolded, placed on the closet floor.

No. 7, anthrax blood, folded, attached to frame of closet floor, seven feet from the floor.

No. 8, anthrax blood, unfolded, placed between the lower mattress and springs.

No. 9, anthrax blood, unfolded, attached to frame of the door leading into the adjoining room, six feet from the floor.

No. 10, anthrax blood, unfolded, placed between the mattresses.

No. 11, anthrax blood, unfolded, placed under the carpet, eight inches from the edge; the carpet again laid down, but not tacked.

No. 12, anthrax blood, unfolded, placed in the middle of the book, between the leaves, the book being closed.

No. 13 was a piece of blanket soaked with anthrax blood, which was not exposed in the room, but was prepared for purposes of comparison.

No. 14 was another piece soaked with septicæmic blood, and also not exposed.

Two half-quills of fresh bovine vaccine virus were placed on the stand of drawers, and one half-quill on the top of the frame of the door leading into the adjoining room. The corresponding halves similarly marked were placed in a tight preserve-jar, which was at once put in a refrigerator in another part of the house.

In the middle of the room was placed a large coal-scuttle, nearly filled with wet ashes, and in this an iron pot, holding four pounds of broken sulphur and two pounds of flowers of sulphur; this was then well moistened with alcohol, and a lighted match applied. When the sulphur was well burning the door of the room was closed, which was at 1.25 P.M. At 11.25 P.M. the hall door and window were opened for one hour, and the room thoroughly aired. At the end of this time the odor of sulphur was distinctly perceived, but there was no difficulty in breathing in any part of the room. The sulphur in the pot was completely consumed. At the end of the hour the door and window were again closed, and kept so until 10 A.M. the following day, the 19th. When the door was again opened the air of the room was so impregnated with sulphur that respiration was impossible, and an airing of ten minutes was necessary before it could be entered.

At the end of this time the pieces of blanket were collected, and at 12 M. healthy rabbits were inoculated by Dr. Sternberg with the blood soaked out from the pieces of blanket in sterilized beef-tea. The rabbits, as fast as inoculated, were put in a cage, each in a separate compartment, and given the same numbers as those of the pieces of blanket with the blood of which they had been inoculated. The inoculation was completed within an hour.

The vaccine which had been exposed to the fumes was put into the jar containing the non-fumigated virus, and the jar replaced in the refrigerator, where it was kept until the material was used in vaccination.

RESULTS.

Rabbit No. 3, inoculated with septicæmic blood from folded piece which had been fumigated, was found dead in the cage at 7 A.M., April 21st, forty-three hours after inoculation. He was apparently well the night before; the exact time of death is not known.

Rabbit No. 14, inoculated with non-fumigated septicæmic blood, died at 2 P.M., April 21st, fifty hours after inoculation.

Rabbit No. 7, inoculated with anthrax blood from folded piece which had been fumigated, was found dead at 7 A.M., April 23d, ninety-one hours after inoculation, being apparently well the night before.

April 20th, a child, 7 months old, previously unvaccinated, was vaccinated by Dr. Griffiths in two places upon the same arm, one with virus from the fumigated half, and the other with virus from the non-fumigated half of the same quill. The latter was successful; the former failed utterly.

The same was practised upon a young lady, 20 years of age, showing no vaccine cicatrix, and stating that she had never been vaccinated, with a fumigated and a non-fumigated half of a quill with the same result, namely, failure from the fumigated and success from the non-fumigated slip.

A calf was vaccinated in the same way on the inner sides of the two thighs with the same result.

Interpretation of Results.—There seems to be no doubt that sulphurous acid gas, produced from burning sulphur, destroys the vitality of vaccine virus. This has been hitherto demonstrated by Dr. Sternberg, and this experiment confirms it.

It will be noticed that the rabbit inoculated with non-fumigated septicæmic blood, No. 14, died, as did also No. 3, the one inoculated from the folded piece of blanket, while all the other rabbits inoculated with septicæmic blood, were apparently unaffected and survived—even No. 4, which was inoculated with blood from the blanket placed between the two mattresses in close contact. I cannot understand how the gas could more readily have found its way between the mattresses, and destroyed the germs there placed, than between the folds of a small piece of blanket hung up in the room.

As the rabbit inoculated with non-fumigated anthrax was apparently unaffected, while one inoculated with fumigated anthrax died, I think no conclusions of any value can be drawn from this part of the experiment.

Finally, after a careful review of the experiment and its results, I am led to regard the vaccine experiment as a success, and confirming what has already been well settled,—the experiment with septicæmia as unsatisfactory, and the one with anthrax as a failure.

As a matter of precaution, the rabbits were kept for one month after inoculation, at the end of which time all were well, save the three already referred to.

TRANSPLANTATION OF THE CONJUNCTIVA OF THE RABBIT TO THE HUMAN EYE,

IN A CASE OF SYMBLEPHARON, ASSOCIATED WITH CONVERGENT SQUINT, SUCCESSFUL; SUBSEQUENT CORRECTION OF SQUINT BY TENOTOMY.[1]

By FRANCIS L. PARKER, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL LECTURER ON DISEASES OF THE EYE AND EAR, IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, CHARLESTON, S. C.

Case.—July 2, 1883. Elias E., of Summerville, S. C., aged eight years, was injured by an explosion of gunpowder in the face and left eye on the 19th of February, four months ago. He suffered intensely for three weeks, and was confined to his room. When convalescent, the face had peeled, the outer half of the left eye was closed by cicatricial tissue uniting a part of the upper and lower lids to the globe, the inner half could be opened by forcing open the lids with the fingers. The right eye had escaped injury He was subsequently operated upon by Dr. ——, on the 15th of June, without relief, as so often happens in such cases.

On July 22d, the case was brought to me. There was a large symblepharon uniting the outer half of the upper and lower lids, and the outer canthus of the eyeball, and extending by a broad pterygium band over two-thirds of the outer half of the cornea. The surface of the symblepharon was injected and covered with numerous granulations, some of them extending over the surface of the cornea. The eye was about half open. There was also convergent strabismus, which remained stationary on closing the other eye. Vision was limited to counting fingers, owing to the partial occlusion of the pupil, and opacity of the cornea. The pupil dilated freely under atropine; the inner part of the conjunctiva was so injected, that it was difficult to determine the limits of the cicatricial tissue. The patient was ordered a collyrium of zinc and rose-water, two grains to the ounce, with frequent applications of warm water, with a tonic of iron and bark, and a generous diet. At the end of a month most of the granulations on the outer half of the ball had subsided, and the congestion of the inner half of the eye had cleared up, thus defining the limits of the symblepharon. This was so extensive that transplantation of healthy conjunctiva of some kind presented the only chance of relief. I proposed to use the conjunctiva of the rabbit.

On August 3d, I performed the operation, assisted by Drs. H. D. Fraser, John Forrest, and Jno. L. Dawson, Jr. The patient being chloroformed the operation was commenced by Arlt's method; dissecting up the broad pterygium-like bands from the cornea and globe, thus liberating the ball, then folding it upon itself, and attaching it out of view under the outer canthus by two fine silk sutures. This allowed free rotation of the eye. It was impracticable to complete the operation by combining Mr. Teale's plan of dissecting up, and transposing healthy conjunctiva from the inner half over to the outer half of the denuded surface of the ball, more than one-half of the outer conjunctiva ocular and palpebral having been removed.

I then gave a black English rabbit, held by two assistants, chloroform. I divided the inner and outer canthi of his right eye, so as to evert the upper lid freely, and dissected off two-thirds of the conjunctiva from the ball, and upper and lower lids, and transferred it to the point of my left index finger by the aid of delicate forceps, keeping the epithelial surface upwards. This required great care, as the conjunctiva of the rabbit rolled up in a mass as soon as it was severed. When spread out upon the point of the finger, the attached or under surface adhered smoothly to it. I then trimmed it in shape and quickly transferred the graft in posi-

[1] Read at the annual meeting of the South Carolina Medical Association, April, 1885.

tion, uniting it by ten points of fine animal sutures (made of the tendons of squirrel tails) to the cut edges of the conjunctiva of the boy's eye. The curved border of the rabbit's conjunctiva, cut away from its cornea, was well adjusted to the outer border of the cornea of the lad. The graft had a slightly bluish cast, contrasting with the white remaining portion of the boy's conjunctiva.

The patient bore chloroform badly, interfering with the rapidity of the operation, which lasted an hour and a half. The eye was dressed with a cold cloth, with a light compress of absorbent cotton, secured over both eyes, as in the dressing after operation for cataract.

August 4.—Vomiting continued yesterday and last night, temperature 100°, pulse 102. He was ordered milk and lime-water, with a mustard cataplasm to the stomach, and morphia in small doses; dressings undisturbed.

5th.—Vomiting lessening, more comfortable temperature, 100°; pulse 96; dressings removed, graft examined and found in good position; it looked rather paler than when first transplanted. Same dressings continued.

6th.—Vomiting ceased, taking nourishment, cheerful; the graft is slightly injected on the lower half, the upper part is in good position but has a slightly shrivelled appearance; dressings replaced.

8th.—Graft injected all over, and it seems to have taken throughout its whole surface. The two silk sutures were removed, the animal sutures are being absorbed; they have produced no irritation to the conjunctiva. The bandage was removed from the good eye, and retained on the bad one. The lad is playing about the room.

10th.—Progressing favorably; dressings removed.

15th.—Patient discharged and returned to Summerville, where I saw him again on the 20th, playing with his companions, and quite comfortable so for as his eye was concerned.

October 1.—On reporting to-day, all the movements of the eye were good; it was still crossed, a few cicatricial bands extending from the upper and lower lids to the adjoining portion of the graft at the outer canthus, but did not encroach on the cornea, or interfere with the movements of the eye. On closing the good one the bad eye became straight, which it could not do before the operation. The cornea had cleared considerably, he could easily tell letters in D. 3 (Snellen).

Up to this time, since the operation, no wash was given for the eye, as I did not know what effect it might have upon the graft, and could not watch the effect, as I was absent from the city, and did not see the patient from the 20th of August, to the 1st of October. The graft was now so thoroughly united, I ordered a mild zinc wash with a view of clearing up the cornea, and preventing the formation of any additional bands of adhesion.

17th.—To-day the opacity of the cornea not having improved, the zinc wash was discontinued, and a solution of hydrobromate of eserine, one-half grain to the ounce of water was substituted, four or five drops to be instilled into the eye three times a day.

30th.—Under the influence of eserine the opacity of the outer half of the cornea has lessened, the outline of the pupil is distinct. Vision has improved, reads words in D. 1 (Snellen). The small cicatricial bands referred to are paler and smaller; solution of eserine discontinued.

31st.—To-day I operated for strabismus, making a double tenotomy. Drs. W. C. Ravenel, and Jno. L. Dawson, Jr., were present. The patient was not as much affected by the after-effects of chloroform as on the previous occasion; the result was satisfactory, and on the 17th the patient was exhibited at my clinic with the black rabbit from whose eye the graft had been taken. The lad has since that time (nearly two years) been at school, and has had no further trouble. I now have the pleasure of presenting him to the Association.

Remarks.—This operation was first performed by Mr. Wolfe, of Glasgow, in 1872. He transplanted the human, as well as the rabbit's conjunctiva successfully in a number of cases. I have seen very few cases reported by American surgeons. It is likely that it has often been performed without the cases being reported. I have been informed of four cases: one was a partial success, the three others were failures. No report has been made of the cases. Dr. Henry D. Noyes, of N. Y., published in the *Medical Record*, February, 1883, the fullest account of cases in this country, and the method of operating, which I have seen. He says:

"Many European surgeons have done the operation, but in this country it has, so far as my information goes, not been extensively imitated. Soon after it was announced I made a trial of it, and Dr. W. I. Little, whose case has recently been published, when he was my assistant in the New York Eye and Ear Infirmary during 1873-4, aided me on more than one occasion. I do not find a record of my earliest operations, but since 1878 there have been seven operations done at the Infirmary, of which one was performed by Dr. Callan, and six were performed by myself. In the majority the lesion was symblepharon caused by burns of the eye, but about four years ago I employed the method to increase the size of the conjunctival sac that a patient might be enabed to wear an artificial eye."

As to the success attending the operation, Dr. Noyes says: "in no instance have I meet with entire failure, while the degree of benefit has been various." The rest of the article describes minutely the steps of the operation and the management of the rabbit, as done by Dr. Noyes, and also by Mr. Wolfe.

The only important difference between the two methods, is that Dr. Noyes transfers the graft from the eye of the rabbit to a piece of cork in a saucer of water, where it is secured by pins and trimmed into shape, it is then transferred to its place either on the palpebral or ocular surfaces as he prefers, and secured by sutures eight to ten, or as many as may be required. Mr. Wolfe measures the shape of the flap of conjunctiva before excising it, and transfers it directly to the palpebral surface, and secures it by sutures; he thinks this preferable to placing the graft on the ball. Dr. Noyes has applied the graft to both ball and lid. To make the cul-de-sac, the stitches are brought through the eyelid and tied over a bit of stick on its outer surface. Both use black silk sutures inserted in the flap of the conjunctiva with a knot, to

mark the epithelial from the raw surface; the other ends of the sutures are threaded with needles. After transferring the graft in position, the same needles and sutures are used to secure it. Mr. Wolfe uses four black sutures; Dr. Noyes two. Both take the conjunctiva from the inner canthus. Dr. Noyes slits up the inner canthus and turns back the angles and stitches them temporarily, which facilitates dissection of the conjunctiva. Both consider quick transportation without previous handling of the conjunctival graft very necessary to success. Dr. Noyes prefers the black rabbit to the white, because the "conjunctiva is firmer and can therefore be more easily handled," and for convenience places the rabbit in a pasteboard box with his head through a closely fitting hole, and gives the anæsthetic and makes his dissection in that position. Mr. Wolfe provides two rabbits, holding one in reserve in case of accident.

In my case I selected the black rabbit, because the cornea is smaller in proportion to the size of the ball than in the white one, affording a larger piece of ocular conjunctiva for dissection. It was necessary to dissect up the cul-de-sac and a part of the palpebral conjunctiva of both lids to secure a graft of sufficient size. This was done by the aid of two delicate forceps, one held by myself, the other by an assistant. On removing the graft it rolled up upon itself, but with care I had no difficulty in detecting the difference between the surfaces. It was then spread out on my left forefinger to which the raw surface adhered closely, and by carrying the finger to the boy's eye, I trimmed it in shape pretty accurately. The graft was taken from the outer side of the rabbit's eye. I slit up the outer and inner canthi, and everted the lids to gain more room for dissection, and because the outer side of the ball affords a larger piece of ocular conjunctiva than the inner, and is more easily dissected away than the palpebral conjunctiva, which is more closely adherent.

In preparing the eye for the graft, Mr. Wolfe and Dr. Noyes dissect separate or remove all cicatrices and adhesions so as to give free motion to the eyeball in all directions. The presumption is that these are cut entirely away. In my case, after dissecting the bands of adhesion from the ball, I inverted the pterygium-like growth under the upper and lower lids, and attached it by two sutures by Arlt's method in operating for pterygium. This, I think, is an important provision in the operation, as it leaves a surface more or less covered by epithelium to come in contact with the epithelial surface of the graft, instead of a larger raw surface resulting from the entire removal of the adhesive bands.

These directions may appear to one who has never performed the operation, or seen it done unnecessarily minute. He will not think so if he attempts the operation without carefully studying the details so necessary to success. I performed it on general principles without refreshing my memory on these details, and did not see Dr. Noyes's article until afterwards when I was looking up the subject. It would have assisted me very much, as it is I think by far the clearest description of the operation I have read.

The sutures I used were animal, made of the tendons of squirrels' tails, which can be split as fine as the finest silk. The objection to them is that only a few in each tail can be used, the others are too short to tie easily. They should be kept in carbolized oil, and before using them should be taken out and wiped and dried an hour or two. This makes them stiff and facilitates the tying; otherwise they are sticky and difficult to handle. The advantages of using these delicate animal sutures are these: they quickly soften after being inserted, produce no irritation, are absorbed on the third day as a rule, except the knots, which are pulled away by forceps without alarming the patient, by cutting them with scissors as when silk is used. It is not necessary even to remove the knots, they disappear or are separated and escape with the secretions of the eye in three to five days. In this case I secured the graft with ten sutures. I had occasion to pull away only one knot, even this was not necessary, as it was not irritating surrounding structures, and mashed up in the bite of the forceps.

Speaking of these sutures, I may digress for a moment to say that I use them habitually in all operations upon the eye, usually requiring fine silk sutures, so as to avoid the necessity of cutting and removing them. In suturing the conjunctiva in the operation for pterygium; bringing forward the recti muscles, in canthoplasty (Agnew's modification), or wounds of the eyelids and face: they are especially adapted to children, in many of whom the removal of silk sutures gives as much trouble as inserting them at the time of the operation. In one case I assisted in using them in suturing a lacerated cornea, after removing the injured lens, and the globe was preserved intact. Union resulted with a leucomatous cornea; the sutures were absorbed. Latterly I have experimented with sutures made from the opossum's tail; one tail furnishes from thirty to forty sutures, and as many short ones about the length of the longest squirrel tail sutures. The sutures of the opossum's tail are very strong, the largest can be split into three or four delicate ones sufficiently strong for most operations about the eye, or for suturing wounds about the eyelids and face. The largest ones are applicable for many purposes in abdominal surgery, more particularly for securing the bleeding surfaces of adhesions of the peritoneum in ovariotomy, or for suturing wounds of the intestine, etc. They are stronger than catgut, produce absolutely no irritation, and are completely absorbed in from three to five days.

MEDICAL PROGRESS.

Influence of Different Agents upon Eberth and Koch's Bacilli of Typhoid Fever.—E. Bagenoff, in the *Vrachebnaia klin. Gazzeta*, 1885, Nos. 5 and 6, states the following facts concerning the bacilli of typhoid fever of Eberth and Koch.

1. The bacillus of typhoid fever is preserved in water and may even multiply to a certain extent. Therefore, drinking-water should be considered as a source of infection of typhoid fever.

2. The milk of the cow is not a favorable medium for developing the bacilli of typhoid fever; nevertheless, these bacilli may live and be multiplied therein, and

therefore the milk of the cow may be an intermediate means of transmitting the infection of typhoid fever.

3. Gastric juice destroys the bacilli of typhoid fever.

4. The parasiticide action of the gastric juice depends only upon the action of the hydrochloric acid contained therein.

5. Pepsin, bile, and the pancreatic secretion do not destroy the vitality of these bacilli.

6. Bile and the pancreatic fluid even seem to favor the development of the typhoid bacilli.

7. Cold arrests the development of these bacilli, but does not destroy them.

8. A temperature of from 98.6° F. to 107.6° F. is most favorable for the development of the bacilli of typhoid fever. Above 113° F. their development is impeded and is entirely arrested when the temperature exceeds 122° F.; *the bacilli* perishing, but their *spores* preserving their vitality.—*Gazette Médicale de Paris*, May 2, 1885.

Eucalyptus as an Antiseptic in Certain Diseases of the Respiratory Passages.—Dr. Bonamy, after treating pulmonary gangrene, diphtheria, and croup antiseptically with eucalyptus in connection with other remedies, considers the influence of the eucalyptus as exceedingly beneficial, and attributes to it much of the success of the treatment employed as indicated below:

1. Atomization of the infusion of the leaves of eucalyptus, repeated every two hours, in the near vicinity of the child.

2. Application of lemon-juice upon the pseudo-membranous spots.

3. Potions containing chlorate of potassa and milk, to which lime-water had been added or the flowers of sulphur (fifteen to thirty grains in twenty-four hours).

4. Wines, champagne—Bordeaux, Malaga—chocolate, coffee, etc.

Though the treatment is complex, it is not more so than the disease. The eucalyptus, administered internally and externally, seems to answer the first indication, namely, to combat the infectious element. The lemon-juice applied locally, and the chlorate of potassa and flowers of sulphur administered internally, seem to answer the second indication, viz., to destroy and to detach the false membrane while the wines, etc., fill the fourth indication of supporting the strength of the patient; for though the vital force of the child is strong, nevertheless it is necessary to provoke reaction. Like the mixture of tar and turpentine recommended by Dr. Delthil, eucalyptus responds only to one of these indications, but in the opinion of Dr. Bonamy, it possesses superior efficiency and to it in a great degree he attributes the simplicity with which the disease is evolved in young patients in whom tracheotomy is performed, and upon others.

In addition to the beneficial results attained in pulmonary gangrene and diphtheria, Dr. Bonamy strongly recommends eucalyptus in whooping-cough in the form of inhalations and draughts, as exercising an evidently salutary influence upon the violence and frequency of the cough and upon the duration of the disease.

Dr. Bonamy concludes his observations by suggesting that for each infectious entity and for each group of organs, a special disinfectant will be found to correspond, and that the antiseptic power of any substance is not always directly in consequence of its intensity, but rather by reason of its approximation by this or that organ or its influence upon one or another infection. Thus eucalyptus seems in pulmonary affections to possess the same direct influence as does quinine upon malarial disease, and mercury upon syphilis.—*Bulletin Général de Thérapeutique*, May 15, 1885.

The Contagiousness of Pulmonary Tuberculosis in Children.—Prof. Ollivier, in a paper read before the Académie de Médecine de Paris, April 28, 1885, insists upon the transmissibility of tuberculosis during childhood, and supports his views by reference to cases in his own clinical experience. In order to protect children from the contagion of the disease, he holds that strict attention to hygiene is necessary, and suggests the following points to be observed:

1. Isolation in families, as in hospitals, of tuberculous children.

2. The non-permission of healthy children to remain for a long time with tuberculous children, and the entire interdiction of healthy and tuberculous children from occupying the same room during sleep.

3. The perfect ventilation of the chambers occupied by tuberculous children,

4. To cleanse carefully the playthings, clothing, linen soiled by expectorated matter, or to destroy the latter by a powerful physical or chemical agency to prevent their drying in the atmosphere.

By attention to the above precautions, Prof. Ollivier believes that this disease, which is continually increasing, may be diminished in children as well as in adults. —*L'Union Médicale*, May 23, 1885.

Cancerous Return After Ablation of Cysts of the Ovary.—M. Terrillon, at a meeting of the Société de Chirurgie de Paris, after discussing the cancerous return sometimes exhibited after ablation of cysts of the ovaries, concluded his observations as follows:

1. There sometimes is seen subsequent to the ablation of a multilocular ovarian cyst after a long or shorter period of apparent health, the development of cancerous disease which is fatal by reason of its general or local effects.

2. This cancerous degeneration is exhibited under two conditions entirely distinct from each other, sometimes appearing in the region of the locality operated upon, the pedicle, peritoneum, and the abdominal cicatrix, and at others appearing in a remote organ, such as the stomach, rectum, uterine neck, the bones or ganglia.

3. In the first case a local return must be admitted, due to implantation of vegetations from the tumor upon the peritoneum, or to the grafting of cancerous elements.

4. The return is easily explained by the nature of the cysts. It seems actually admitted that the cysts of the ovary, properly so-called, have a structure which enables them to be considered as epitheliomata, susceptible of being transformed into sarcomata, carcinomata, etc. The ablation of a cyst which is not united to other parts except by a slight pedicle explains the ordinary absence of return after operation. Certain varieties of cysts with sarcomatous or vegetative walls seem especially predisposed to return.

5. It is impossible actually to establish the proportion of patients who present secondary tumors after ovariotomy, though the number does not seem to exceed two

or three per cent. The mean duration of life in the case of return does not exceed one or two years. Return seems more frequent in patients operated on at an age of forty or fifty years.—*L'Union Médicale*, May 5, 1885.

Therapeutics of Helenin.—Senor Baeza writes, in a Spanish medical journal, in very warm praise of the drug helenin, which is made from the plant *Inula Helenium* (Elecampane), and which, though by no means new to Spanish pharmacy, has only lately been discovered by Dr. Korab to possess antiseptic properties in a very remarkable degree. In comparative experiments made with salicylic, boracic, and carbolic acids, helenin was found to excel all the others in its power of arresting putrefaction. It has also the advantage of being less irritating than carbolic acid, and can be given internally much more freely. A few cases in which it has been advantageously employed are reported. In a case of retained placenta where carbolic acid injections had to be stopped from the intense irritation and pain produced, and where by the fifth day septicæmia had set in, injections were commenced of 20 centigrammes (3 grains) of helenin in 300 grammes of water. At the first injection the odor, which was horrible, disappeared. After two days of this treatment, the placenta was spontaneously expelled, and was found to be odorless, and in a few days the woman was convalescent. In these cases the proportion of helenin recommended is 0.6 per 1000 of water. A case of anthrax which, though treated with quinine, charcoal, carbolic acid, and chlorine water, was gradually invading the surrounding tissues, a fatal result being feared, immediately began to improve on the application of a solution of helenin. A case of ozœna where the breath was so foul that the patient, besides frequently gargling with chlorine solution, was obliged to keep a mint lozenge perpetually in the mouth, was quickly improved by treatment with gargles and lozenges of helenin. A case of itch in a child yielded rapidly to a lotion and embrocation of helenin. Turning now to cases in which the drug has been administered internally. A woman with intermittent fever which had lasted two months, though treated with hypodermic injections of quinine and many other drugs, was given 25 centigrammes of helenin combined with 1 gramme of quinine in 20 pills during each intermission, and was very shortly cured. A patient with phthisis causing colliquative diarrhœa, which could not otherwise be controlled, was given helenin, and though this did not cure him or save his life, it put a stop to the most distressing symptom of the disease. Senor Baeza's own child, aged 15 months, was suffering from enteritis due to dentition. It was given in spoonfuls, gr. 1½ of the drug in about 3 ounces of mucilage, with the result that the diarrhœa immediately began to abate and soon stopped. Dr. Ferrán, who has been engaged in a series of most important experiments with "vaccinia" induced by hypodermic injections of cholera cultivations, has examined the action of helenin on the cholera bacillus, and states that it differs from the action of all other agents, being more destructive to the bacillus. We may mention that helenin is advertised in the *Correspondencia Medica* at 1.50 pesetas (1s. 3d.) per gramme.—*Medical Times and Gazette*, May 2, 1885.

Nephrectomy.—At a meeting of the Académie de Médecine held May 5, 1885, M. Polaillon reported a case of nephrectomy in which the patient was a woman aged 27 years who entered the Hôpital de la Pitié, suffering with a painful swelling in the left side. M. Chauffard confirmed the presence of a tumor which appeared to be in relation with the kidney. Puncture with the aspirator, twice practised at intervals of four hours, evacuated each day from six to eight ounces of a turbid fluid having the odor of urine and laden wtth pus which separated on standing. The urine passed also deposited pus on standing. To complete the diagnosis, M. Chauffard administered thirty grains of salicylate of soda to the patient, and the day following the presence of the drug was confirmed in the fluid obtained by aspirating the tumor. He then injected into the tumor fifteen and one-half grains of a solution of fuchsine, and an hour subsequently the urine was colored red. It was, therefore, shown that the tumor was a cyst containing urine and pus, and that it communicated on the one hand with the kidney and on the other with the bladder through the medium of the ureter. M. Chauffard, therefore, concluded that there existed a pyelonephritis, and considered it probable that the ureter was partly obliterated by a calculus.

M. Polaillon was called in consultation, and the diagnosis confirmed, and inasmuch as the cyst rapidly refilled after puncture and as only transient relief was afforded the patient by this procedure, operation was decided upon, and performed by M. Polaillon assisted by M. Chauffard.

A vertical incision was made extending from the lower border of the twelfth rib to the crest of the ilium. Having arrived at the muscular tissue the bistoury was abandoned and the galvano-cautery substituted therefor, and almost entirely without loss of blood penetrated to the kidney. The posterior surface of the organ was then explored with the finger, and it was discovered that considerable enlargement existed; the organ extending from the vault of the diaphragm to the superior limit of the pelvis. The original incision being now seen to be insufficient, a second incision was made starting from the lower end of the original incision and running forward along the crest of the ilium for two and one-half or three inches, thus affording sufficient space to admit the ablation of the kidney and of making the necessary ligations.

The displacement of a large renal calculus occupying the bottom of the incision caused some tearing of the renal tissue and was followed by a flow of pus mingled with urine and blood. By aid of the forceps introduced into the renal cyst two large calculi were removed. To arrest the hemorrhage produced by the laceration of the kidney numerous ligatures of gut were applied, and, finally, the kidney was detached with the scissors about two-fifths of an inch below the inferior ligature.

The cavity, which was very extensive after removal of the kidney was washed out with carbolized water, and, finally, when hemorrhage was controlled, the lips of the wound were closed by four sutures, a drain introduced, and antiseptic dressing applied. The results of the operation were most happy and the patient is in such condition as renders her recovery assured.—*L'Union Médicale*, May 7, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 20, 1885.

THE SURGERY OF ANEURISM OF THE ABDOMINAL AORTA.

THE surgical treatment of aneurism of the abdominal aorta, a subject replete with great practical interest, has recently attracted no little attention from the publication of two cases by PROFESSOR LORETA, of Bologna, and MR. LUNN and DR. BENHAM, of London, accounts of which may be found, respectively, in the *Memoirs of the Royal Academy of Sciences of the Institute of Bologna*, Vol. 6, 1885, and the *British Medical Journal* for April 11, 1885.

The patient of Loreta was a sailor, thirty years of age, who, on admission into the hospital in December, 1884, was found to have a large pulsating tumor, accompanied by a loud bruit, in the epigastric and left hypochondriac regions, which was traceable to violent efforts in furling a sail in February, 1883. There was little pulsation in the femoral arteries, and the limbs were cold, and the seat of sharp, lancinating pains. On the 19th of December, an incision was carried from the base of the ensiform cartilage to the umbilicus, superficial adhesions were separated, and many deep adhesions between the sac, the stomach, omentum, transverse colon, and liver were divided; but as it was found impossible to dissect the sac from its union with the spleen, diaphragm, and the cardiac end of the stomach, or to trace the tumor down to its mouth, the idea of closing its mouth by ligature or suture, or of emptying, inverting, and stitching up the sac, had to be abandoned. The sac was, therefore, punctured with a delicate trocar, and rather more than two yards of silvered copper wire were introduced into it, when the abdominal wound was closed.

Without entering into minute details of the subsequent progress of the case, it may suffice to say that the bruit had entirely disappeared on the twenty-second day; that the tumor was completely consolidated, and diminished three-quarters in volume, at the expiration of one month; and that the patient was discharged on the seventieth day, apparently cured. Twenty-two days subsequently, however, death suddenly ensued from rupture of the aorta, at the point of union of the artery with the front wall of the sac. The latter was reduced to the size of a walnut, and was filled with organized fibrin and the unaltered wire, which was rolled up into a globular mass.

The patient of Mr. Lunn and Dr. Benham was a shoemaker, thirty-two years old, with a history of syphilis. Ordinary measures having failed to afford relief, distal compression of the aorta by means of Carte's tourniquet, applied just above and to the left of the umbilicus, was kept up for four hours and three-quarters, under chloroform. The tumor soon became harder and smaller, and the pulsation was diminished; the man continued to do well for seven days, when persistent vomiting of grumous material set in, and was accompanied by a feeble and very rapid pulse, intense thirst, and other untoward symptoms. His condition became worse, and death ensued on the twelfth day, when the aneurism was found to be cured; the superior mesenteric artery was completely blocked; and two feet of the jejunum were gangrenous.

The case of Professor Loreta is the first on record in which an aneurism of the ventral aorta has been reached by laparotomy. The insertion of wire into the sac is, however, not novel, that plan of treatment having originated with the late Mr. Moore, at the Middlesex Hospital, in a case of aneurism of the thoracic aorta. Although the introduction of foreign materials such as wire, watchsprings, horsehair, catgut, and silk, with the view of inducing coagulation of its contents, has uniformly been followed by death or failure, the possibility of complete consolidation of the tumor being effected in this way is demonstrated by the case of Loreta, a result which justifies its repetition in cases in which other measures are inapplicable. From the situation of the aneurism proximal compression of the aorta was out of the question; and had the blood-supply of the diseased arterial wall below the tumor not been interfered with by the compression exerted upon the vessel by the coagula in the sac, Loreta's case would doubtless have proved to be a brilliant success.

The case of Mr. Lunn and Dr. Benham is also an illustration of the cure of aneurism, but it likewise shows the almost utter hoplessness of distal compression, which failed in the case of Marshall, and proved fatal in that of Skerritt, from rupture of the sac, and.

as we have seen in the case under consideration, from gangrene of the jejunum, either as the result of direct pressure, or of failure in its supply of blood from occlusion of the superior mesenteric artery. In the patient of Bryant, distal compression of the aorta for sixteen hours induced death by peritonitis, the aneurism having been one of the cœliac axis. In addition to these objections, it is doubtful whether the compression in any of these cases was truly distal, and whether it would not have been more accurately described as combined distal and direct compression.

We cannot but think, with Mr. Jonathan Hutchinson, that surgical measures should not be resorted to until after the failure of general remedies in all cases of aneurism of the abdominal aorta. In a man under his care he succeeded in bringing about a cure in three months by very large doses of acetate of lead, doses which produced toxic symptoms, with a dry diet, absolute rest, and the application of ice to the abdomen. He regards the combined use of acetate of lead, ergot, and iodide of potassium, pushed almost to the extent of poisoning, as constituting the best treatment of these most dangerous cases; and Tufnell's success in two cases, which were cured, respectively, in twenty-one and thirty-seven days, by a restricted diet, rest, and a more cautious use of drugs, goes far to support Mr. Hutchinson's views.

In the event of failure of medical treatment, proximal pressure, whenever it is practicable, holds forth the best prospect for a successful issue. Thus a cure resulted in the cases recorded by Murray, Heath, Moxon and Durham, Greenhow, and Philipson, while Pollock met with a failure, and the patients of Paget and Durham died, respectively, of peritonitis and bruising of the pancreas. Hence the cures amount to 62.5 per cent., while the deaths number only 25 per cent., the risks, apart from prolonged anæsthesia, being, as in distal pressure, from peritonitis and contusion of the viscera. Should proximal pressure be impossible from the situation of the sac, it becomes a serious question, in view of the dangers of distal pressure, whether the operation of Loreta is not the only resource. In the language of Mr. Holmes, in his comments upon the cases that have called forth this article, which may be found in the *British Medical Journal* for April 18, 1885, "we incline to this method," Loreta's, "rather than to a pressure, which was rather doubtfully distal." Whether this view be correct or not, further experience can alone determine; and that this experience will be forthcoming is assured by the trials which modern surgeons do not hesitate to make of every promising novel operation. Before undertaking it, they should, however, consider the risks from embolism, since Dr. Maclean states, in the *British Medical Journal* for May 9, 1885, in connection with the case of Mr. Moore, that, "in the fresh preparation innumerable clots, of varying consistence, were hanging from the wires, ready to drop into the blood; and emboli, exactly like them, were visible in the arteries of the organs, carefully dissected to show them."

THE TREATMENT OF OBESITY.

There can be no doubt that if an efficient, and at the same time, harmless treatment of obesity could be attained, it would be very popular with those afflicted with the tendency to over-accumulation of fat, not only because of the personal deformity which would thus be avoided, but also on account of the increased ease with which the individual thus relieved would perform his role in life as a worker and bread winner. Further, the frequency with which physicians are often asked for a remedy for this condition makes it a matter of importance to them from a practical point of view. Hence, we know our readers will be interested in the discussion of this subject which took place in the Congress for Internal Medicine, recently sitting at Weisbaden.

Prof. Ebstein, who read the introductory paper, very sensibly said, first, that no treatment dare be considered rational which results in inanition or a conspicuous destruction of other tissues than adipose. Further conditions of such treatment are that it shall be easily carried out, and that it shall involve no useless inconvenience or great sacrifices in the life of the patient.

It is also evident that the method of treatment may be based upon the withdrawal of certain articles of food, upon regulation of habits of life, or both. In point of fact, all methods heretofore adopted have aimed to restrict the excessive use of certain articles of food, as albumen, fat, and carbohydrates, which modern physiology teaches are the most important alimentary principles concerned in the formation of fat. A proper nutrition does not permit the withdrawal of albumen, but it is possible to place the fats and carbohydrates in such relation as to prevent an undue accumulation of body fat. Ebstein's method does not interfere with the ingestion of albuminous food, and may be said to be characterized by a more liberal allowance of fats, although he also restricts these somewhat, and protests against his system being called a "fat cure" in the sense that it is a cure by the use of fats. He claims that by permitting the ingestion of a moderate amount of fat, hunger and thirst are diminished and a reduction in the over-ingestion of food rendered more easy. The hydrocarbons on the other hand, of which sugars and starches are the type, are decidedly restricted.

A second characteristic feature of Ebstein's method is a limitation of liquids ingested, a part of the treatment which, as has been said, is facilitated by per-

mitting the use of a moderate amount of fat. This is supplemented by measures which secure an increased loss of water by sweating, such as forced muscular exercise, or suitable baths. Drugs are to be avoided, while the natural mineral waters, especially those containing a large amount of sodium sulphate, as Carlsbad, and Marienbad, so much vaunted for this purpose, are useless.

Ebstein objects to the method of Banting, which restricts the patient to an almost pure albuminous diet, because, although it accomplishes its object in removing excessive fat, it is not without danger. Oertel's method, through deprivation of water, is also efficient, but on account of the discomfort produced by the extreme thirst, is not well borne.

In the discussion which followed the reading of the paper, it was evident that all were not in accord with Ebstein. Thus, Henneberg, of Göttingen, the co-referee, who adduced a large number of facts based on the fattening of animals, said it was the universal testimony of farmers that the free use of water operates unfavorably on the fattening of animals. He also adduced the important fact, which should not be lost sight of in any system, that animals, once fattened, do not lose flesh even when the quantity of food is considerably cut down, provided they are kept at rest. Active exercise, however, rapidly reduces their fat. In the fattening of animals all the three foods—albuminous, fatty, carbohydrates—contribute, and food poor in fats is still efficient in fattening when it is supplied in abundance. Experiment also showed that in the case of herbivora, given quantities of carbohydrates produce more adipose tissue than equal amounts of fatty foods.

Bauer, of Münich, agreed with Ebstein in that the true Banting system might be harmful, but thought with Voit, that a modification of this system by which a limited amount of non-nitrogenous food is permitted, could be applied with efficiency and without disadvantage.

Zuntz, of Berlin, saw no good reason why Ebstein should distinguish between fats and carbohydrates. He thought the indication was simply to cut off the fat-producing foods, and it mattered not how it was accomplished. In the matter of diminishing the ingestion of water, he made the important point that it makes a difference whether the kidneys and organs of circulation are normal or not. In heart and renal disease, it is difficult for the system to work off any excess of water which is, therefore, disposed to accumulate. So, too, Zuntz has found that the addition of a saline solution to the food facilitates the taking up of oxygen, and the excretion of carbonic acid—ten to fifteen per cent.—and the combustion of fat must evidently be influenced thereby.

Unna, of Hamburg, said that as there is a difference in the conditions of deposit of muscular fat, subcutaneous fat, and visceral fat, any system of treatment which is not based on this fact is erroneous. He does not tell us, however, what the differences in these conditions are.

Baelz, of Tokio, remarked that, in Japan, obesity is extremely rare among the laboring classes, who live exclusively upon vegetables, which is perhaps ascribable to the fact that the Japanese consume very little water and almost no alcohol.

While it is evident from the above that there is no clear cut road for the removal of obesity, we think we may take courage to advise, with some hopefulness, those who may consult us on this subject. It is evident, moreover, that we must avail ourselves of one or more of the means to this end, according to the circumstances of the case. We would remind our readers, however, that the idea of active exercise must never be lost sight of, and that more can be accomplished by combining it with a moderate restriction of the fat-producing foods than by their total elimination unaccompanied by measures which favor the combustion of the elements of fat.

THE EPIDEMIC AT PLYMOUTH.

That the epidemic at Plymouth, Pennsylvania, which is still prevailing in a mitigated form, is one of typhoid fever there seems no longer any reasonable doubt. If any previously existed, it is removed by the supplemental paper by Dr. Taylor, published in the current issue of The News, the careful perusal of which will well repay our readers.

It only remains to point a moral from the sad narrative We are forced to admit, from a study of the facts, that a stream may be contaminated by the undisinfected discharges from a single case of typhoid fever, and the mischief which may result from such contamination is immeasurable. The lesson to be learned is, that if we would successfully avert such mischief, it is imperative that every evacuation from a typhoid fever patient be thoroughly disinfected before it is thrown away. In no other way can drinking water be certainly protected from contamination. It is important, too, that care should be taken to throw the dejecta where they will not drain into wells or streams, the water from which is used for drinking purposes. To do this, in every instance, is, perhaps, possible. Hence, the previous injunction, which, if successfully carried out, must secure exemption.

But any one who has had experience with the treatment of the sick among the poorer and middle classes, knows how difficult it is to carry out orders with regard to the management of dejecta. And even physicians are sometimes strangely indifferent to its importance. Hence, it behooves the authorities of towns and municipalities to add their efforts towards preserving the purity of the drinking water.

Every precaution should be taken to keep the sources of the supply absolutely free from contamination by drainage. The fact that a city wherein no such provision is made has been exempt from epidemics for years is no guarantee that such exemption will continue. It is to be remembered that sewage contamination alone is not sufficient to cause typhoid fever. It must be sewage containing the germs of typhoid fever, which, whatever its exact nature, seems capable of multiplying itself indefinitely. Moreover, the distance of the point whence the water-supply is taken, from the possible source of contamination, is no protection.

The City of Philadelphia has been none too soon in providing the "intercepting sewer," by which the drainage of Manayunk and the Falls village is to be carried to a point below the dam at Fairmount, at which the water is taken for the city's supply. The recent experience at Plymouth may well serve as an incentive to redoubled energy in completing this public work, the importance of which cannot be measured by its cost. With the knowledge we now have of its etiology, we ought to be able to stamp out typhoid fever as we ought to be able to stamp out smallpox, and the day will come when both of these desirable events will have been accomplished.

OSPHRESIOLOGY.

DOCTOR MONIN, Secretary of the French Society of Hygiene, has recently written a monograph upon the odors of the human body. The Society of Medicine of Paris has given him its triennial prize for this work. The subjects successively treated in it are the odor of the skin and its appendages, the odor of the breath, of expectorations, of vomited matters, and of eructations, of feces and intestinal gases, of the urine, of the female genital organs, and of suppuration and gangrene.

Various pathological conditions are indicated by the odor of the skin, or of its perspiration, and by that of the breath. For example, the skin has an ammoniacal odor in cholera, and in dysentery the perspiration has the odor of the anal dejections; in hysteria the hair has the odor of ozone. In diabetes the breath has a sourish odor; if this odor be slight, it is due to aldehyde, but, when more marked, it is due to acetonæmia; a garlic odor of the breath in infants indicates intestinal worms, and upon this indication alone anthelmintics may be given.

Of course, the detection of faint odors will depend upon the olfactory power of the individual, and one may be able to perceive distinctly that which another fails to recognize, for doubtless there are just as great variations in the sense concerned as have been shown to exist in the sense of hearing, or in that of seeing. It is probable that science, which has done such marvels in making the unseen seen, so vastly increasing the size of an object of research, will one day find means to make odors more distinct, and thus assist professional investigation.

THE OBSTINATE VOMITING OF PREGNANCY.

CHARPENTIER contributes to the June number of the *Archives de Tocologie* an interesting article upon the obstinate vomiting of pregnancy. The purpose of the article is to show that in some cases of obstinate vomiting, the cause is not in the pregnant condition. In one of several cases narrated by him it was the manifestation of a general infection due to absorption of septic products contained in an abscess. In another patient, who was hysterical, the vomiting was caused from her being addicted to morphine; she was cured by change of place, and by hypodermatic injections of water. In a third, the cause of the disorder was tuberculous meningitis.

Charpentier very justly teaches that we ought not, in all cases, to attribute obstinate vomiting to the pregnant condition; in some it is necessary to seek behind the pregnancy another etiological factor, a factor which will often be found in a local, or general malady.

SOCIETY PROCEEDINGS.

MASSACHUSETTS MEDICAL SOCIETY.

One Hundred and Fourth Annual Meeting, held at Boston, June 9 and 10, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 9TH.—FIRST DAY.

DURING the forenoon the members of the Society made the usual visits to the Massachusetts General, City, and Children's Hospitals.

At the General Hospital Dr. J. Collins Warren performed an amputation of the thigh, and showed numerous interesting cases in the wards which were being dressed with sterilized cotton.

At the Children's Hospital Dr. A. T. Cabot performed MacEwen's operation of osteotomy of the femur for knock-knee, and showed a case in which after trephining a child six years of age, who had previously had from six to twenty convulsions daily, remained free from them.

DR. H. C. HAVEN also showed a very interesting and obscure cure of abdominal tumor in a boy of nine years.

At the City Hospital visits were made to the surgical wards, and numerous cases in the service of Dr. E. D. Homans were shown, in which the good results of thorough antisepsis were made apparent. A hæmatocele had healed by first intention after being thoroughly curetted, and a similar result had been obtained with a chronic lumbar abscess. Two cases of strangulated hernia, successfully operated upon by Dr. Wm. P. Bolles were shown, and there were several interesting operations, among them were two for cataract, by Dr. H. W. Williams, and a plastic of the nose, by Dr. Geo. W. Gay.

At 12 o'clock the members met in Huntington Hall, and listened to the following interesting papers:

Pathogenesis of Certain Affections of the Skin, by George N. Tilden, M.D., of Boston.

Consanguineous Marriage: Their Effect upon Offspring, by Charles F. Withington, M.D., of Roxbury.

Labor Complicated with Fibroids, by James R. Chadwick, M.D., of Boston.

The meeting then adjourned until 3 o'clock.

At 3 o'clock the members again met in Huntington Hall, and listened to papers on *The Climatic Treatment of Phthisis*, by Harold Williams, M.D., of Boston.

How a Lesion of the Brain Results in that Disturbance of Consciousness Known as Aphasia, by Morton H. Prince, M.D., of Boston.

The Relation of Insanity to Certain Nervous Affections, by Henry R. Stedman, M.D., of Roslindale.

WEDNESDAY, JUNE 10TH.—SECOND DAY.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Charles D. Homans, M.D., of Boston.

Vice-President.—George N. Munsell, M.D., of Harwich.

Treasurer.—Frank W. Draper, M.D., of Boston.

Corresponding Secretary.—Charles M. Swan, M.D., of Boston.

Recording Secretary.—Francis W. Goss, M.D., of Roxbury.

Orator.—Richard M. Hodges, M.D., of Boston.

During the day, as upon the preceding day, there was an exhibition of electrical and new and original apparatus in the Technology Building. The apparatus used by Dr. J. Collins Warren for the sterilization of cotton was shown, and Dr. Vincent Y. Bowditch exhibited and demonstrated the use of the pneumatic aspirator devised by Dr. Herbert F. Williams, of Brooklyn, N. Y.

The business meeting was called to order at Huntington Hall at 9 o'clock in the morning, by the PRESIDENT, CHARLES D. HOMANS, M.D.

The reports of the Recording Secretary, Francis W. Goss, and the Treasurer, Dr. Draper, were presented.

At the last annual meeting a resolution offered by Dr. Asa Mullet, providing for more stringent relations regarding the

ADMISSION OF CANDIDATES

to the Society, was submitted to the consideration of a committee. Yesterday the committee reported adversely on the adoption of the resolution, and the report was adopted without debate.

A series of resolutions which have been adopted by superintendents of the various American institutions for the insane, petitioning Congress to pass a law prohibiting the

EMIGRATION OF THE DEFECTIVE CLASSES,

were adopted. The resolution set forth that while those persons who have emigrated to this country since 1847 compose with their descendants but one-eighth of the population, they furnish one-third of the paupers, one-third of the criminals, and one-third of the insane.

DR. JOHN O. MARBLE, of Worcester, then read a paper on

CREMATION IN ITS SANITARY ASPECT.

He urged the necessity of the universal adoption of cremation, and proved its superiority over all other methods of disposing of the dead, by a clear exposition of the great evils attendant upon them, referring of course particularly to the ordinary method of graveyard interment.

DR. WILLIAM L. RICHARDSON, of Boston, read a paper on the

DIAGNOSIS AND TREATMENT OF OCCIPITO-POSTERIOR POSITIONS.

He dwelt upon the great value of external palpation in the diagnosis of fœtal positions, and briefly described the method. He then described his method of flexing an extended head, by applying the forceps inverted.

DR. JOHN HOMANS, of Boston, then read a paper upon

THE INFLUENCE OF OVARIOTOMY ON SURGERY,

which was of great interest. He traced the progress which has been made in ovariotomy since it was first practised in 1809, and showed how out of it so many, if not nearly all, of the valuable abdominal operations of modern surgery had grown. He also spoke of the comparative innocuousness of simple abdominal incision the future which may be in store for it as a diagnostic and therapeutic measure.

DR. FRANKLIN K. PADDOCK, of Pittsfield, at 12 o'clock delivered

THE ANNUAL DISCOURSE.

He gave an interesting review of the history of wound treatment, and a clear concise description of the modern antiseptic method. He said, that although known to those of the members who had favorable opportunities of becoming familiar with and practising it, there are many members who do not make use of the antiseptic method, and perhaps even a few still who regard it with scepticism. He therefore felt called upon on this fitting occasion to urge upon the members the necessity and duty of adopting it.

A vote of thanks was given the speaker, after which the Fellows of the Society called in order of seniority, and headed by President Homans, marched to

THE DINNER.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Ninetieth Annual Meeting, held at Long Branch, June 9 and 10, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 9TH.—FIRST DAY.

The Society met in the dining-room of the Ocean House and there were one hundred and twenty-five members present, all the district societies being represented. There were also present Dr. Beckwith, delegate from the Medical Society of Connecticut, Dr. Anita E. Tyng, from the Medical Society of Rhode Island, Drs. E. S. F. Arnold, John P. Garrish, from the New York State Medical Association, Drs. W. R. Hoch, Albert Fricke, M. P. Hara, from the Medical Society of Pennsylvania.

DR. S. H. HUNT, as Chairman of the Committee of Arrangements, extended a cordial welcome to the members to Long Branch. He extolled the attractions of Long Branch and spoke enthusiastically of the new and successful winter resort.

DR. BUSBY, delegate to the Pennsylvania Medical Society, and DR. J. N. QUINBY, delegate to the American Medical Association, read their reports.

The Committee on Ethics reported no business.

The following committees were appointed:

Committee on Treasurer's Accounts.—Drs. J. G. Ryan, E. A. Marsh, D. C. English.

Nominating Committee.—Drs. Jas. S. Green, Chairman; E. North, D. A. Currie, Jos. Parrish, E. L. B. Godfrey, G. G. Carroll, W. F. Newell, Jos. Fewsmith, Jr., Geo. C. Laws, J. Paul, W. S. Creveling, J. L. Bodine, A. V. N. Baldwin, H. G. Norton, J. G. Rynson, R. L. Disbrow, W. K. Newton, L. W. Reed, C. R. P. Fisher, Douglas I. S. Clark.

Society adjourned until 7.30 P.M.

EVENING SESSION.

VICE PRESIDENT, DR. PARRISH, announced as the first order of business

THE ANNUAL ADDRESS,

by the PRESIDENT, DR. P. C. BARKER, of Morristown. His subject was, the *Present Status of the Germ Theory of Diseases.*

The address was a careful digest of our knowledge on this subject at the present time. He spoke of it as the Romance of Medicine, traced the origin of sanitary science, its progress and the many effects its development has had on our civilization. He pictured the condition of England during the visits of the plague, and the effect upon the world's history caused by epidemics. He then gave a succinct history of the origin and development of the theory. The first steps were taken when chemists commenced the study of ferments and fermentations. These phenomena suggested similar causes for disease to Boyle two hundred years ago. Then came the study of the causes of putrefaction and the experiments of Pasteur and Schroeder, and later, the discovery of the rods of splenic fever by Rayer and Davaine. After this came Lister and his wonderful revolution in surgery and surgical dressings. He then described minutely the different processes of liquid and dry cultivations, and the laws of life and conditions that are favorable or unfavorable to the various microorganisms. He used Colui's classification in describing these minute organisms, detailed the manner and means for examining microscopically and the effects of reagents. He further discussed the bacilli of cholera and tuberculosis, and Drs. Koch's and Ferrán's researches in cultivating and inoculating, respectively. He then gave a *résumé* of the logical deduction from this theory, and the lessons taught by recent epidemics and urged by sanitary science for the prevention of these diseases.

THE ANNUAL REPORT OF THE STANDING COMMITTEE

was then read by its Chairman, DR. T. J. SMITH. This report embodied those of the different medical societies in the State, and recorded the diseases which had prevailed in the several districts, and whatever was of interest to the profession in their various neighborhoods.

The report of the Treasurer, Dr. Phillips, was read and referred to the Committee on Treasurer's Accounts.

The report on *Medical Jurisprudence* was read by Dr. Godfrey, Chairman of the Committee.

THE REPORT OF THE CORRESPONDING SECRETARY,

DR. ELMER J. NEWTON, included the answers of the various county societies to the circular of the State Society regarding preliminary education. All approved the proposed change in the by-laws requiring a certain standard of education preliminary to beginning the study of medicine, and many societies indicated that they had already instituted such regulations in their respective counties.

WEDNESDAY, JUNE 10TH.—SECOND DAY.

MORNING SESSION.

DR. JOHN W. WARD, of the Trenton Asylum, read a paper on

GENERAL PARESIS.

This disease has obtained comparatively recent recognition, and the general practitioner is urged to, if possible, recognize the disease in its incipiency, because it presents a much more favorable chance for benefit from treatment. Although written of as early as the seventeenth century, it was not believed to be a disease *per se*, but a complication of insanity. Statistics show that the disease is on the increase.

It is divided into three stages: 1st, that of fibrillar tremblings; 2d, muscular incoördination and mental enfeeblement; 3d, advanced paresis and entire paralysis with complete loss of mind. The disease is first detected by the commission of some actions much at variance with the patient's character. Then the motor symptoms show themselves unmistakably, and advance step by step with the mental symptoms. The writer considers the disorder is always preceded by a period of melancholia. The first stage is marked by an inability to coördinate the movements of the tongue and slight loss of consciousness, with unusual acts of absentmindedness. The second stage is simply an exaggeration of the first. Ideas of an exalted and extravagant character supervene, and these delusions are characteristic. The mental symptoms may have an almost entire cessation for a short period, but the motor manifestations do not remit, and the general health is not much deteriorated. The third stage is usually ushered in by one or more epileptiform seizures, and a depreciation of the general condition commences, which is progressive in character, and accompanied by a loss of coördination and an absolute loss of mind. Treatment, if ever beneficial, may be so in the beginning of the first stage. The disease is to be differentiated from muscular atrophy, lead poisoning, mercurial poisoning, and locomotor ataxia. These diseases have characteristics which render them not likely to be mistaken. It is usually confined to middle life, more common in men than women and is probably not hereditary. Sexual excess is probably an important etiological factor, although writers are not agreed as to its influence. Some cases show meningeal thickening and adhesions to the skull, others show changes in the gray matter of the brain and the medulla oblongata and upper part of the spinal cord, but there are no characteristic pathological changes.

The prognosis is uniformly bad, as no authentic cases of recovery can be cited. The average duration of the disease is about three years from the time of observance of the first symptoms, but death usually occurs from some intercurrent disease. Treatment has thus far availed nothing. The administration of the bromides as the indications demand, is probably the best. The author has given ergotine a trial with no satisfactory results.

DR. JAMES, the appointed essayist, was prevented from being present at the meeting on account of serious illness. It was voted that he be requested to place a copy of his paper, *Toleration in Medicine*, in the hands of the proper committee for publication in the *Transactions*.

THE JUDICIAL COMMITTEE

recommended that the circular in regard to membership of the American Medical Association, be published in the *Transactions*, also, that the proposed "Act to Establish State Board of Medical Examiners and Licensers," received from the American Medical Association, be referred to the Committee on Education, and that in reference to the communication from the Nebraska Society, the Corresponding Secretary reply that the exchange of reports would seem to cover the objects sought by the scheme proposed. The report was, on motion, adopted.

THE COMMITTEE ON EDUCATION

made an exhaustive report as to "what is feasible to test the competency of graduates of various medical colleges, who hereafter seek to settle in this State," ending with the following propositions:

1. That the power of licensure to the practice of physic and surgery in this State ought to be separated from the function of teaching, and be invested in some authority within the State.

2. That, in the opinion of this Society, the Governor of the State is the proper authority in whom this power should be invested.

3. That in order that this power may be intelligently exercised, all persons whatever seeking to practise physic and surgery in this State, before licensure by the Governor, ought to be thoroughly, carefully, and impartially examined by a competent medical board, who should require the usual evidences demanded by colleges of the first class, of previous study, etc.

4. That it is the opinion of this Society that the board of examiners should be composed of seven of the members of the Medical Society of New Jersey, who have been in practice not less than five years and have received the degree of Doctor of Medicine, selected by the Governor from a list of twelve persons nominated by the said Medical Society.

5. If the appointment of such a board be not feasible, this Society will not disapprove of the formation of two boards appointed from the two Medical Societies of the State, providing that the qualifications in Article III. be required of every applicant.

6. This Society does not approve of a mixed board of persons holding antagonistic theories of medicine, etc.

7. That this Society does not deem it expedient for this Society, in its corporate capacity, to make application to the Legislature of the State for an amendment to its Act of incorporation to accomplish the object contemplated, but would respectfully recommend the State Board of Health to take measures to bring the subject to the consideration of the Legislature. Action on this report was postponed one year.

THE STANDING COMMITTEE

reported the following amendment to By-Law, Chapter III.

Board of Examiners.

Sec. 1.—The Standing Committee shall appoint at the Annual Meeting each year two Boards of Examiners, one for the Northern and one for the Southern District of the State. Each Board shall consist of five members to be selected from among the members of the district societies of the respective portion of the State.

Sec. 2.—The Northern District shall comprise the counties of Bergen, Passaic, Sussex, Warren, Morris, Essex, Hunterdon, Hudson, Union, and Middlesex. The Southern District, the counties of Monmouth, Mercer, Ocean, Burlington, Camden, Gloucester, Atlantic, Salem, Cumberland, and Cape May.

Sec. 3.—It shall be the duty of the Board to examine the credentials and qualifications of all persons contemplating the study of medicine in the State. Every applicant shall be required to present to the Board a diploma from some reputable college, or a certificate of a completed course of study in a reputable school where the following branches of learning and science have been taught, viz., English language and literature, and history. Mathematics including arithemetic, algebra, and geometry. Latin language, including its grammar, and ability to translate with facility the books of the Commentaries of Cæsar, the Orations of Cicero, and two books of Æneid of Virgil. Greek language, including its grammar, the Anabasis of Xenophon, and two books of the Iliad of Homer. Intellectual and moral philosophy, logic, rhetoric, descriptive and physical geography, and the elements of physics, chemistry, and natural history, including botany and zoölogy. In case the applicant possesses no such diploma or certificate, the Board shall proceed to examine him in these branches. The Board shall also require evidence of certificate or otherwise as to the moral character of all applicants. If the examination is satisfactory, a certificate shall be given by the Board to the applicant, commending him as a suitably qualified person to be received under the care of a physician for medical instruction.

Sec. 4.—The Boards shall meet on the first Tuesday in March and September of each year, the Northern Board in Newark and the Southern Board in Camden.

Sec. 5.—An allowance of ten dollars per day, when in session, shall be paid by the Treasurer of the Society on the order of the President of the Board to each member of the Board for his services.

Sec. 6.—These Boards shall report through their Presidents to the Standing Committee each year, at least one week prior to the annual meeting, giving the number of days in session, the number of applicants examined, and the results of the examinations.

Sec. 7.—Each district society shall provide in its by-laws that its members obligate themselves, under penalty

of forfeiture of membership, to receive no person under their care as a student of medicine who has not passed the necessary examination, and received the approval of one of the Boards of Examiners of this Society.

Sec. 8.—Any member of a district society may, however, receive a student of medicine during the interim of the meetings of the Board, provided that he notify the President of the Board of Examiners for his district that he has received such student. But all students so received shall appear before the Boards of Examiners at their first meeting thereafter, and obtain the certificate required.

On motion, the report was received and referred to the next annual meeting.

THE COMMITTEE ON TREASURER'S ACCOUNTS

reported that they had examined the said accounts, and found them correct, as follows:

Receipts for 1883	$262.19
From district societies	1124 00
Interest on U. S. bonds	62.00
	1448.19
Disbursements paid as per vouchers	614.77
Balance,	$833.42

The Committee further stated that the Treasurer reports:

U. S. 4 per cent. registered bonds at par value	$1550.00
Amount in Newark Savings Bank	182.85
Total,	$1732.85

The Committee recommend: 1. That the Treasurer be instructed to purchase for the Society, out of the funds in his hands, one $500 U. S. 4 per cent. registered bond, and that he shall present all the assets in his possession for examination at each annual meeting. 2. That the Treasurer be instructed to renew his bond for five thousand dollars. 3. That the assessment of the district societies be $1.50 per capita.

The report was adopted.

DR. WICKES on behalf of the Committee on

REVISION OF THE BY-LAWS,

read its report.

The report was adopted and the Committee instructed to have 1000 copies printed in pamphlet form.

The Business Committee gave as the

SUBJECT FOR DISCUSSION

at the next annual meeting, *The Therapeutical Action of Hydrochlorate of Cocaine.*

THE NOMINATING COMMITTEE

presented the following report:

President.—Joseph Parrish, M.D., of Burlington.

Vice-Presidents.—Charles J. Kipp, M.D., of Newark; John W. Ward, M.D., of Trenton; H. Genet Taylor, M.D., of Camden.

Corresponding Secretary.—Wm. Elmer, Jr., M.D., of Trenton.

Recording Secretary.—Wm. Pierson, M.D., of Orange.

Treasurer.—W. W. L. Phillips, M.D., of Trenton.

Standing Committee.—T. J. Smith, M.D., E. J. Marsh, M.D., D. C. English, M.D.,

The Committee recommended that the *Next Annual Meeting* of the Society be held at Spring Lake, Monmouth Co., on the second Tuesday of June, 1886.

The report was adopted.

The Society adjourned to meet at Spring Lake on the second Tuesday in June, 1886.

MAINE MEDICAL ASSOCIATION.

Thirty-third Annual Meeting, held at Portland, June 9, 10, and 11, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 9TH.—FIRST DAY.

MORNING SESSION.

THE Association met at 10 o'clock, in the Common Council Chambers, City Building, and was called to order by the PRESIDENT, DR. T. A. FOSTER, of Portland.

THE TREASURER'S REPORT.

DR. A. S. THAYER reported on hand at last annual report $618.47. The receipts from new members, annual tax, sale of *Transactions*, and dividends increase this to $1166.12. Cash has been paid out for necessary expenses $448.78, leaving in the hands of Treasurer, $717.34.

COMMUNICATIONS

relative to the immigration of the defective classes, from the President of the American Association of Insane Hospital Superintendents, and one on preliminary education for medical students, from the New Jersey Medical Association, were referred to the Board of Censors.

A letter from the Nebraska Medical Society, relating to a system of interstate medical society representation, was referred to a committee of three for a report at the session of 1886.

A committee consisting of Drs. A. T. Fuller, of Bath, J. B. Walker, of Thomaston, and Sumner Laughton, of Bangor, was appointed to visit

THE MAINE INSANE HOSPITAL

on behalf of the Association.

DR. A. T. FULLER, of Bath, presented the

REPORT OF VISITORS TO MEDICAL SCHOOL OF MAINE.

They stated that their visits to the School during the past term had been frequent and thorough. No criticism could be made upon the instruction afforded or the scholarship of the graduating class. The new plan of formal graduating exercises was commended. The committee expressed itself as opposed to the plan of yearly examinations now in vogue.

DR. CHAS. R. CRANDALL, of Portland, read a paper on

ABDOMINAL SURGERY: ITS GROWTH AND TRIUMPHS.

DR. S. C. GORDON, in the discussion following this paper, reported a case of hemorrhage from the kidney consequent upon injury. The patient, while working beneath a car, suddenly straightened up and struck his back, over the left kidney, against a projecting bolt. This was followed by severe pain and free hemorrhage, and the expulsion of clots evidently from the ureters, often ten and twelve inches in length. Several of these clots were declared, by certain botanic practitioners who

attended him, to be "palisade worms" of the kidney. He gradually recovered in part, and has for the past year and a half been subject to repeated hemorrhages, often to the amount of a quart at a time. Life has become a burden to him, and he is ready for anything that promises relief. He proposed to make nephrectomy through an abdominal incision, and considered this a favorable case for such operation.

Dr. S. H. Weeks would operate by lumbar incision along the lower border of the last rib, four or five inches forward, as in Bryant's operation, if the operation were for other than cystic disease; in that case, he would use laparotomy.

Afternoon Session

Dr. T. A. Foster, of Portland, delivered the

president's address,

in which he outlined the growth of the Association, and defined its relations with other organizations. An organization like this is like an individual: its separate members, its tissues, which through segregation form the organs through which its various functions are manifested. It has its emotions and passions to be checked, its reasons and judgments to be tempered with justice, its ossified or crystallized ideas to be melted in the crucible of liberal investigation, its hereditary superstitions to be swept away by a more common-sense view of things; it has also its element of passiveness, its tendency to inactivity, its lack of self-respect. Unless the proper adjustment of its internal relations is maintained, it will be difficult to attend to the adjustment of its external relations. The relations of the Society and its members to other societies, trades, and professions, were shown by carefully arranged tables; one of these gave the name, residence, and school of practice, and classification into counties. In Maine there are 879 recognized physicians, a decrease of 100 in four years. In Cumberland County, the most populous, the ratio of physicians to the public at large is 1 to 585; while in Aroostock County it is 1 to 1263. There are 693 regular physicians in the State; of these 257 are members of this Association. It was recommended that measures be taken to increase the membership.

The speaker considered the relations of the Society to the question of codes and charlatans, which were both best let alone; to the retail druggist, and the profession at large, the institutions for medical instruction, and the legal profession; with regard to the latter, it might be said that in no direction were these of more importance than in the legislative halls. Physicians, as a rule, are poor lobbyists, and numbers of them in a body seem to have a terrifying effect upon legislative committees. More could be accomplished in securing medical legislation by laboring with members at home prior to sessions. A State Board of Health has, after years of struggle, been secured; how long it will require to secure a registration act remains to be seen.

Of the relations of the medical profession to the press, the speaker said: "So far as it touches our profession, it is strongly in favor of irregular practice and quack medicines. Doubtless this results from its adopted rules of action based upon business principles. The community is evidently highly sensational, it demands startling news, it loves humbuggery, and never is so well satisfied as when thoroughly imposed upon. The successful reporter is he who bores the hardest and always brings oil, either from his boring or his imagination. On this rule charlatanry is based, hence the natural sympathy between it and the press. The rule of action of the regular physician is modest and consistent secrecy, and when through the action of the press, or in any other way, this rule is broken, as it was to a marked degree in Garfield's case, and has so recently been to a most mortifying degree in the case of General Grant, we can but feel that a lasting injury, if not disgrace, comes to the profession."

Relations with irregular practitioners are easily enough adjusted; retaliation upon such elevates them to our footing and degrades us to theirs. Relations to the general public may be considered under three heads: with the wealthy, with the honest poor, and with the criminal classes. From the rich we must look for and demand the fullest reward for our services, from the poor be not too eager to exact the pound of flesh. All over the country, the criminal classes are made the special objects of sympathy by an army of so-called philanthropists. Crime is thus cultivated as surely as the farmer cultivates his crops of corn and potatoes, and this mass of criminals are to the body politic what undigested food and effete matter are to the individual. Philanthropy acts as an opiate and the tardy and ineffectual operations of the law is like habitual constipation.

Such seed is sown broadcast and encouraged by the legal marriage of the criminal classes, not only outside but inside of jails, penitentiaries, and workhouses; as an organization, the profession should protest against such proceedings.

In no way should the physician assume the duties of the lawyer in dealing with crime, neither should he act the clergyman in his attempts to prevent sin, but he should be found in the front ranks of true moralists, realizing the fact that vice in all its forms invites disease.

Dr. Jas. A. Spalding, broached a plan for the formation of a

physicians' mutual aid society,

similar to that in operation in New York, and the matter was referred to a special committee, which subsequently reported asking a continuation of the question till next year. It was deferred.

Dr. B. T. Sanborn, Superintendant of the Maine Insane Hospital, read an interesting paper on

acute melancholia.

The conclusion was as to treatment, that diversion and employment afforded the strongest hope of successful treatment.

operation for external urethrotomy.

Dr. E. H. Hill, of Lewiston, detailed a case of operation after removal of an epithelioma of the penis. No meatus could be found. At the peno-scrotal junction, without a guide, the canal was opened, and a grooved staff introduced into the bladder. The tissues were divided from the centre of the perineum forward to the opening with one sweep of the knife. The urethra was dissected and detached from the cavernous bodies, and transversely divided. Its free extremity was brought to

the upper commissure of the perineal wound, and its longitudinal edges stitched to the skin, leaving exposed a urethral opening fully one inch in length. The cavernous bodies were transfixed with a knitting-needle to prevent retraction of the stump, the better to secure any bleeding vessels, and to make two curvilinear incisions, one on each side at the root of the penis, beginning in the median line at about one and a half inches above the pubes and ending a little above the penoscrotal junction, and to sever the organ with scissors. The actual cautery was applied, the fold of skin brought over the stump, united, and a drainage-tube inserted. Catheter was required for only two days. The patient lived a little over a year, and succumbed to a return of the disease.

Dr. S. C. Gordon, of Portland, described

A NEW PERINEAL OPERATION,

having for its object a lessening of the calibre of the vagina, as well as restoration of the perineal body. This was accomplished by making a U-shaped denudation having the perineum for its base, and its arms extending up the sides of the vagina. Then with a single needle armed with No. 1 or No. 2 catgut, beginning at the extremity of one of the arms, the denudation is closed by continuous suture to the base; this is repeated on the other side; finally, the perineal denudation is closed. Thus the vagina is at once shortened and contracted. He would not use wire sutures unless there was extreme uterine retroversion. Then he puts in place a pessary, and makes the operation outside.

Evening Session.

Dr. F. H. Gerrish read a paper on

MORPHINE AS A SUBSTITUTE FOR HANGING, IN THE EXECUTION OF CRIMINALS.

The following resolution was introduced:

"*Resolved*, That in the opinion of the Maine Medical Association, the execution of criminals by hanging should be abolished, and poisoning by the hypodermic injection of morphine substituted therefor."

After a somewhat rambling discussion on the merits of capital punishment, the resolution, which had not been discussed, was laid upon the table.

Dr. I. T. Dana read a paper dealing with

CHRONIC BRIGHT'S DISEASE,

more particularly referring to treatment by fulfilling certain indications: 1. To avert hyperæmia and inflammation of the kidneys. 2. To unload obstructed tubules. 3. To build up the blood and promote nutrition. 4. To improve the condition of the nerve-centres. 5. To promote elimination of urea and other excrementitious elements from the blood. 6. To evacuate dropsical accumulations. 7. To sustain the heart. 8. To relieve distress from dyspnœa.

Wednesday, June 10th.—Second Day.

Morning Session.

Dr. A. S. Thayer reported cases of

ACUTE RHEUMATISM TREATED BY ADMINISTRATION OF SALICIN.

Dr. C. O. Hunt favored topical application of salicylic acid in olive oil, in the proportion of two drachms to an ounce, when the stomach revolted.

Dr. S. P. Warren advocated oil of gaultheria, one-half drachm in water and glycerine every two hours.

Dr. H. F. Twitchell, of Freeport, reported

A CASE OF PLACENTA PRÆVIA CENTRALIS,

arguing as a cause a fall received six weeks after cessation of menstruation.

Prof. Alfred Mitchell, of Brunswick, did not favor the theory of causation. In cases of placenta prævia, he would turn by the bipolar method, and allow nature to complete delivery slowly.

Dr. Boardman, of Boston, said his experience was, that premature labor should be induced and completed without delay. He thought it a great mistake to wait, and had known of six cases of fatal hemorrhage within a short time from mistaken waiting, and relying on stimulation to prepare the patient for the operation. Such surgical obstetrics he did not believe in: while waiting for the woman's strength to return, death comes in its stead.

Dr. E. E. Holt, of Portland, read a paper based upon his first series of

100 CASES OF CATARACT OPERATION.

Special reference was made to causation. The history of the growth of the lens was illustrated by diagrams, and its bearing upon the formation of cataract pointed out. Methods of operating and bandaging were illustrated upon a mask. The discovery of Kohler, in producing anæsthesia by cocaine hydrochlorate, has been of more value to ophthalmology than any other since the invention of the ophthalmoscope.

THE COMMITTEE ON REMOVAL OF THE MAINE MEDICAL SCHOOL

reported that they had conferred with the committee from the Faculty of the School, Alumni Association, and Trustees of Bowdoin College, that the sentiment was favorable, but it would necessarily be referred to the Trustees for further action.

THE COMMITTEE ON INVITATION TO THE AMERICAN MEDICAL ASSOCIATION

to hold the meeting of 1886 in Portland reported that, from inability to raise a sufficient fund to cover estimated expenses it was thought best, after consultation with the President and Chairman of the Censors, to report action inexpedient. The report was accepted.

THE ELECTION OF OFFICERS

resulted as follows:

President.—Sumner Laughton, M.D., of Bangor.

Vice-Presidents.—C. G. Actams, M.D., of Portland; F. E. Hitchcock, M.D., of Rockland.

Permanent Secretary.—Charles D. Smith, M.D., of Portland.

Treasurer.—A. S. Thayer, M.D., of Portland.

Corresponding Secretary.—J. C. Caldwell, M.D., of Buckfield.

Board of Censors.—Geo. H. Cummings, M.D., of Portland; B. F. Sturgis, M.D., of Auburn; E. Adams, M.D., of Litchfield; H. E. Hill, M.D., of Saco; A. L. Hersey, M.D., of Oxford.

Dr. S. H. Weeks made some extended remarks upon the symptoms, diagnosis, and treatment of

FRACTURES OF THE NECK OF THE FEMUR.

Two interesting specimens were exhibited, one of an intracapsular fracture, showing bony union; the other impacted fracture, also intracapsular. In the latter case no symptoms or signs of fracture could be detected for two weeks after the injury, although the subject was a hospital patient and under constant observation. In the discussion, Dr. Oakes, of Auburn, advocated the plaster-of-Paris dressing as valuable in allowing patients to get up from the bed at once and escape the debilitating confinement consequent upon the usual mode of dressing.

Dr. Charles D. Smith, of Portland, exhibited a specimen of comminuted intracapsular fracture extending from behind upward and forward, and involving nearly one-third of the head. This was removed from a man seventy-nine years of age, who died one week after injury, never having rallied from the shock. The injury was received by a fall forward upon all fours, and when seen one hour afterward presented the unusual symptom of *marked inversion* of the foot; the great trochanter formed a prominent protuberance on the front of the thigh; crepitus could not be detected at the post mortem; the capsule was found much lacerated, and pus within and without the joint.

Dr. Allen, of Camden, read a paper on a case of *Displaced Ovary and Phantom Tumor.*

Dr. S. C. Gordon reported

CASES OF TAIT'S OPERATION.

He doubted the ability of any one invariably to detect disease by conjoined touch; in his experience he had always depended upon other symptoms than touch, and his diagnosis had been abundantly proven by other symptoms.

Dr. Boardman thought the value of Tait's operation could not be overestimated; it should, however, be restricted to cases of demonstrable disease, and with this view exploratory incision might be made, and would be perfectly justifiable.

Dr. J. O. Webster, of Augusta, read a paper based upon

HEALTH STATUTES,

passed by the last legislature of Maine. Its conclusions were:

1. A local board of health should be established in every city and town of considerable size.

2. It should be an independent board, not containing any other municipal officers ex-officio, all its members to be elected with sole reference to their fitness for this work.

3. The members of the board, or its executive officer, if it have one, should receive reasonable compensation.

4. Such local health regulations as the board may find necessary, in addition to their powers under the State law, should be adopted as by-laws or ordinances by the town or city.

Evening Session.

Dr. S. H. Weeks, of Portland, delivered

THE ANNUAL ORATION,

an able effort devoted to a *Review of Modern Medicine*, the essentials for success in its practice, and forecasting what remains to be done.

While progress has been made in the pathology and management of most diseases, especially of those affecting the kidneys, heart, and lungs, what marked gain has there been in curing and preventing disease during the present century at all analogous to that discovery by Jenner in the last?

The father of medicine taught that deep-seated cancers have a fatal termination sooner when meddled with than when left to themselves. What better prediction can be made after an experience of two thousand years? One-half the human race continues to die in infancy and early childhood. Phthisis in all nations still destroys one-sixth of all who die. Cholera continues to spread, and yellow fever bids defiance to the resources of medical skill. Diphtheria still desolates the families of rich and poor. Bright's disease and valvular lesions of the heart are still incurable.

General paresis saps mind and life; locomotor ataxia totters and stumbles into the tomb; and typhus and typhoid fevers, measles, and scarlatina run their accustomed course, modified, but not cut short a single hour. And to-day our best medical authorities admit that, while contagious and infectious fevers, and other self-limited diseases, may be watched and guided, they cannot always be cured. It is hoped this will not always remain true.

Medicine can only advance by the education of the profession; the development of a higher standard has and will keep pace with that of every other phase of human life.

A warm tribute was paid to the ability represented by the new State Board of Health, finally obtained after years of labor; and the hope expressed that its efforts, aided by those of this Society, may produce a rich harvest.

At the close of the oration, the members, their ladies, and delegates from other societies, were entertained at a reception given by the retiring President, Dr. T. H. Foster. Members of the Association, and delegates were also entertained by Dr. E. E. Holt, at his residence on Congress street.

Thursday, January 11th.—Third Day.

Closing Session.

Dr. Chas. D. Smith, of Portland; Sumner Laughton, of Bangor; and J. C. Caldwell, of Buckfield, were appointed a committee on

INTERSTATE REPRESENTATION.

Dr. F. H. Gerrish, chairman of committee to obtain a

STATE BOARD OF HEALTH,

reported that a satisfactory law had been passed. The Board organized and work has begun.

The Board is made up of Dr. F. H. Gerrish, of Portland, Chairman; Dr. C. E. Young, of Augusta, Secretary; Dr. J. O. Webster, of Augusta; Dr. O. A. Horr, of Lewiston; Hon. S. J. Young, of Brunswick; Hon. Lewis Barker, of Bangor; E. C. Jordon, Esq., of Portland.

The law establishing this Board has been secured by the efforts of the Maine Medical Association acting alone, with little or no help from the public, and the Committee which, after years of trial and discourage-

ment, have finally accomplished the object, was composed of Drs. F. H. Gerrish, of Portland; S. H. Weeks, of Portland; J. M. Bates, of Yarmouth.

The Committee appointed to consider the

RECOMMENDATIONS OF THE PRESIDENT'S ADDRESS,

reported that, without reference to the indiscriminate refilling of prescriptions by retail druggists, a committee should be appointed to devise some method of prevention, and report in 1886; a recommendation was also made to increase the number of representatives to other State societies as deemed advisable.

A new committee on the

MEDICAL REGISTRATION BILL

was appointed, with Dr. J. M. Bates as Chairman.

The date of the *next annual meeting* was fixed for June 1, 1886, and the place Portland.

LECTURESHIP ON PUBLIC HYGIENE.

Dr. J. O. Webster offered the following resolutions, which were adopted without dissent:

Resolved, That, in the opinion of this Association, a Lectureship on Public Hygiene should be established in the Medical School of Maine, with an annual course of not less than six lectures.

Resolved, That the Secretary send copies of this resolution to the Trustees of Bowdoin College, and the Faculty of the school.

After the usual votes of thanks, the Association adjourned.

CORRESPONDENCE.

THE INTERNATIONAL SANITARY CONFERENCE AT ROME.

Rome, May 30, 1884.

The International Sanitary Conference has now been in session for ten days, and it is evident that notwithstanding the warm weather and the general desire to get away from Rome as soon as possible, there is little prospect of adjournment before the middle of June.

The following countries are represented either by one or more technical delegates, or by a diplomatic delegate, or by both, viz.: Germany, Argentine Republic, Austria, Belgium, Brazil, Chili, China, Denmark, Spain, United States, France, Great Britain, Greece, Guatemala, India, Italy, Japan, Mexico, Holland, Peru, Portugal, Roumania, Russia, Servia, Sweden and Norway, Switzerland, Turkey, and Uraguay.

The names of many of the technical delegates are quite unknown in our country, but the names of a few of those who are most prominent, and who exercise the most influence in the Conference may be mentioned.

It is proper to say first that the Conference was organized by the election of the Italian diplomatic delegate, Cadorna, as President. No vice-presidents were elected, the President being authorized to name a presiding officer for the day in case of his inability to attend the session.

S. Exc. le Chev. Cadorna, President of the Council of State, Minister of State, Senator, etc., is an old gentleman who may be an accomplished diplomat, but who was evidently not equal to the task of directing the discussions of the technical delegates present, and this for several reasons, the principal one being that he does not understand either English or German, and that several of the delegates speak only in one or the other of these languages. Thus the English delegates, with the exception of Dr. Thorne, who speaks French quite fluently, use their own language in addressing the Conference. Dr. Koch and the delegate from Austria, Dr. Hofmann, always speak in German, the Spanish delegate makes flowery speeches in pure Castilian, while one of the Italian delegates makes it a point to address the Conference in his native tongue. With a President who understood only the Italian and the French, the Conference was like a ship at sea without a rudder.

Fortunately this difficulty had been anticipated, and by a preconcerted arrangement a subsection, comprising the technical delegates alone, was at once organized, with the accomplished Dr. Moleschott as president. It would be difficult to find another man equally qualified for the position. Originally from Holland, Dr. Moleschott has been for many years engaged in the practice of medicine in Rome. He is a professor in the University of Rome, a life-senator of Italy, and a man of varied acquirements, scientific and literary. But, above all, he is a polyglot; he understands, and speaks with facility, all of the languages above mentioned; and he has a happy faculty for giving a *résumé* in a few words, in French, which is recognized as the official language of the Conference, of a long-winded address delivered in English, German, Spanish, or Italian. I should say here, that the longest address is limited to ten minutes, in accordance with a resolution introduced by Sir Joseph Fayrer, one of the delegates from India.

Dr. Koch, the delegate from Germany, both on account of his fame, and the respect with which his opinions are received by a majority of the delegates present, is perhaps the most prominent and influential member of the Conference. He has not made any long speeches, and has taken special pains to avoid all reference to his "comma-bacillus," not because he has lost faith in it, but as a matter of prudence. At his suggestion, and by common consent, it was agreed at the outset that all disputed questions relating to etiology should be avoided, and that the Conference should occupy itself entirely with practical questions relating to the prevention of cholera, and thus far all efforts to consider any other disease have failed, and there is a manifest intention on the part of the European delegates to confine the discussions to this disease alone. They intimate that questions relating to yellow fever and other epidemic diseases may be brought up later, if desired, but it is evident that they will not be willing to give any considerable time to their discussion, and that there will be a strong pressure for immediate adjournment as soon as the questions relating to the prevention of cholera have been disposed of.

The delegates from Great Britain are Sir W. G. Hunter, M.D., and Dr. Thorne Thorne, of the Local Government Board. The Indian government is also represented by two delegates, viz., Sir Joseph Fayrer, M.D., and Dr. T. R. Lewis, Surgeon in the English Army and Professor at Netley. The French delegates are Drs. Brouardel, Proust, and Rochard. Russia sends but a single technical delegate, Dr. Eck. From Portugal there is the accomplished Dr. Silva Amado, who was a

delegate to the Sanitary Conference of Washington, in 1881. The Spanish delegate is Dr. Taboada. Turkey is represented by Dr. Zohéros Pacha; Austria, by Prof. Hofmann; Holland, by Dr. Ruysch; Switzerland, by Drs. Sonderegger and Reali; Sweden and Norway, by Drs. Bergman and Dahl; Italy, by Drs. Baccelli, Moleschott, Semmola, and Buonomo.

The first working session of the subsection composed of technical delegates, was held on the afternoon of May 23d, and the ball was opened by the introduction, by the delegate from the United States, of the following proposition:

"Experience has demonstrated that land quarantines and sanitary cordons are impotent to arrest the progress of an epidemic of cholera; they are, therefore, unjustifiable."

After a full discussion, the wording of this proposition was changed, at the suggestion of M. Rochard, as follows:

"Land quarantines and sanitary cordons are useless."

This was adopted by a vote of twenty in the affirmative, against one negative vote, which was cast by the delegate from Turkey.

At the next session the delegate from the United States introduced the following proposition, which gave rise to a protracted discussion upon the subject of maritime quarantine, and developed the views of the leading delegates present upon this important question:

"An arbitrary time quarantine for vessels and persons arriving from cholera-infected ports is not justified by experience, is often attended with great inhumanity, and tends to prevent true sanitary progress."

The debate upon this proposition was renewed at the following session, but was terminated by its withdrawal in favor of a programme introduced by the French delegation, which approached the question in a different way. In withdrawing his proposition the delegate from the United States remarked that he was not disposed to deny the value of a rational quarantine, but that the proposition introduced by him, which had served as the basis of the discussion which had taken place, was in opposition to an "*arbitrary time quarantine for persons and vessels.*"

The programme submitted by M. Brouardel, of the French delegation, was as follows:

Measures to be taken against the propagation of cholera by ships ("*par voie de mer*"):

1st. Importance of the salubrity of ports. Information relating to the sanitary condition of ports of departure (endemic or epidemic diseases).

2d. *Ships at sea* ("*trajet*"). Disinfection on board; independence of physician; isolation of the sick: ports not infected, without sick. Special question, *The Red Sea.*

3d. *Port of entry.* Ships coming from ports not infected, without sick, not to be detained. Ships coming from a suspected port to be inspected, continuation of sanitary measures taken at the point of departure and during journey. Infected ships; debarkation and isolation of the sick and of the passengers; disinfection of vessels; ships transporting merchandise and rags; ships transporting pilgrims and troops. Special measures; return of pilgrims from Mecca; *Caspian Sea.*

This programme having been unanimously adopted as the basis for further discussion, and the importance of maintaining the "salubrity of ports" being admitted unanimously, the question relating to "information relating to the sanitary condition of ports of departure" was taken up. The following proposition, submitted by Dr. Silva Amado, was adopted:

"Consuls should be permitted to obtain information from the local sanitary authorities of ports and cities (*des villes principales*), so that they may be enabled to visé bills of health, and if necessary to give precise information by telegraph to their Governments." The vote upon this proposition was *Yeas*, 10; *Nays*, 2; declined to vote, 8.

As this proposition did not include the right to visit a ship about to sail, and as this was considered a point of extreme importance by the American delegates to the Washington Conference of 1881, the delegate from the United States introduced the following proposition:

"Consuls should be permitted to verify the exact sanitary condition of vessels about to sail for ports in the country which they represent by a personal inspection, or by an inspection made by a physician authorized to represent them." This proposition was made the order of the day for the next session, and upon the reassembling of the Conference was debated at length.

While most of the delegates admitted the propriety of such an inspection being made, there was great opposition to the form of the proposition which made it the duty of *Consuls* to make or cause to be made the inspection contemplated. The delegate from the United States therefore modified the proposition as follows:

"It is desirable that the exact sanitary condition of ships about to sail should be verified by a personal inspection made by a duly authorized agent of the country of destination." The vote upon this proposition was as follows: *Yeas*, United States and Italy, 2; *Nays*, Austria, Denmark, Spain, Japan, Holland, Roumania, Russia, Servia, Sweden, 9. Abstained from voting, Germany, Hungary, Brazil, France, Great Britain, India, Mexico, Portugal, Norway, Switzerland, Turkey, 11.

This vote shows clearly that the opposition which the National Board of Health met with in an attempt to obtain the consent of the various powers to a similar proposition, through their delegates to the Washington Conference, is as strong to-day as it was in 1881.

A vote was next taken upon a proposition, submitted by Dr. Silva Amado, to the effect that "the consul of the country of destination should have the right to *assist* at the sanitary inspection of a vessel destined for his country, made by the local sanitary authorities, in accordance with rules to be established by an international convention." This was passed by a vote of 8 affirmative, against 6 negative, with 8 abstentions. It is evident that a proposition which has received so little support from the technical delegates is not likely to be received with much favor by the diplomats, and will not form part of an international sanitary convention. Indeed there seems to be little prospect at present that the Conference of Rome will be any more successful than was that of Washington, of Vienna, or of Constantinople, in reconciling differences of opinion, and national jealousies and prejudices, to such an extent as to make an international convention practicable

Rome, June 3, 1885.

In my last letter I referred to the disfavor with which the Conference received the proposition of the delegate from the United States, to the effect that the sanitary condition of vessels about to sail should be verified by a personal examination made by an authorized agent of the country to which it is destined. This question has again been brought before the Conference by the report of a special committee, and at last the propriety of such an examination has been recognized by a vote of 20 to 1. The first two paragraphs of the report referred to read as follows:

"1. From a sanitary point of view, it is necessary to distinguish two classes of vessels, those which have a physician on board and those which have not. We consider the latter as little ships (*petits navires*), whatever may be their tonnage or the number of their crew; whether they are propelled by steam or by sails."

"II. The captain of these vessels not provided with a physician—"*petits navires*"—should address himself to the *consul of the country to which his vessel is destined*, in order that his ship may be inspected by a physician before it is loaded, and for an examination of his passengers. This examination is independent of the inspection made by the local sanitary authorities."

The second paragraph above quoted, as reported by the committee, read, "The captain, etc., should address himself to *the consul of his nationality*." The delegate from the United States insisted upon changing this to the consul of the country of destination. This amendment was effected, and the paragraph adopted by a vote of 20 to 1.

At the session of May 27th, the delegate from the United States proposed that a committee should be appointed to consider the question of disinfection. This proposition having been favorably received, the President appointed the following committee: Sternberg (U. S.), Koch (Germany), Proust (France), Thorne Thorne (England), Eck (Russia), Semmola (Italy), and Hofmann (Austria).

At the first meeting of the committee the delegate from the United States, who had been named first by the President, proposed that Dr. Koch should be made the chairman of the committee. This was agreed to, and after several protracted sessions, the following report was unanimously adopted:

The committee recommends as means of disinfection against cholera:

1. Steam at 100° C. (212° Fahr.).
2. Carbolic acid, chloride of lime.
3. Aëration.

Carbolic acid and chloride of lime are to be used in aqueous solution:

Weak Solutions: Carbolic acid, 2 per cent.; chloride of lime, 1 per cent.

Strong Solutions: Carbolic acid, 5 per cent.; chloride of lime, 4 per cent.

These means of disinfection will be applied as follows:

I. For the disinfection of person the weak solutions should be employed.

II. For the disinfection of clothing, bedding (*des linges, des habits, des couvertures*), and other articles of this kind:

(*a*) destruction; (*b*) steam passed through the articles for one hour; (*c*) boiling for thirty minutes; (*d*) immersion for twenty-four hours in one of the weak disinfecting solutions; (*e*) aëration for three or four weeks, but only in case the other means recommended are inapplicable.

Articles of leather, such as trunks, boots, etc., should be either destroyed or washed several times with one of the weak disinfecting solutions.

III. Vomited matters and the dejections of the sick should be mixed with one of the strong disinfecting solutions, in quantity at least equal to the amount of material to be disinfected. Linen, clothing, bedding, etc., recently soiled by the dejections of the sick, which cannot be immediately subjected to the action of steam, should be at once immersed in one of the strong disinfecting solutions, and left for four hours.

IV. The dead should be enveloped in a sheet saturated with one of the strong disinfecting solutions, without previous washing of the body, and at once placed in a coffin.

V. Disinfection of merchandise and of the mails is unnecessary (steam under pressure is the only reliable agent for the disinfection of rags—*les chiffons en gros*).

VI. When cases of cholera occur upon a vessel at sea, the locality where the case occurs should be disinfected. The floors and walls of the cabin, or other locality, should be washed at least twice with one of the weak disinfecting solutions, and then exposed freely to fresh air.

In the case of objects of considerable value, which have not been in immediate contact with the sick, and which would be seriously injured by a rigorous disinfection, the physician on board may determine what measures are necessary to protect the sanitary interests of the vessel.

The bilge-water should be pumped out, and replaced by sea-water, at least twice at each disinfection of a vessel.

The *closets* should be well washed with one of the strong disinfecting solutions at least twice a day.

VII. If the drinking-water is open to suspicion, it should be boiled before it is used, and the boiling should be repeated, if it is not used, within twenty-four hours.

All suspected food should be destroyed, or at least recently cooked.

VIII. Hospitals should be disinfected by washing the floors and walls with one of the weak disinfecting solutions, by a subsequent free ventilation and cleansing, and finally by repainting. The wards to be disinfected should, as far as possible, be isolated from those in use.

The latrines should be disinfected at least twice a day by pouring into them the strong disinfecting solutions in quantity at least equal to the amount of the dejections received since the last disinfection.

IX. The clothing worn by physicians and attendants should remain in the hospital, and should be regularly disinfected.

Physicians and attendants should use the weak disinfecting solutions for washing their hands, etc.

When this report was submitted to the Conference there was some disposition to object to the limited number of chemical disinfectants recommended. Dr. Koch explained that it had been thought best to limit the recommendation to two of the most generally useful chemical agents, with the full understanding, how-

ever, that the list of reliable disinfectants could have been extended, and that other agents, such as mercuric chloride, were valuable under certain circumstances. He hesitated to recommend mercuric chloride, because of the danger attending its general use, and also because its disinfecting action was, to some extent, interfered with by the fact that it entered into combination with albuminous material, and thus failed to come in contact with germs enclosed in albuminous masses.

The delegate from the United States remarked that he had not come to the Conference prepared to endorse carbolic acid in preference to mercuric chloride, but that he was in full accord with the other members of the Committee on Disinfectants, as to the propriety of limiting the recommendations to two chemical agents, and that he had accepted carbolic acid as one of these upon the high authority of Dr. Koch, who, from recent experiments, was convinced that for disinfecting the dejections of cholera patients, this was one of the most reliable agents, and that in the proportion of five per cent. it could be safely recommended for this purpose. Dr. Sternberg acceded the more readily to this, inasmuch as Dr. Koch, upon the strength of experiments recently made in the United States, made no objection to placing chloride of lime beside the disinfectant which his own recent experiments had induced him to consider with especial favor. As to mercuric chloride, the delegate from the United States remarked that he considered the danger attending its use to be greatly exaggerated, and that he should continue to recommend it for certain purposes, and especially for washing surfaces, soiled linen, etc. In dilute solutions the metallic taste would prevent the swallowing of a fatal dose, and it was perhaps no more dangerous than carbolic acid, or concentrated solutions of other metallic salts, the mineral acids, etc. The concentrated solutions could be colored by the addition of potassium permanganate, as proposed by the Committee on Disinfectants of the American Public Health Association, or by an aniline dye (blue) as had been practised by Dr. Sonderegger, the delegate from Switzerland.

Several members having referred to the omission of sulphur dioxide from the list of disinfectants, the delegate from the United States, speaking for the committee by request of Dr. Koch, explained this omission as follows:

While it is demonstrated by laboratory experiments that this gas in a tightly closed chamber, and especially in the presence of moisture, has a certain value as a disinfectant, yet the conditions of successful disinfection are so difficult to attain in practice that there can be no doubt that much of the so-called disinfection with this agent is a farce, and that the success often ascribed to sulphur fumigation is probably largely due to the subsequent free ventilation and general cleaning up which commonly follow such fumigations. Dr. Koch has shown that the escape of sulphur dioxide is extremely rapid from a chamber which has been closed more thoroughly than can commonly be accomplished in ordinary practice. On the other hand, the destruction of micrococci and bacilli without spores, requires long exposure to a considerable amount of this agent, while spores are not destroyed by it in the greatest possible concentration. Moreover, it has been shown by Koch, and by the speaker's more recent experiments, that the penetrating power of this agent is very slight, and that material protected by a single thickness of blanket, may escape disinfection when exposed for many hours in an atmosphere in which sulphur dioxide has been generated in large quantity.

It seems, therefore, so far as cholera is concerned, to be more rational to rely upon a thorough cleansing of surfaces, and the immersion of soiled articles in a disinfecting solution, or exposure to steam. For, the object is not to disinfect the atmosphere of an infected room, but its contents which have been soiled by the discharges of the sick, etc.

It is futile to think of disinfecting the atmosphere of the sick-room, for in a properly ventilated apartment this is constantly changing while the room is occupied, and when it is vacated can be replaced by fresh air in a few moments by opening doors and windows.

Upon motion of Sir Joseph Fayrer, the report of the Committee on Disinfectants was adopted *en bloc*, by a vote of 20 affirmative, to 1 negative (Turkey).

NEWS ITEMS.

CHICAGO.

(*From our Special Correspondent.*)

SANITARY CONDITION OF CHICAGO.—Typhoid fever is prevalent in Chicago. Dr. Oscar C. De Wolfe, Commissioner of Health, says that fifteen years ago typhoid fever was comparatively unknown in Cook County; on the other hand, malarial fevers of all types were common. Now, the hospital wards are gradually filling up with typhoid fever cases, while acute intermittent or remittent fevers are relatively seldom observed.

Dr. M. Maunheimer corroborated the testimony of Dr. De Wolfe.

It is difficult to estimate adequately the sanitary condition of the city. Professor James Nevins Hyde, M.D., in a recent editorial, alluded to the subject in the following vigorous terms:

"When a stranger visits the City of Chicago for the first time, his earliest request is to be shown the waterworks and the stockyards. These are the features for which the town has established a reputation."

"The sacred singer of Israel once cried in a burst of poetic imagery, 'Moab is my wash-pot!' Chicago might well echo with the refrain, 'Lake Michigan is my wash-pot, my drinking-cup, and my chamber-pot!'"

"Her water-works are indeed great. They supply her with water from the lake fully and freely—in fact, as fully and as freely as she restores to it again the refuse of her corporate body. If there be any germ of disease in her excreta, any virus lurking in her animal refuse, she receives it again in part after it has been thrown off."

"Not content with emptying her own ejecta into the lake from which she drinks, Chicago pours into it also the drainings from her immense cattle-yards, and from the great slaughterhouses, where the animals brought to her doors from the whole of the Northwest, are cut up and packed for the consumption of the world."

The South Fork is that fork of the South Branch of the Chicago River, which starts at Thirty-ninth and Halstead streets, and empties into the South Branch in Bridgeport, near the pumping works. "The foulest, filthiest, deadliest section lies just north of the Union

Stockyards, and is about one mile in length, from one hundred to two hundred feet in width, and from nine to eighteen feet deep." (Daily paper.)

Professor Hyde goes on to say:

"The Witches' Cauldron here correctly described, exhales its pestilential breath about two miles from the spot where some of the wealthy 'packers' of this city have erected palaces which a king might envy, their costly stones overlooking the fashionable thoroughfare where youth, beauty, premature age, and folly drive their showy equipages in a splendid ignorance of what is floating beyond!" Nevertheless, the authorities insist that Chicago is in a better sanitary condition than any other city in the world. Mark Twain says of Chicago people, "That they are cultivated and charming, but are inclined to underestimate themselves."

PROVIDENCE.

(*From our Special Correspondent.*)

A New Medico-legal Society in Rhode Island.—Fifteen of the twenty-four medical examiners of the State of Rhode Island, assembled in Providence on the 11th inst. to lay the foundation for a State Medico-Legal Society. After some discussion a temporary organization was effected with Dr. William H. Palmer, of Providence, as President, and Dr. F. B. Fuller, of Pawtucket, as Clerk. A committee consisting of Drs. Garvin, of Lansdale, Morgan, of Westerly, Fuller, of Pawtucket, and Wilcox and Palmer, of Providence, was appointed to arrange for a permanent organization, and report at the next meeting.

MONTREAL.

(*From our Special Correspondent.*)

Hospital Medical Appointments.—At a meeting of the Governors of the Montreal General Hospital, for the election of officers, held May 21st, Dr. Richard L. MacDonnell was elected to the vacancy in the staff of physicians caused by the resignation of Dr. Osler. Dr. Alexander Blackader and Dr. F. W. Campbell were appointed Assistant Physicians, and Dr. James Bell, Assistant Surgeon. At the same meeting Dr. William Gardener was appointed Gynecologist, and Dr. George W. Major, Laryngologist to the Hospital. These two gentlemen are the first to hold these appointments.

Health Officer.—No medical officer of health has yet been appointed, the City Council having refused to accept the nomination of the Advisory Medical Board. The ex-vaccination physician has been appointed temporarily to the position, but has no chance of holding the appointment permanently.

The city is still without public vaccinators, and no attempt is being made to supply the need. Smallpox is yet amongst us, there being thirteen cases in the Smallpox Hospital, and several in the eastern part of the city.

Uric Acid Calculus of Enormous Size.—We desire to place on record some particulars of one of the most remarkable calculi that the records of surgery furnish. It was removed by the high operation (Petersen's modification), on Wednesday morning, by Sir Henry Thompson, from a man aged sixty-two. The stone was of an oval form, of pure uric acid, without any phosphatic incrustation whatever. It weighs 14 oz. avoirdupois (405 grammes), and measures 4½ in. long, 3¼ in. wide, and 2⅛ in. thick. The operation was rapid, and performed without difficulty; and the patient's present condition is unusually good and promising.—*The Lancet*, May 2, 1885.

NOTES AND QUERIES.

TREATMENT OF MENTAL DISORDERS IN THE EARLY STAGE.

To the Editor of The Medical News.

Sir: Allow me to call attention to a printer's mistake in the report of the Committee on Lunacy and Idiocy in the proceedings of the State Medical Society.

On page 644, second column, June 6, 1885, and on the top line, it reads, "The use of stimulants should be ordered in asthenic cases." Now, the report was just the other way, as the next sentence of the report will show. If the word "avoided" had been used, it would have been correct. The argument of the report was in favor of general toxic treatment with iron and a good diet, avoiding all kinds of stimulants on the ground that their effect was only temporary and likely to lead to the formation of an injurious practice afterwards.

Very truly yours,

John Curwen.

June 8, 1885.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 2 TO JUNE 15, 1885.

Horton, S. M., *Major and Surgeon.*—Ordered for duty as Post Surgeon at Fort Riley, Kansas.—*S. O. 78, Department of Missouri*, June 1, 1885.

Cleary, P. J. A., *Major and Surgeon.*—Ordered for duty as Post Surgeon at Fort Lyon, Colorado.—*S. O. 78, Department of Missouri*, June 1, 1885.

Porter, Jos. Y., *Captain and Assistant Surgeon.*—Granted leave of absence for six months on account of disability—*S. O. 126, A. G. O.*, June 3, 1885.

Richard, Charles, *Captain and Assistant Surgeon.*—Granted leave of absence for three days.—*S. O. 128, A. G. O.*, June 5, 1885.

Robertson, R. L., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 123, A. G. O.*, May 29, 1885.

B. E. Fryer, *Major and Surgeon.*—Ordinary leave of absence extended six months, from July 1, 1885, on surgeon's certificate of disability.—*S. O. 129, A. G. O.*, June 6, 1885.

The order directing Major P. J. A Cleary, Surgeon U. S. A., to change station from Fort Union, New Mexico, to Fort Lyon, Colorado, is revoked.—*S. O. 81, Department of Missouri*, June 8, 1885.

C. N. B. Macauley, *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Lisseton, D. T., and ordered for duty at Fort Abraham Lincoln, Dakota Territory.—*S. O. 61, Department of Dakota*, June 5, 1885.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JUNE 13, 1885.

Wyman, Walter, *Surgeon.*—To inspect unserviceable property at Baltimore, Md., June 6, 1885.

Carter, H R., *Passed Assistant Surgeon.*—To inspect unserviceable property at San Francisco, Cal., June 6, 1885.

Battle, K. P., *Assistant Surgeon.*—To inspect unserviceable property at New Orleans, La , June 6, 1885.

Wyman, Walter, *Surgeon.*—To proceed to New York City and assume charge of the service, relieving Surgeon Sawtelle, June 8, 1885.

Banks, C. E., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, June 12, 1885.

ORIGINAL ARTICLES.

FATAL OBSTRUCTION OF THE ILEO-CÆCAL VALVE BY A GALL-STONE.

BY RUSSELL H. JOHNSON, M.D.,

OF PHILADELPHIA.

My patient was a gentleman well advanced in the seventies, showing unmistakably the feebleness of old age, but still able to enjoy his daily walk and give some attention to business. I saw him first upon the morning of the 20th of July. The preceding evening he had taken some purgative pills to relieve a condition of constipation which was more or less habitual with him. I found that the bowels had acted slightly, but that vomiting had occurred some hours before my arrival, and still continued at intervals. The patient had an anxious expression of countenance, the conjunctivæ were slightly jaundiced, features sunken and pale, hands and feet cold, axillary temperature normal, and pulse weak and compressible. He complained of some abdominal pain, not great however. Inspection showed the abdomen of normal contour, not painful upon pressure, no meteorism, neither could any tumor be detected. There was, however, an apparent but very moderate dulness in the ileo-cæcal region. The vomiting was most distressing, allowing the patient but short intervals of rest, and immediately caused by any movement as sitting up in bed, or the ingestion of even small quantities of nourishment. The matter vomited at this time contained particles of food and large quantities of bile, and was ejected with considerable retching.

But little change occurred in the symptoms during the following six days, excepting that the patient grew weaker and more exhausted as the disease approached its fatal termination. The abdomen, daily examined in the hope that new light might be thrown upon the case, remained very much as above noted, showing no symptoms of general or local peritonitis. It was but to a very trifling degree painful upon pressure, and was distended by a very moderate amount of tympanites. The dulness in the right hypochondrium did not increase, and no tumor was felt. The vomiting, although upon several occasions controlled for three or four hours, or longer, invariably returned, becoming more and more alarming in character, simple rejection of the ingesta and bile giving place to stercoraceous vomiting, accompanied by frequent eructations of fetid gases. Attacks of hiccough added still more to the patient's discomfort.

After the small evacuation on the 20th, the bowels remained obstinately constipated; the patient was however frequently annoyed by a feeling of tenesmus, and an idea that the bowels were about to be moved. The secretion of urine at first presented nothing worthy of remark, but became gradually more scanty, and during the last eighteen hours of life was completely suppressed. The patient gradually sank, and on the 26th of July, six days after the initial attack, died, exhausted by the constant vomiting and his inability to take nourishment.

The family gave their consent to an autopsy, which I immediately made, and found the cause of the obstruction to be a large stony concretion, firmly wedged into and completely occluding the ileo-cæcal valve. No other lesion was observed excepting injection and inflammation of the intestine immediately surrounding the stone. The stone was an inch and three-quarters in length, and one inch or over in diameter. Oval in form, dark brown in color, with a hard smooth surface, and a fatty greasy feeling. Having placed it in the hands of a chemist for analysis, it was reported to consist of cholesterine, inorganic and coloring matters, the cholesterine vastly preponderating, forming some eighty per cent. of the whole.

How to explain the presence of so large a concretion in the intestine is a matter of some interest. If this had proved to be an intestinal stone, we would be put to no trouble on that score. Enteroliths, however, are usually found in the large intestine, and consist in great measure of lime and magnesia, or of hardened feces and mucus, having perhaps some foreign body for a nucleus. The chemical analysis, however, of this body, shows it to be composed entirely of cholesterine, therefore a true gall stone.

Being a gall-stone, could it, when of dimensions permitting its escape from the gall-bladder, have passed into the intestine, and there lying in a sack or diverticulum, grown to its present size. The very different conditions under which the bile appears in the intestines, render this supposition highly improbable. Whatever other changes in the condition of the bile contribute to the formation of these calculi, certainly rest and stasis are among the most important factors—conditions which would not be found in the intestine, where the admixture of the bile with the products of digestion and the peristaltic movements of the intestine, would be very unfavorable conditions for the precipitation and crystallization of biliary constituents. Is it possible, then, that a gall-stone of such unusual size, could have traversed the cystic and common ducts? Can we suppose that a concretion which caused fatal intestinal obstruction ever passed through such narrow canals? Where do we find forces powerful enough to accomplish such a result?

The force which propels gall-stones through the excreting ducts is by no means thoroughly understood by observers.

The force exerted by the onflow of the dammed-up bile, by the contractions of the gall-bladder and abdominal muscles, appear hardly or but just adequate to the expulsion of small stones, certainly in-

sufficient for the extrusion of a stone one and three-quarters in length by one in diameter. Another reason for supposing that the intestine was reached by other than the natural route was the fact that most careful and painstaking inquiry failed to elicit any history of hepatic colic; and we may rest assured that the intense pain and other marked symptoms incident to the passage of a gall-stone through the ducts would have impressed themselves indelibly upon the sufferer's memory. This remarkable fact is especially mentioned by Murchison and others, who have reported a number of cases of large gall-stones causing in some cases death, and in others finally passed per anum after more or less alarming symptoms; the patient, in fact, being unaware of the occurrence of anything unusual until the stone, reaching the intestine, caused symptoms of obstruction.

I think, then, that the facts of this case warrant the conclusion that the gall stone under consideration escaped from the gall bladder by means of a fistulous tract connecting it with the duodenum. There is nothing improbable in this supposition. A large foreign body lying in the gall-bladder, and closely approximated to its walls, must in time cause inflammation, and finally ulceration, of its tissue. The local peritonitis accompanying these changes would, by the exudation of lymph, cause the agglutination and adhesion of the opposing surfaces of the gall-bladder and duodenum; and thus, by one of the conservative efforts of nature, give the patient at least a chance for his life.

Such a local peritonitis may occur without giving rise to any well-defined symptom, as the history of this case and of others reported makes sufficiently obvious.

Autopsical examinations (especially those made by Murchison) have in many instances shown the presence of these fistulas, and lead us to infer that it is not a very unusual occurrence.

The treatment of this case presents nothing of special interest. One of the most prominent indications for treatment was to control the vomiting, and to attain this desired result a variety of medicines was employed with, it must be confessed, very indifferent success, with the single exception of morphia. Morphia, however, proved useful; and, under its influence the patient enjoyed tolerably prolonged intervals of rest from the harassing attacks of vomiting, which permitted him to sleep, and, to some extent, to recover from his exhaustion. The morphia treatment was the more willingly persevered in as it met the indications for intestinal obstruction, and was given in such doses as appeared necessary to control or moderate peristaltic action, and to lessen pain and colic. Enemata were used early in the attack, not so much in the hope that they would prove of service in overcoming obstruction (for the occlusion was supposed to lie in the small intestine) as for the purpose of emptying the lower bowel, and thus in some measure rendering the patient's condition more tolerable. The injections, however, merely brought away a small amount of fecal matter from the rectum and sigmoid flexure.

Externally hot applications were made over the abdomen.

The administration of nourishment was a matter of great difficulty. The smallest amounts of milk and lime-water, or of beef tea, were immediately rejected by the stomach, and, finally, the attempt had to be abandoned, and life maintained by nutritious rectal enemata. These were fortunately retained, and in great measure absorbed. It was not until the last day or two of life that the rectum became too irritable to permit of this method of administering nourishment.

In conclusion, it may be added that the exhaustion and collapse rendered stimulants necessary.

URIC ACID:

(1) ITS MEDICAL RELATIONS: (2) A RELIABLE METHOD OF QUANTITATIVE ESTIMATION.

By T. WESLEY MILLS, M.A., M.D.,
LECTURER ON PHYSIOLOGY, MCGILL UNIVERSITY, MONTREAL.

The quantity of uric acid secreted daily varies from 7½ to 15 grains under normal conditions, or, what seems to be of more practical moment, the quantity of uric acid secreted daily is, according to the estimations of H. Ranke, in the proportion of 1 : 41 to 1 : 61 of urea.

The quantity of uric acid is lessened at the onset of acute gout, followed later by a rise. It is also diminished by chronic gout, osteomalacia, and the different forms of Bright's disease. In diabetes mellitus there is a diminution of the uric acid with an increase of the urea.

There is in fever a marked increase according to all observers, and especially in croupous pneumonia, this being both absolute and relatively to the urea.

Bartels found in a case of poisoning by carbonic oxide (CO), the proportion of uric acid to urea to be 1 : 30.

Senator thought he had proved by experiments on animals that dyspnœa caused an increased amount of uric acid secretion, and Bartels has shown that the same holds in the case of men. But it has been recently clearly shown by several quantitative calculations by different observers, that in leukæmia the normal proportion of uric acid to urea found in the urine is greatly disturbed. That there is at all events a great increase in the quantity of uric acid, so that the proportion, instead of being as stated above, may be 1 : 20, or even 1 : 16.

The explanation offered in this case as well as in the case of the increase in dyspnœa (whether owing to disease or artificially induced), is diminished oxidation in the body generally. The "respiratory" power of the blood must plainly be lessened in leukæmia. This taken in connection with the well-known fact that in the laboratory uric acid can be oxidized to urea, affording a hypothetical basis for the assumption that it actually is so oxidized in the body, and that interference with the normal supply of oxygen on the one hand, or with the process of oxidation on the other, may keep more than the usual quantity of uric acid back from its change to urea; all this lends great plausibility to such an hypothesis.

I have satisfied myself of the truth of the above-

stated fact as to an increase of the uric acid and disturbance of its proportion to urea in leukæmia, by an estimation according to Salkowski's method presently to be described.

The quantity of urea for twenty-four hours, was by Liebig's method found to be 29.260 grains. That of uric acid, 1.0423. The ration, 1 : 28.

Manifestly before such calculations can be of great value the method of estimation must be reliable.

The method that was for a long time followed, and is still largely used, is that of Heintz, which is as follows: To 200 cc. of urine, 10 cc. of hydrochloric acid are to be added, allowed to stand in a cool place for forty-eight hours, then collected by filtration, etc., on a weighed filter, washed, the wash water collected, measured, and a correction by way of an addition made to the amount of urea actually found.

There was however, supposing all the uric acid to be precipitated, a variable error arising from the very fluctuating quantity of pigment adhering to the crystals. More than a year ago I undertook to ascertain definitely by actual comparative estimations how reliable this method really was, and with the following results: Having first ascertained that Salkowski's silver method was absolutely accurate, calculations were made by this method and compared with the results obtained by Heintz's method. The figures here given in a single example, using the same urine for each method, will make the matter clear.

I. Heintz's method:

	Grains.
Weight of watch-glasses, clip, filter with uric acid	15.223
Weight of watch-glasses, clip only .	15.208
Weight of uric acid .	00.015

II. Salkowski's method:

	Grains.
Weight of watch-glasses, clip, filter with uric acid	22.8235
Weight of watch-glasses, clip only .	22.7735
Weight of uric acid .	00.0600

The corrective addition for Heintz's method would not equal that for Salkowski's, so that it is clear that in this case the amount found by Heintz's method is only one-fourth what it ought to be, notwithstanding that after the addition of hydrochloric acid the urine was allowed to stand seventy-two instead of forty-eight hours. After the application of Salkowski's method no uric acid can be detected in the filtrates.

To insure success with it, the minutest details must receive attention. I shall, therefore, give Salkowski's own account of it in full.

250 cc. urine are to be treated with 50 cc. ammoniacal magnesian mixture (made by mixing one part crystallized magnesium sulphate, two parts ammonium chloride, four parts ammonia of sp. gr. 0.924, and eight parts water), and at once filtered. Take of this 240 cc., representing 200 cc. urine, and treat with a solution of silver nitrate of about three per cent. strength. This produces a flaky gelatinous precipitate, easily distinguishable from silver chloride. A little ammonia may be added to insure the solution of all the silver chloride. Upon standing, this precipitate soon settles to the bottom, leaving the supernatant fluid clear.

A little of the latter must be drawn off with a pipette into a test tube, and tested for silver by the addition of nitric acid to acid reaction. If a turbidity is visible, enough (slight excess) of silver nitrate has been added. If not, the fluid withdrawn must again be made alkaline with ammonia, and poured back and more silver nitrate added and tested anew. The whole is then filtered at once (to avoid decomposition), through a folded filter made of good rapidly filtering paper, and of about 12 cm. diameter. The precipitate is to be brought upon the filter with a trimmed feather and washed several times with water.

It must be washed until evidence of the presence of silver can no longer be obtained by treatment with nitric acid as above, nor of chlorides by the addition of silver nitrate. One hour on the average suffices for this part of the work. The filter with the precipitate (or the precipitate washed off by a wash-bottle), to be brought into a wide-mouthed flask, about 200 cc. of water added, shaken well, and submitted to a stream of sulphuretted hydrogen not too weak, with constant shaking. The contents of the flask are next heated to the beginning of boiling and a few drops of hydrochloric acid added until the reaction is decidedly acid. Filter free from silver sulphide (and paper), using a folded filter to expedite the process, then wash several times with hot water. The filtrate should be clear and colorless. Evaporate the filtrate as rapidly as possible in a porcelain dish over a free flame to a few centimetres. Add a few drops of hydrochloric acid and after twenty-four hours standing in the cold, the precipitate that has separated is collected on a weighed filter, washed first with water, then with alcohol, and finally with absolute alcohol and ether. The wash water is to be collected, measured, and for every 10 cc. of it 0.48 milligramme is to be added to the weight of uric acid found.

Very concentrated urine (fever) is to be diluted to double its bulk.

The above account of this method is a free translation of that given in *Die Lehre vom Harn. von Dr. Salkowski und Dr. Wilhelm Leube*, in which elaborate work the whole subject of uric acid is fully discussed.

As this method is tedious and laborious, I have tried to find another less open to these objections, and first of all by different degrees of concentration of the urine before treatment with hydrochloric acid. By this means much more uric acid can be obtained, but it is liable to be, and in fact generally is, mixed with much pigment, the separation of which is a matter of great difficulty. However, if Heintz's method is to be used, some concentration and allowing the urine to *stand for at least a week* will give results much more nearly correct. But there can no longer be any doubt that this old method of Heintz is very incorrect. I succeeded, indeed, in finding a new method, but, upon the whole, not less tedious than that of Salkowski, so that I feel confident in

stating that, for the determination of uric acid, Salkowski's method is the best known and is absolutely reliable.

A CASE OF LATE CUTANEOUS SYPHILIS (ACNE-LIKE SYPHILODERM OF THE NOSE), ILLUSTRATING THE OCCASIONAL NECESSITY OF LARGE DOSES OF POTASSIUM IODIDE.

BY HENRY W. STELWAGON, M.D.,

PHYSICIAN TO THE PHILADELPHIA DISPENSARY FOR SKIN DISEASES, CHIEF OF THE SKIN DISPENSARY OF THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, ETC.

THE patient, an intelligent male German, whose case furnishes the material for this paper, applied for treatment at the Northern Dispensary in August of 1883. On the right side of the nose, near the junction of the ala with the cheek, were three or four papular elevations, the apices of which were slightly depressed with a central point of suppuration. Each lesion was about the size of a small split-pea. In appearance they resembled abraded acne papulo-pustules. There was some infiltration, with more or less redness. On other parts of the nose, and in the immediate neighborhood of the same, were several small pea-sized, shallow scars, the remains, evidently, of recent lesions. At a point near the base of the nose was an acne-like papulo-pustule. The eruption had made its appearance three months previously. The forehead presented scars similar to those about the nose, except that they were much paler and less distinct, and in other ways showed that they were remains of an eruption of some years past. No other symptoms presented. Questioning elicited that the patient, fifteen years ago, had had a venereal disease, which he had always considered simply a gonorrhœa. So far as the patient remembered, there had been no symptoms of cutaneous disturbance until eight years later, when the eruption on the forehead made its appearance. At this time, also, there appeared a suppurating, gummatous swelling upon the left forearm, the scar of which is still plainly visible. After a few months' treatment the eruption and the gummatous ulceration disappeared, leaving the cicatrices already mentioned. Since then, up to the time of the present eruption, patient had enjoyed his usual good health, and had observed no other symptoms, either objective or subjective.

Patient is a married man, and the father of four children, three of whom died in the first two months of life; the fourth is still living, and is perfectly healthy. The wife, so far as he is cognizant, has never had any cutaneous disease, or shown any symptom which could be looked upon as suspicious.

So much for the history and condition of patient when admitted for treatment.

The diagnosis of syphilis was made, and patient placed upon potassium iodide and the red iodide of mercury, five grains of the former and one-twenty-fourth of the latter three times daily. An ointment of thirty grains of white precipitate to the ounce of lard was ordered for local application. In the next two weeks a few new papulo-pustules appeared on other parts of the nose, somewhat inflammatory, and with considerable surrounding hyperæmia. The other lesions were slowly retrograding. The dose of the potassium iodide was increased to ten grains, and that of the mercury to one-sixteenth. Two weeks more passed, and the eruption still remained uninfluenced; new lesions slowly appearing, and the old ones as slowly disappearing. A shallow depression and scar marked the site of each disappearing lesion. When two or three lesions existed close together, the intervening skin was slightly reddened and infiltrated. With the eruption there was more or less papillary and connective tissue hypertrophy. Indeed, the resemblance to acne rosacea was striking: the papulo-pustules, to a certain extent, simulating the acne lesions, and the superadded redness and hypertrophy, together with the presence of a few small dilated capillaries, completing the picture. The iodide was now increased to twenty-grain doses, with an increase also in the mercury biniodide. No change taking place in two weeks, the iodide was still further increased to thirty grains three times daily. Fourteen days under this dose showed no appreciable improvement.

The patient had now been under treatment two months, and the character and course of the disease remained unchanged; the older lesions disappearing and new ones appearing, evolution and involution taking place very slowly. At this time there were probably more lesions present than at the beginning of the treatment. There were several on the parts adjacent to the nose, and the hyperæmia had increased. So striking was the resemblance to acne, that the case was again carefully investigated, but with the same diagnosis resulting. The same treatment—thirty-grain doses of potassium iodide, and one-twelfth of a grain of biniodide of mercury—was continued a month longer, but with no benefit. The local treatment was changed from time to time, the oleate, corrosive sublimate, red oxide, and the ordinary mercurial ointment all being tried.

Against my better judgment, or at least in desperation, the above plan of treatment was discarded, and the case treated as acne. At first there seemed slight improvement. The disease, however, continued, and after several weeks of varied treatment the result was negative. About this time there appeared a slight nodular swelling of the left ulna. The first impression of the nature of the eruption was thereby confirmed, and the antisyphilitic treatment resumed. Beginning with thirty-grain doses of the potassium iodide and one-twelfth of the mercury biniodide, the former, two weeks later, was increased to forty grains three times daily, and continued fourteen days. The nodular swelling disappeared, but the eruption was but slightly, if at all, influenced. The dose was now increased to fifty grains, and no improvement resulting, to one drachm. It was not until the drachm doses were given, that any change was noted.

From this time forward, however, the improvement was marked, and within three weeks after this dose had been reached the eruption had practically disap-

[1] Read at the eighth annual meeting of the American Dermatological Association, Highland Falls, New York, August 29, 1884.

peared. Up to the present time there has been no relapse. The scars, of course, still remain, and resemble, in size, character, and appearance, those observed to follow the so-called atrophic acne. There remains also more or less papillary hypertrophy. Up to the date of the administration of drachm doses, the eruption had fluctuated slightly from time to time, remaining, however, essentially the same; never violent, but of an indolent character. Strange to say, the stomach stood the large doses admirably. Nausea and irritation occasionally occurred, but seemed to be produced by the menstruum rather than by the potassium iodide, as a change of such was always followed by a disappearance of the gastric uneasiness.

While I am aware that large doses of the potassium iodide have been given in visceral and nervous syphilis, in the latter particularly by Dr. S. Weir Mitchell, yet in cases of cutaneous syphilis, such amounts, especially continued for so long a period, are unusnal. My own experience would indicate that it is rarely necessary to exceed the dose of thirty grains, three times daily, and in the great majority of cases ten-grain doses will suffice.

MEDICAL PROGRESS.

Ball Weighing Four Pounds Encysted for Thirty Years.—M. Vaslin, at the recent meeting of the French Surgical Congress, exhibited a ball weighing about four pounds (200 grammes), which had remained encysted for thirty years. The projectile measured eight and four-fifths inches in circumference, and was extracted from the left side of an old soldier, upon whom M. Vaslin held a post-mortem the latter part of 1884. The man was wounded in 1855, but recovered very rapidly from the injury and never experienced any suffering from its effects until 1870. At this time the wound, which had been closed for fourteen years, opened and a fragment of clothing escaped. However, the pain occasioned thereby in his side and leg was not sufficient to interrupt the performance of his ordinary duties. In 1884, M. Vaslin was called to visit the patient, and introducing a probe into the fistula, above Poupart's ligament, discovered a hard body which he suspected to be a ball. Operation was refused, and in November, 1884, all the phenomena of a suppurating psoas abscess were established, and notwithstanding free incision and drainage the patient died.

The ball which penetrated the iliac fossa in 1855, had little by little until 1870, obeying the laws of gravity, traversed the muscles of the pelvis, and at this time arriving at the level of the iliac fossa caused the pain then experienced. During the fourteen years intervening the ball progressed along the bone, wearing a deep channel into its substance, extending from near the crest of the ilium toward the bottom of the cotyloid cavity, and at this time the ultimate manifestations occurred. The case, though rare, is not unique, both Larrey and Weis having reported similar encystment of bullets during a protracted period.—*Revue Médicale*, May 16, 1885.

Thallin.—Prof. Maragliano, at a meeting of the Italian Medical Society, held in Genoa, April 28, 1885, reported the results of his experiments made upon thallin. He observed that in apyrexia thallin exercises a slightly depressing effect upon the temperature, and that the pulse and respiration are also slightly diminished in frequency, while the intraärterial pressure is slightly increased.

In patients in whom pyrexia is present, thallin constantly lowers the temperature, the reduction varying with the dose. Doses of about 4 grains cause a reduction of about 1⅕° F.; doses of 7½ grains a reduction of from 1⅘° F. to nearly 6° F.; doses of 11½ grains reduced the temperature from 2⅓° F. to 7⅕° F.; while doses of 15½ grains cause a reduction of from 3½° F. to 8½° F.

The reduction of temperature ordinarily begins in an hour after the administration of the drug and attains its maximum in two hours if the diminution is about 2.7° F., and after three or four hours if it is greater. The effect of the drug persists from one to ten hours according to the dose. The reduction of temperature is ordinarily accompanied by perspiration, more or less profuse.

The disappearance of the fever is sometimes preceded by the shivering and chill. Frequency of the pulse and of respiration diminishes proportionately to the reduction of temperature and to the dose of the drug.

Thallin does not produce vomiting nor any other gastric disturbance, and may be administered in the quantity of 110 grains in twenty-four hours without inconvenience of any kind. It is found in the urine an hour and a half after its administration, and the greater quantity of it is eliminated in the first ten hours.

Twenty hours after the administration of the drug the urine does not give the characteristic reaction with the chloride of iron. After the administration of the drug the urine assumes a characteristic darkish-green color, which sometimes is absent after small doses. Prof. Maragliano has administered thallin in divers febrile diseases, and finds the fever depending upon pulmonary phthisis to be the least resisting, while that of fibrinous pulmonitis is the most intractable. Prof. Maragliano also finds that the drug diminishes the quantity of urea and of carbonic acid eliminated in twenty-four hours in apyretic subjects, and that it causes in the apyretic, as well as in patients with elevated temperature, a dilatation in the cutaneous vessels and an increase in the elimination of heat.—*Gazzetta degli Ospitali*, May 20, 1885.

The Influence of Salicylate of Soda and the Salts of Quinine upon the Peripheral Circulation.—At a meeting of the Academy of Medicine, of Genoa, held April 28, 1885, Dr. Pedrazzi reported the results of his experiments to determine the effect of the salicylate of soda and the salts of quinine upon the peripheral circulation, of which the following are the conclusions:

1. Salicylate of soda produces dilatation of the peripheral bloodvessels.

2. Dilatation begins to be manifested in about two hours after the administration of the drug.

3. Dilatation from the indicated dose has a duration varying from two to four hours, after which the vessel tend to return to their primitive calibre.

4. During the peripheral dilatations the calorimeter shows an increased loss of heat from the cutaneous surface, an increase which in the first five minutes varies between 7⅕° and 9° F.

5. The normal temperature is either not modified or is scarcely lowered a tenth of a degree.

6. The sulphate and the bicarbonate of quinine dilate the peripheral vessels.

7. Along with the dilatation of the vessels the dispersion of heat from the cutaneous surface is increased.—*Gazzetta degli Ospitali*, May 20, 1885.

TREATMENT OF CHOLERA.—DRS. T. LAUDER BRUNTON and P. H. PYE-SMITH, at the conclusion of a paper upon researches relating to the pathology and treatment of cholera, say: We think that the directions in which further researches after a remedy for cholera are most likely to prove successful are:

1. The discovery of an antiseptic which will destroy pathogenic organisms in the intestine and prevent the formation of the cholera poison, while they are not themselves poisonous. Corrosive sublimate is a sufficiently powerful antiseptic, but it may itself prove poisonous to the patient as well as to the pathogenic organisms. It is possible that amongst the members of the aromatic group of bodies the desired substance may be found having the desired properties.

2. The discovery of some substance which will antagonize the action of the cholera poison after its absorption. As a preliminary step in this direction, further experiments are needed on the nature and action of alkaloidal substances obtained from cholera dejecta as well as from artificial cultivations in various media and under various conditions, electrical and otherwise.

3. Observations on the effect of stimulation of the mesenteric plexus by currents passed through the uninjured abdomen in poisoned animals and in patients suffering from the disease.—*The Practitioner*, June, 1885.

PRESERVATION OF SOLUTIONS OF COCAINE.—In an article on this subject in *Ephemeris*, May, 1885, the writer, after reviewing his numerous experiments to determine the best preservatives of solutions of cocaine, says: It will be seen that all these observations, extending over about six months, are insufficient to establish anything more than a strong probability that boric acid in the proportion adopted, namely, a half of one per cent., will protect these solutions, until they are used up in the ordinary practice; and, therefore, the writer takes advantage of this probability, and hereafter will abandon the use of salicylic acid for the protection of solution of hydrochlorate of cocaine, and substitute boric acid. This boric acid will be used in the proportion of 0.5 per cent. so long as there is no evidence of this proportion failing to protect. But in case it should fail in any considerable number of instances upon prolonged experience, the proportion will be increased to 1 per cent.

Some of the British journals have recently recommended camphor water as a good protective agent for these solutions, and rationally it should be protective as are all the substances belonging to the aromatic series, but camphor is more irritant, or less sedative to mucous surfaces than boric acid, and the proportion necessary to protect does not seem to have been yet carefully determined.

TWO CASES OF LAPAROTOMY PERFORMED FOR ILEUS.—At a meeting of the Berlin Medical Society, held May 6, 1885, PROF. BARDLEBEN exhibited two patients upon whom he had operated for ileus.

The first patient was a young man aged twenty-four years, who during his youth had frequently suffered from abdominal pains. August 17, he came to Dr. Frerich's clinic, suffering from intestinal obstruction, extremely violent vomiting, and with the abdomen greatly swollen. During the three succeeding days he was treated with opium and intestinal irrigation, but without any good result.

The diagnosis of ileus was accordingly made, and laparotomy performed. Abundant exudation was found in the abdomen, and the small intestine was found to be constricted at two points, at each of which incision was made, and the bowel released, but the intestine, nevertheless, did not regain its calibre at the constricted points. The bowel was, however, of moderate calibre, and its lumen such that it was not necessary to resect the portion between the two points of constriction. It was found, however, that owing to the macerating effect of the exudate upon the bowel at the ensnared regions, the serous coat was torn, and at these points, therefore, five fine sutures were introduced. At the conclusion of the operation considerable vomiting occurred, but the general condition of the patient was much improved. Large doses of opium were administered, and the bowels emptied by enemata. Notwithstanding the quantity of opium administered, the patient during the night succeeding the operation was very restless, and thereby removed the antiseptic dressing which had been applied to the abdominal wound. The swelling continued, and on the third day, when vomiting first ceased, it was evident that the wound had not cicatrized, but was still discharging pus abundantly. On the seventh day examination showed that superficial suppuration had been so abundant that although the peritoneum was healed at the bottom of the cavity opened by the incision, coils of the intestine were plainly visible, and even at one spot seemed to lay bare. Nevertheless, the case progressed favorably, and on the thirteenth day granulation had covered the intestinal coils, and perfect recovery took place, the patient at present enjoying perfect health.

The second patient exhibited was a man 47 years of age, who from early manhood had a left inguinal hernia.

April 23, 1884, he was seized with intense abdominal pain and severe vomiting. A week later he was brought to Prof. Frerich's clinic, and treated with opium and intestinal irrigation, with no beneficial results.

May 2d he was transferred to the surgical clinic. Examination showed that no strangulation existed, and the distended intestinal coils were plainly recognizable through the abdominal walls. The abdomen was very sensitive on the left side. The 5th of May the patient had a natural motion of the bowels and the vomiting ceased for one day, but then returned, though it was less violent than before. May 7th, the vomiting became more violent than it had previously been, and symptoms of collapse were developed with remarkable rapidity. Laparotomy was at once performed, and the intestine was found twisted upon itself, and retained in that condition through the existence of a firm exudate.

The malposition was remedied without difficulty, the exudate removed, and cure resulted without delay.—*Deutsche med. Wochenschrift*, May 14, 1885.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JUNE 27, 1885.

GERMAN ANALYSES OF ENGLISH AND AMERICAN MEAT EXTRACTS.

IN view of the large number of meat preparations now in the market, and the merits claimed for them in the treatment of debility and exhausting diseases, it cannot fail to interest our readers to know how they bear the test of German scrutiny. A. STUTZER, of Bonn, has published in the *Berliner med. Wochenschr.* for April 15th, the results of an examination of nine preparations, including Murdock's liquid food, Valentine's meat juice, Johnson's fluid beef, Benger's peptonized beef jelly, Savory & Moore's fluid beef, Brand & Co.'s essence of beef, Reed & Carnrick's beef peptonoids, and Kemmerich's and Liebig's beef extracts, the first four being American, the next three English, and the last two German.

He first determined in each the proportion of organic matters, salts, and water, and then further treated the organic substances. In doing the latter he determined how much of the nitrogenous matters belonged to the easily digested albumen and pepton. He lays special stress upon these last, because on them the nutritive value of animal food depends. Two preparations, Carnrick's beef peptonoids and Johnson's fluid beef, contained albuminous substances in the form of fibrin, not soluble in water, of which the value must be determined by artificial digestion, since in this way only can be ascertained what proportion of the fibrin can be digested. He further noted the nitrogen in the shape of flesh bases, kreatin, carnin, etc., since these, with the potash and phosphoric acid associated with them, play an important rôle as food and stimulus for the nervous system.

The flesh extracts of Kemmerich and Liebig are chiefly used for healthy men, but are nevertheless recommended to convalescents to improve digestion and stimulate the circulation, results which are accomplished partly through the abundant flesh bases and partly through the phosphate of potash. This is in accordance with Liebig's own view, which did not claim for his extract any active nutritive power, but recommended it simply as a relish. Kemmerich's flesh extract contains a larger proportion of pepton and albumen, namely, 22 per cent., and he claims correctly for it the properties of a true nutriment, as well as a nervous stimulant.

Murdock's liquid food, which is an extract of beef, mutton, and fruits, made in Boston, is claimed to have 13½ per cent. of soluble albumen, which Stutzer has confirmed. The fluid contains 8.3 per cent. of alcohol, and on opening the well-sealed vessel the odor was not pleasant, and there seemed to be a partial decomposition of the contents, a tendency to which characterizes albuminous fluids if long kept, especially if they contain fruit juices prone to fermentation.

Valentine's meat juice, made at Richmond, Va., is also a fluid which contains kreatin, potash, and phosphoric acid along with a small quantity of albumen and pepton, and 59 per cent. of water.

Johnson's fluid beef, made in Canada, belongs, on account of its containing peptons and digestible albumen, to the better extracts, although the proportion of water is large, being 50 per cent. Stutzer found still more water, nearly 90 per cent., in Benger's peptonized beef jelly and Brand's essence of beef, of which the first is made in Manchester, England, the second in London.

The fluid meat—peptonized meat—of Savory & Moore possesses, according to Stutzer, very different properties. It contains chlorides in considerable amount, and is apparently made with hydrochloric acid in order to peptonize the meat, the acid being neutralized with sodium carbonate. In this method of peptonizing, with the aid of acids, Stutzer considers that the action proceeds too far and that the pepton resolves itself into substances, the nature of which is not precisely determined, but which probably do not possess the same nutritive value as pepton.

Essentially different from any of the above is the preparation known as beef peptonoids, made by Reed & Carnrick, of New York. It is a very fine dry powder, made of beef, gluten of wheat, and condensed milk, a mixture, therefore, of nitrogenous matters of animal and vegetable origin, and is easy of digestion. The gluten is carefully separated from other organic matters of wheat and contains only 1.25 per cent. of starch, and 0.25 per cent. of cellulose.

The determination of the nutritive value of these preparations can best be made by comparing the easily digestible albumen and pepton in the different preparations. In such a mode of comparison the most nutritious will be found to be Reed & Carnrick's beef peptonoids, of which 100 parts by weight contained the same amount of albumen and pepton as 178 parts of Johnson's fluid beef, 285 of Kemmerich's flesh extract, 482 of Murdock's liquid food, 745 of Brand and Co.'s essence of beef, 764 of Savory & Moore's fluid meat, 898 of Liebig's flesh extract, 902 of Benger's peptonized beef jelly, and 966 of Valentine's meat juice.

Reed & Carnrick's preparation contains, in addition to the nitrogenous matter, 10.67 per cent. of fat, and 10.02 per cent. of soluble non-nitrogenous matters in the shape of dextrin and sugar.

In this comparison, says Stutzer, Liebig's extract takes a subordinate position, because it is found to be only an appetizing, and not a nutritious substance. If, on the other hand, the comparison is made as regards the flesh bases contained in them, it is found that 100 parts by weight of Liebig's extract contain the same amount of nitrogen in the form of kreatin and carnin as 126 of Kemmerich's meat extract, 537 of Valentine's meat juice, 558 of Johnson's fluid beef, 1844 of Benger's peptonized beef jelly, 4161 of Murdock's liquid food, 5053 of Brand's essence of beef, and 7782 of Reed & Carnrick's beef peptonoids.

From the above very interesting analysis it will be seen that the different articles of food have a far different value, according as they are regarded as nutritive or appetizing, and the indications in each case should be carefully considered before they are prescribed. If these analyses are correct, and they bear the stamp of reliability, it is very evident that an undue value is claimed by the makers for certain of these preparations, and that physicians who have been basing their use upon the representations of the makers, rather than on actual chemical composition, will find a reason for any disappointment in results which they may have noted.

SPINA BIFIDA.

AT a recent meeting of the Clinical Society of London, the proceedings of which may be found in the London medical weeklies for May 30th, a committee, consisting of MR. HOWARD MARSH, MR. PEARCE GOULD, MR. H. H. CLUTTON, and MR. R. W. PARKER, made a lengthy report upon the pathological anatomy and treatment of spina bifida, which throws new light upon this not infrequent deformity.

By spina bifida is meant a congenital malformation of the vertebral canal, with protrusion of some of its contents, in the form of a fluid tumor, due, as a rule, to deficiency of the neural arches of the vertebræ, with consequent posterior projection of the tumor. The varieties met with are, first, meningocele, or protrusion of the membranes above; secondly, meningo-myelocele, or protrusion of the membranes, along with the spinal cord; and, thirdly, syringo-myelocele, a condition characterized by protrusion of the membranes, together with the cord, the central canal of which is dilated so as to form the cavity of the sac, the innermost lining being formed by the expanded and atrophied substance of the cord. Of these three varieties, the second is the most frequent, while the first comes next, and the third last. In meningo-myelocele, the most common variety, therefore, the thin, translucent membranous covering of the tumor represents in part the attenuated spinal cord, and the nerves, which are always found on the inner surface of the wall of the sac, arise from the intramural portion of the cord, instead of being distributed to it, as generally described. In the other two varieties, it is interesting to note, from both a pathological and practical point of view, that the sac is free from nerves. From these facts, it naturally follows that spina bifida, instead of being a mere dropsy of the central canal of the cord, is due to a primary defect of development, or a want or arrest of differentiation, of the blastodermic layers of the embryo.

In view of the fact that the most common variety of the deformity consists in great part of nerve tissue, the committee express decided opposition to ligation and excision of the sac, and advocate the injection of Morton's fluid, a plan of treatment which shows a percentage of success of between 50 and 60. This fluid, it will be remembered, consists of ten grains of iodine and thirty of iodide of potassium to an ounce of glycerine. As absolute contraindications, they mention marasmus and hydrocephalus, while paralysis, a thin sac, or an ulcerated one, impulse between the tumor and the anterior fontanelle, and the presence of the cord in the sac, render the result uncertain. They also point out that the operation should not be performed, unless for special reasons, in infants under two months of age.

In his brochure upon the treatment of spina bifida by a new method, published in 1877, Dr. Morton gives the details of fifteen cases in which his solution was injected, of which twelve were successful, and three died; and up to the middle of 1882, not less than twenty-three cures were recorded out of twenty-nine cases. These results are so utterly at variance with our own experience with the remedy, that we can only account for them by the assumption that all of the failures have not been reported, and the percentage of failures derived by the committee would seem to warrant the correctness of this view.

FERRÁN ON THE MORPHOLOGY OF THE COMMA-BACILLUS.

For weeks past the daily journals have contained notices of the experiments and inoculations of Dr. Ferrán, of Barcelona, but the current number of Leyden's *Zeitschrift f. klin. Medicin* contains the first published account of his investigations upon the life-history of the comma-bacillus. He regards the organism as specific and distinct from all others, and the comma-form represents only one stage of its existence. By means of careful modifications in the modes of culture the development has been traced. In gelatine or in weak alkaline flesh broth the commas grow into long spiral filaments, in which small spore-like bodies may be seen, as in the hyphæ of the anthrax-bacillus. This stage is not reached in ordinary cultures unless means are taken to remove the part rendered fluid, as this contains ingredients poisonous to the growth. In neutral or weak alkaline flesh broth this development is most rapid, and a few hours at 37° C. suffice to exhaust and render acid the medium. If now, more neutral or weak alkaline broth is added and the temperature reduced to 15–25° C. very remarkable changes occur. Large antheridia or spore-like bodies are formed on the filaments, which become free and enclosed in hyaline capsules.

For the further development of these structures it is necessary to add to the culture medium from ten to twenty per cent. of human or hog bile, and to keep the temperature from 18° to 25° C. Under these conditions the spores grow and attain the size of red blood-corpuscles, or even larger, and assume a mulberry shape. From these bodies long thin protoplasmic filaments exude, which ultimately assume a spiral form, increase by division, and from them the original comma-form is produced. A plate giving illustrative figures of the various steps in the process accompanies the paper. The comma-bacilli, antheridia, and mulberry-shaped masses, were also found by Ferrán in his own stools during a slight attack of diarrhœa, which he attributed to infection from the cholera cultures. Detailed statements are given of the mode in which Dr. Ferrán prepares the cultures, so that his observations can readily be tested, and no doubt they will be carefully repeated by Koch and others.

There is one criticism which will occur to everyone who knows anything of the life-history of the micro-organisms of disease. The group of fungi, schizomycetes, to which the bacilli belong, multiply, so far as we know, only by fission and the formation of spores in the filaments. Now, Ferrán's description and figures show a development of conidia-like bodies such as occur in the hypomycetes (moulds), a morphological inconsistency which is opposed to all previous observations.

No information is conveyed as to the methods of preparing the cultures for inoculation, but from other sources it would appear that ordinary cultivations are employed. In persons so treated the blood contains micrococci, spirilla, and comma-bacilli, a rather suspicious circumstance, as the opinions of other observers seem unanimous that in true cholera the organisms are not in the blood. The inoculations may produce very troublesome sores on the arm, and, according to a correspondent of the *British Medical Journal*, several persons have died after submitting to the operation.

TORTICOLLIS.

In the *Archiv für klinische Chirurgie*, Bd. xxx., 1884, may be found a noteworthy paper from the pen of Professor Petersen, of Kiel, in which the theory of Stromeyer, adopted by nearly all other writers, that torticollis results from rupture of one of the sterno-cleido-mastoid muscles during parturition, followed by cicatricial retraction, is combated. Petersen holds that subcutaneous laceration of the muscle leads to its elongation, and that the so-called hæmatoma of the muscle, instead of being the cause of the torticollis, is one of its effects, the muscle yielding readily because it is congenitally too short.

In a still more recent paper, published in the *Centralblatt für Chirurgie*, No. 14, 1885, Professor Volkmann, of Halle, considers the etiology of congenital torticollis, and bases his conclusions upon observations made upon the living subject. Being dissatisfied with subcutaneous section of the sterno-mastoid muscle in aggravated cases, he has successfully resorted, in at least twelve instances, to its division through a free incision carried along the inner border of the muscle, and as the result of minute examinations of small sections of the muscle, and of the discovery of bands of contractured tissue, he arrives at some conclusions which throw great light upon the affection, and seem to show that, as in talipes, adapted shortening of the fasciæ and other tissues maintains the deformity after the involved muscle has been thoroughly divided.

In some cases the muscle and adjacent tissues had undergone no changes whatever. In others, the muscle, to the extent of several inches, was converted into a white, comparatively non-vascular, tendinous mass; its sheath was not demonstrable, being united to the altered muscle by cicatricial bands; the sheath of the vessels was thickened, and the deep fascia was converted into resisting bands. In a third class of cases, the changes were not so marked, the muscle being the seat of a circumscribed callous patch, or traversed by a few tendinous cords. In none of the cases was there the slightest evidence of fatty transformation.

From these observations it follows that certain cases of torticollis result from trauma during delivery, which is followed by inflammation of the muscles and associated tissues. The changes which are met with are indicative of an active process, and Volkman thinks that they disprove the view of Petersen, who attributes the shortening of the muscle to a vicious position of the fœtus in the uterus.

SOCIETY PROCEEDINGS.

NEW HAMPSHIRE MEDICAL SOCIETY.

Ninety-fifth Annual Meeting, held at Concord, June 16 and 17, 1885.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, JUNE 16TH.—FIRST DAY.

MORNING SESSION.

THE meeting was called to order by THE PRESIDENT, JOHN WHEELER, M.D., of Pittsfield.

After the report of the Committee of Arrangements, the Secretary, Dr. G. P. Conn, read the report of the Council, concerning a memorial from the Woman's Christian Temperance Union, of New Hampshire, asking the Society to make some expression of opinion upon the question of

PRESCRIBING ALCOHOLIC STIMULANTS,

which had been considered, and was reported upon as follows:

Resolved, That the members of the New Hampshire Medical Society fully indorse the position taken by the American Medical Association at St. Paul in 1882, regarding the "conscientious caution in the prescribing of alcoholic stimulants," and regard the same as one of the primary principles of the profession, to which the members of this Society have always adhered and will continue so to do.

The request of the Medical Society of New Jersey for coöperation in an effort to elevate the standard of

MEDICAL EDUCATION

was introduced, and it was voted to indorse the report of the Medical Society of New Jersey, and that a committee be appointed to report upon the same at the next meeting of the New Hampshire Medical Society.

The proposition of the American Medical Association to establish

A STATE BOARD OF MEDICAL EXAMINERS

was favorably reported upon, and a committee appointed to memorialize the New Hampshire Legislature for the passage of a bill in accordance with the recommendations of the American Medical Association at its last meeting in New Orleans.

DR. WHEELER then read

THE PRESIDENT'S ADDRESS.

He said the Society should sustain good morals, good sanitary measures, and good laws, and the State should protect all these essentials to society and humanity. The laws of our State exact no especial requirements of clergymen except that of good morals; the law is a path of more legal responsibility, but the medical profession is the most important of them all to humanity and to society. His touch must be trained, his hearing acute, his memory ready, and he must be full of judgment else life may be sacrificed. His duties are often immediate and sudden, and he must be prepared for all emergencies. He should be a man of much wisdom.

A doctor is confronted and surrounded by strong legal obligations and responsibilities. Suits of malpractice are among the liabilities and are not unfrequently brought without any grounds upon which to base the charge. To avoid malicious suits, a bond should be given by the plaintiff before a suit is commenced, to reimburse the physician if the case is not sustained. The laws of our State allow six years in which to bring a suit, and in the case of a minor twenty years. One year should be the limit. The patient could lose no legal right thereby, while the physician would have some protection. Legislation to limit the time to one year was suggested.

Hygiene has been fostered by the physicians, and the State Board of Health is the outgrowth of this after a struggle of several years. Although the Board is young its work has already been of great value to the State, and it is doing much to restrict disease. Should cholera or any serious epidemic occur in the State, we should look to this Board for relief and to save life.

Medicine is still progressive, Much that was once held to be valuable in the treatment of disease is now cast aside as worthless, or is supplanted by something much better. The progress is rapid. Much has been accomplished in the last thirty years, as witnessed in chemistry, pharmacy, therapeutics and surgery. The discovery of disease germs was a wonderful stride, and physicians may now cease to wonder how diseases and epidemics are scattered broadcast. The investigations of Pasteur, Koch, Kline, Sternberg, and others, have given a great impetus to the germ theory of disease. The results are still shaded by doubt, but they are the prelude to greater discoveries in the future.

A centennial of the Society in 1891 was recommended, and a history of the Society for its first one hundred years. A record of its illustrious and distinguished members will be of much value and interest, and it is due to history that one be prepared.

DR. WM. CHILD, of New Hampton, read an essay entitled

"SANITAS, SANITATUM, OMNIA SANITAS,"

which was directed to the exposure of medical shams. In the profession are to be found truth and science which are ennobling to the medical faculty, but still it is full of shams, among which are many new remedies, pills, pellets, and powders; many of them are half secret and proprietary. The worst of all is that they are daily increasing, and most of them are for incurable diseases. The tendency is too strongly towards shams and shoddies. The regular medical journals advertise them in high-colored language, with testimonials. They are written for physicians only. When we wrangle over our code, and covertly act in violation of such code, then we are open to severe criticism. The physician who practises by the last medical journal may be a progressive one, but he is not a safe one. Still, disease has not decreased. Well-tried medicines have been abandoned for those but little known.

DR. T. B. SANBORN, of Newport, read a paper on

EPILEPSY.

This disease has been subject to much study, yet without much satisfaction in the results obtained. Lesions of the cord were shown by Brown-Séquard to cause the disease. Heredity plays an important part in the disease, and the mental faculties are generally impaired. It is sometimes simulated, a novel test being to tickle the bottoms of the feet. The bromides should not be used in anæmic cases. The drug is valuable, but it should be used with caution. It must be used in increasing quantities to be effectual, hence one of its dangers. The sodium salt is preferable. Nitrite of amyl is valuable in many cases. A plain but nutritious diet should be prescribed. Iron and quinine are of great service.

AFTERNOON SESSION.

DR. C. B. NICHOLS, of Franklin Falls, read a paper on

GYNECOLOGICAL DIAGNOSIS.

He asserted that many physicians refuse or neglect to examine into diseases embraced in this department of medicine and surgery, and too often ridicule those who make a specialty of this branch of practice. First, a proper examination of the patient is necessary, and for this purpose a properly constructed table is indispensable. The Chadwick table was recommended as one of the best. Reflex uterine neuroses are often manifested by headaches, pain in the back nausea, melancholia, and many other symptoms. He believed the greatest advance made for many years in this department was by Emmet in the operation which he conceived in 1861, and which was made public in 1869. It has stood the test of time as well as heated opposition.

DR. H. M. FRENCH, of Concord, then read a paper on

NASAL CATARRH.

The causes are many and varied, but the most common are cold from drafts, etc., heredity, inhalation of dust, fumes of certain substances, etc. Iodide of potassium will frequently produce it. Unventilated halls and churches are prolific causes. All the mucous membranes of the head may be involved. The first stage is dry, the second consists of a thin discharge which next thickens and then again becomes thin and disappears. It may be the precursor of bronchitis, pneumonia or other inflammatory condition; the chronic form follows. The disease may be due to heredity, or may from the first assume a chronic form. The mucous membrane of the nose thickens, and the septum is sometimes turned to one side and necrosis may follow. The discharges are purulent in this stage, and in some instances casts of the nostril are thrown off. In simple cases relief and recovery may be expected, but in severe chronic cases relief only may be obtained.

Cleanliness and drainage are two elements of success. In treatment the spray system is the best in both acute and chronic cases. The spray is so fine as to reach all parts, and the relief in some cases is almost instantaneous. Sniffing salt water and the use of gargles are of little use. A spray apparatus was exhibited. Carbolic acid, carbolized glycero-tannin, and other medicaments in spray were recommended. The relief is rapid, and the treatment is agreeable to patient. Sponge-bathing, friction of skin, good diet, and other hygienic conditions are also essential.

A REPORT ON SURGERY,

by DR. G. H. BRIDGEMAN, of Keene, was read by DR. C. R. WALKER.

The plaster splint was taken up, and its origin discussed as well as its virtues, including its wide range of application. Statistics of gunshot wounds of knee-joint, and results and treatment in European wars, were given. A report of an interesting case in the writer's practice was given in which a small pistol-shot passed through the knee-joint. The case was treated as a simple puncture. The knee was fixed, and constant irrigation maintained from a pail of water, from which candle wicking was suspended. Cases in the practice of others were referred to. Ligation of subclavian artery in its second part was reported, but the case proved fatal, probably from the accident which necessitated the operation.

Cocaine was discussed, and its possibilities referred to. He had used it in several conditions. In acute gonorrhœa he had found great relief from this and iodoform made into a pencil and applied three or four times daily.

EVENING SESSION.

DR. C. R. GIBSON, of Woodsville, presented a paper on

ANÆSTHETICS.

Chloroform, except with the very young or very old, is a dangerous anæsthetic. This truth is beginning to dawn on the English, and their surgeons are giving it up and using the formula A. C. E. We should never hesitate to give ether; unfortunately it is disagreeable to many. Many apparatus have been devised for its administration, but they are generally failures. They have many objections. The old funnel made of paper with napkins is nearly as bad. The patient should have pure air at each inspiration saturated with ether. He recommended the use of a well-worn napkin with one thickness, kept wet with ether, drop by drop. From five to eight minutes are sufficient in most cases to produce anæsthesia. The violent struggle is nearly done away with by these means, and the nausea is very slight. The room should always be kept quiet during the administration of an anæsthetic. This is the writer's method, and has always been attended with success. Much will depend upon the skill of the physician, which can be attained only by practice.

A REPORT ON OBSTETRICS,

by DR. J. WALLACE RUSSELL, of Concord, was read. Corrosive sublimate, 1 part to 1000 or 2000 parts of water, was recommended as the most valuable antiseptic in obstetrics. Many cases of extrauterine fœtation have been reported during the last year, and electricity has proven the most efficient remedy. An interesting case occurring in the practice of the writer was reported. The case was so peculiar that a diagnosis could not be made.

DR. EDWARD FRENCH, of Concord, read a paper on

MELANCHOLIA.

At the present time these cases are met with in daily practice. No phase of mental disease so engages our sympathies. In every case the thought of suicide is

present sooner or later. Hallucinations of all varieties exist—of taste, hearing, and smell; that of sight is less common. Religious hallucinations are often present. The efforts at suicide are of the most terrible kind, often taking the form of mutilation. It is almost impossible to distinguish the acute cases from acute dementia. It is a suicidal mania. Some interesting cases in the writer's experience were given to illustrate the phases of an acute case. In one case the patient killed himself by pouring scalding water upon his abdomen. Egotism and conceit are frequently marked symptoms. There were 423 cases of suicide in March, April, and May, in the United States. Inability to sleep is one of the first symptoms. Chloral hydrate should not be used, and the bromides sparingly. Opium alone, or combined with hyoscyamus, is a good remedy. Walking with an attendant several miles daily will generally induce sleep. It is important that the patient eat well. The nasal tube is the best for giving forced food; there is, then, no need of forcing open the mouth, and no choking. Mechanical restraint is the best, if any is required. Tonics and cathartics are needed in all cases. The patient should leave home and all old surroundings; this is important. The hospital is the place for most cases. With proper treatment, 60 per cent. should be restored to health. This paper was an interesting one and well received.

WEDNESDAY, JUNE 17TH.—THIRD DAY.

MORNING SESSION.

The reports of delegates to Dartmouth College, and the various medical associations, were presented.

DR. J. W. PARSONS, delegate to the American Medical Association, rendered a report of some length and considerable interest to the Society.

The resolution of the American Medical Association, adopted at its last meeting, at New Orleans, relative to the Code of Ethics, was adopted by the Society.

The report of the Treasurer was read and accepted. The report showed a balance of $550.02 in the hands of the Treasurer.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. George A. Crosby, of Manchester.

Vice-President.—Dr. C. P. Frost, of Hanover.

Treasurer.—Dr. D. S. Adams, of Manchester.

Secretary.—Dr. G. P. Conn, of Concord.

Executive Committee.—Drs. C. R. Walker, of Concord; George D. Towne, of Manchester; J. R. Kimball, of Suncook.

The Executive Committee reported, in part, the programme of the next meeting as follows:

Report on Therapeutics—Dr. J. Frank Brown, of Manchester.

Report on Necrology—Dr. E. L. Carr, of Pittsfield.

Report on Practical Medicine—Dr. I. H. Adams, of Derry.

Report on Surgery—Dr. C. B. Hammond, of Nashua.

Report on Obstetrics—Dr. Frank Blaisdell, of Goffstown.

The meeting then adjourned.

ONTARIO MEDICAL ASSOCIATION.

Fifth Annual Meeting, held at London, June 3 and 4, 1885.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JUNE 3D.—FIRST DAY.

THE Association was called to order at eleven o'clock by THE PRESIDENT, DR. WORTHINGTON, of Clinton.

The forenoon session was taken up with the reception of members and general business.

AFTERNOON SESSION.

DR. POPE, of Bothwell, presented a

CASE OF CEREBRO-SPINAL MENINGITIS,

which began last January and was characterized by high temperatures, the highest being 107½° F., followed by a continuous elevation of 105° for two weeks. There has been gradual but steady improvement.

THE PRESIDENT then delivered his

ANNUAL ADDRESS.

He thanked the Association for the honor conferred on him in electing him to preside. He then briefly reviewed the progress of medical science during the eighteenth and present century. He dwelt more particularly on the changes that had taken place in the treatment of fevers, especially in reference to the use of cold water. He hoped the progress of the past may be but an earnest of the progress of the future.

DR. JOHN L. BRAY, of Chatham, then reported a case of

CÆSAREAN SECTION,

which terminated fatally.

DR. JENKS, who assisted at the operation, gave a lengthened description of the case with his views of the relative merits of Cæsarean section and craniotomy. He was strongly in favor of the former operation, which should in all cases be performed early. In the discussion which followed, a general preference was expressed for craniotomy to Cæsarean section, while many thought that Porro's operation, or some modification of it, should have been resorted to in the case reported.

DR. TYE, of Chatham, introduced the discussion on

DIPHTHERIA

in a most exhaustive paper, in which he pointed out that the disease does not stay its ravages for country or climate, and it is not ashamed to claim its victims in the house of poverty or fears to enter the home of luxury.

The people of Ontario are rapidly becoming educated in sanitary matters, and there are fair prospects that the prevalence of this disease as well as of many others, will soon be limited. The country owes much to the Board of Health for its energy, intelligence, and thoroughness in carrying out the provisions of the Health Act. The health report states that in the whole catalogue of diseases, none so persistently maintains its hold on a locality when once introduced as diphtheria. He then dealt with the various causes of the disease, its prophylaxis and treatment, local and constitutional, especially the latter, on which he places greatest reliance.

DR. BROUSE, of Brockville, in the discussion that followed, said that in some serious cases he had resorted to

calomel. He gave forty grains at the first dose; at the expiration of twelve hours, a dose of thirty grains, and another dose of thirty grains after twelve hours more, making 100 grains in twenty-four hours. The results in this and other cases were so satisfactory that he recommended this treatment in similar cases.

Dr. Graham, of Toronto, suggested the application of blisters to the body to form a raw surface, on which diphtheritic exudation might occur, and possibly thus relieve the throat.

Dr. Fraser, of Sarnia, followed with a paper on

CONTINUED FEVERS.

He deprecated the use of the term typho-malaria as incorrect, there being no such hybrid disease. Cases called typho malaria are simply typhoid, running an irregular course.

Dr. Bucke, of London Asylum, believed there was a fever occupying the middle ground between typhoid and malarial fevers. Just as enteric fever had been in time separated from typhus, so would there be a fever with distinct pathological conditions yet found to exist here.

Evening Session.

Dr. Newton A. Powell, of Edgar, introduced the

DISCUSSION ON PLASTER SPLINTS.

He traced the history of this mode of treating fractures. He advised the use of the finest dental plaster only, the common kind used by plasterers not being suitable for surgical purposes. He strongly urged this method for the following reasons: 1. The fit being perfect, there is little liability to displacement. 2. Support sufficiently firm to prevent displacement is obtained before the busy practitioner has to leave his patient. This is not the case with any similar plastic material. 3. Compression is uniform, limiting extravasation, and controlling muscular spasm. 4. In some form these dressings can almost always be applied at first visit. 5. The material is always at hand, and costs little. 6. The apparatus made from it can be depended upon not to contract in drying, as those made from the plastic materials do. 7. They are sufficiently porous to permit the escape of perspiration.

Dr. Howe, of Buffalo, read a paper on

ALBUMINURIC RETINITIS,

which he illustrated by a series of stereopticon views of the retina in different stages of the disease. The paper was very interesting, and Dr. Howe was tendered the thanks of the Association for it.

Dr. Groves, of Fergus, read a paper on *Urinary Calculi*, and Dr. Edwards, of London, one on *Placenta Prævia*.

Thursday, June 4th.—Second Day.

Morning Session.

Dr. Temple, of Toronto, presented a paper introducing the discussion on *Intrauterine Medication*, in which he discussed the various materials in general use for that purpose, and the conditions under which each is applicable. He esteemed iodized phenol highly, and invariably used it now instead of Churchill's iodine.

Dr. Edwards presented two cases of

PSEUDO-HYPERTROPHIC MUSCULAR PARALYSIS,

in two brothers aged ten and twelve. The older became affected six years ago, the younger about three years. The younger was still able to move about.

Dr. Stewart, of Montreal, thought that if such cases were treated early by galvanization, a cure might be effected.

Dr. Parks, of Buffalo, read a paper on the *Surgical Sequelæ of the Exanthematous and Continued Fevers*.

Dr. Brodie, of Detroit, President of the American Medical Association, who had just arrived, was introduced and most cordially received. He expressed his thanks, and said he attribued his kindly reception largely to the fraternal feelings entertained for the Association over the line.

Afternoon Session.

Owing to the pressure of work, the Association divided into medical and surgical sections.

Surgical Section.

Dr. W. T. Aikins, of Toronto, presiding.

Dr. Atherton, of Toronto, read a paper on

INTESTINAL OBSTRUCTION.

He gave a brief *résumé* of the cause, diagnosis, symptoms, and treatment of both acute and chronic cases, dwelling especially on the former, of which he has met seven cases during the last five years. One of the chief characteristics of acute obstruction is the *sudden onset* of symptoms. In cases of strangulation by bands and of volvulus there is absolute constipation, not even flatus passing. In intussusception frequent bloody stools occur very generally, with more or less tenesmus. In all cases fecal vomiting usually supervenes in the course of a few days. Symptoms of collapse set in sooner or later, according to the age of the patient and severity of the attack. In the diagnosis of intussusception from dysentery, Dr. Atherton thinks the color of the dejections of considerable significance. In all the cases of the former affection he has met with, the discharges were of a *bright pink* color, contrasting strongly with the dark clots and beef-tea-like stools of dysentery. In his cases also there was little or no mucus discharged; this may have been due to the fact that the invaginated bowel did not reach as far as the rectum.

When rest in bed with very spare diet, a few full doses of morphia, the use of several enemata through a long tube, and one or two washings out of the stomach fail to relieve the symptoms, he advises resort to laparotomy after two, or, at most, three days. One of the chief difficulties met with in this operation is the tendency of the distended intestine to escape through the abdominal opening. Very often it is necessary to puncture the gut to permit of its return after relief of the obstruction. The puncture should be made with a very fine trocar, else some fecal extravasation will result. This is due to the overdistended gut having lost its normal contractility.

Dr. Adam H. Wright, of Toronto, read a paper on

THE TREATMENT OF INEVITABLE ABORTION.

He referred to the two plans of treatment, which had been called the expectant and radical methods. In the former, the case is left chiefly to the natural efforts to complete expulsion. The dangers from this are chiefly hemorrhage and sepsis. In the radical method, the uterus is emptied as soon as possible, the cervical

canal being dilated if required. Unnecessary violence is sometimes employed, and the dangers are inflammation and sepsis. The truth probably lies between the two extremes.

He advised, in cases where hemorrhage exists, and cervix is dilated or dilatable, to empty the uterus at once with the finger, in preference to any other instrument. When cervix is not dilated, plug vagina; avoid, if possible, the use of the tent on account of its dangers.

DR. MURRAY, of Thorndale, read a paper on

HEMORRHAGE AFTER ABORTION.

He related the histories of six cases which had been treated by him. He showed the great danger of prolonged hemorrhage from the resulting anæmia alone as well as from other accidents, such as septicæmia. He also illustrated the dangers of injections of iron.

The two papers were taken together and discussed by the Chairman, Drs. Oldright, Temple, Henderson, Powell, and Edwards.

DR. REEVE, of Toronto, introduced the discussion on

COCAINE HYDROCHLORATE

by giving a succinct account of its uses generally and in the treatment of diseases of the eye especially.

DR. HOWE drew attention to two points on which he would like to throw some light: 1st. The desirability of obtaining an exact measure of the amount of anæsthesia from the drug; this is found in the effect on the blood pressure, as measured by the kymograph. 2d. The desirability of noting definitely the reputed ill-effects in irritation said to result from the drug. From a large series of experiments he found no irritating effect of any consequence. He concluded that it does the maximum of good with the minimum of evil.

DR. OLDRIGHT, of Toronto, exhibited a large *Meckel's Diverticulum*, which extended into the umbilical cord and was injured in cutting the cord, and reported a case of *Diaphragmatic Hernia* in a child aged five years. Part of the colon and the kidney were found in the thorax.

DR. HARRISON, of Selkirk, read a paper on *Foreign Bodies in the Larynx*, with the report of a case.

MEDICAL SECTION.

DR. GRAHAM, of Toronto, presiding.

DR. HENDERSON, of Kingston, read a paper on

PULMONARY CAVITIES.

He entered at length into the pathology of phthisis and the relation of the bacillus of tuberculosis thereto. He said that the bacillus is to be found in all forms of the disease and believed it to be chief if not the only direct cause. He pointed out that the practical application of Koch's great discovery has already commenced in the use of greater cleanliness and antiseptic inhalations now practised in the treatment of consumption. It is also possible that the bacillus may be so cultivated as to produce a mild form, which may be inoculated with success as is done in smallpox and anthrax.

DR. OWEN, of Arkona, presented a case of

TRIFACIAL NEURALGIA

in a young man. The hypodermatic injection of morphia was the only remedy that had so far proved efficacious in his hands.

DR. GRAHAM next read a paper on

INITIAL STENOSIS.

He showed a specimen and gave a full history of the case from which it was obtained.

DR. DUNCAN, of Thamesville, presented a paper on

WARBURG'S TINCTURE IN CANADIAN PRACTICE.

He advocated its use instead of quinine, as it gave better results in his experience. The majority of those present considered that quinine, when needed, was more to be relied on.

DIET IN DISEASE

was the subject of a long paper by DR. ARNOTT, of London. He said there is a large class of disease which, though not often fatal, are yet the cause of much suffering and impairment of usefulness, and in the treatment of which the profession has not made satisfactory progress. Several disorders have their origin in the consumption of more nitrogenized food than the constitution or circumstances of the person require, and consequently the regulation of the amount of albuminoid food consumed often constitutes a valuable therapeutic resort. Many diseases may be completely cured and others benefited by excluding albuminoid food from the diet. Vigorous outdoor exercise may answer the same purpose, but such is obviously often unobtainable. In Bright's disease, the diet should not include albuminous food. Foul breath, not due to any local affection, will invariably be rapidly cured by non-nitrogenous diet without the aid of medicine. He mentioned a case of asthma in which this diet in a month had produced great improvement, and upon tasting meat one day he had symptoms of return of his ailment. It is an absurd notion that a person will get weak on this diet. Albuminoid food is a true stimulant, and the want of it is felt by the patient, yet sensations must not be taken for reality.

ELECTION OF OFFICERS

resulted as follows:

President.—Dr. George Archer Tye, of Chatham.

Vice-Presidents.—Dr. Henry Arnott, of London; Dr. James A. Temple, of Toronto; Dr. Robert W. Hillary, of Aurora; and Dr. William H. Henderson, of Kingston.

General Secretary.—Dr. John E. White, of Toronto.

Treasurer.—Dr. James E. Graham, of Toronto.

Corresponding Secretaries.—Dr. A. H. Wright, of Toronto; Dr. John Campbell, of Seaforth; Dr. Aylesworth, of Collingwood; and Dr. John C. Mitchell, of Enniskillen.

Toronto was chosen as the *next place of meeting*, in June, 1886.

COLLEGE OF PHYSICIANS OF PHILADELPHIA,

Stated Meeting held June 3, 1885.

THE PRESIDENT, J. M. DA COSTA, M.D., IN THE CHAIR.

THE PRESIDENT presented, for DR. JOHN GRAHAM, the following report of

CASES OF POISONING BY CARBONIC OXIDE DUE TO A DEFECTIVE FURNACE PIPE.

On March 9th I was called to see the following cases of poisoning from the inhalation of carbonic oxide, the

poisonous gas being conveyed by the hot-air flue from one of our ordinary cellar heaters to the sleeping apartments of the patients.

The heater was situated in the middle of a large cellar; had been in use for a number of years, and each autumn had undergone some repairs. It consisted of the ordinary iron heater, enclosed by brick, forming a hot-air chamber. Inside the air chamber was a terra-cotta pipe, running from the heater, and penetrating the wall of the chamber, thence to the chimney, to carry off the products of combustion. This pipe was cracked for eighteen inches of its length, the crack being open half an inch; and, unfortunately, the crack was in the air chamber. This break is now known to have existed for several years; but up to the time of which I write had apparently produced no worse effects than annoying the family with a smell from the heater. Something more was needed to change the chronic poisoning into acute. The chimney furnished the addition needed. Like too many of its kind, it had several angles, when it might just as easily have been perpendicular, from cellar to roof. It formed part of an outside wall, and the frost had loosened some of the bricks near the top, which, falling down and lodging at one of the bends, partially obstructed it. Complaints came from the servants that the heater drew badly, but the cause was never carefully sought for. Steadily the disintegrating effects of frost and air on brick and mortar continued, until at the time of the accident the chimney was completely blocked. Of course, it is highly probable that on the day in question a more than ordinary quantity had fallen, blocking it suddenly, else we would have had our patients complaining of sickness as well as smells, which they did not.

The patients, Mr. R., aged 78 years, Mrs. R., aged 74, went to bed on the evening of March 9th, about 10 o'clock. Both were in perfect health and good spirits, and the only thing Mrs. R. remembers noticing was that the smell from the heater was a little stronger than usual. Fourteen hours after, the servant, alarmed at their not appearing to her calls, broke in the door and found them unconscious.

When coal is burned with a free supply of air, which, of course, necessitates an unobstructed chimney, the chief product is carbon dioxide. When burned with a deficient supply of air, as when the outlet is obstructed, the product is carbonic oxide. The first is poisonous when inhaled in sufficient quantity; three per cent. of the latter has been shown to produce death in animals in thirty-seven minutes. Carbonic oxide is a little lighter than air, and when heated ascends rapidly. In the case of my patients, the obstructed chimney diminished the supply of air to the fire, and the resulting product was carbonic oxide. Its tendency was to ascend. The chimney allowed no exit, so the crack in the terra-cotta pipe gave out the deadly product, and it ascended by the convenient hot-air flue to the open register in the bedroom, which, with closed windows, contained its unsuspecting victims. Carbonic oxide is tasteless and odorless. We cannot recognize it by any of the special senses. The products of ammonia, sulphur, tar, are what make up the odors from burning coal.

When found, Mr. R. was breathing rapidly with loud bronchial râles, and his skin was dark and congested. Both had vomited some time during the night, and their mouths were covered with frothy mucus. The extremities were cold; pupils dilated, and insensible to light. Patients were allowed plenty of fresh air. Whiskey was given by the rectum, also hypodermically. Ammonia was given by the mouth whenever they were able to swallow, and warm applications were made to their bodies.

In the case of Mr. R., the labored breathing increased, the blood became more and more carbonized, and he died thirty-six hours after the discovery of the accident, without regaining consciousness. There was no failure in his heart, the pulse being full, but increased in frequency. He evidently died from pulmonary œdema. His chest was dull on percussion, the lungs filled with fine râles. For a few hours before death, his temperature rose rapidly, and reached as high as 106°. He had no paralysis.

Mrs. R., when found, was pale and breathing almost imperceptibly. The same means were used in her case to produce reaction, and slowly and gradually the heart's action increased; by degrees the intellectual faculties were aroused, and the patient with much effort was able to inform us that from the time of going to bed until the return of consciousness all was blank. She had suffered no pain; remembered nothing. Her pulse at this time was 60, small and compressible. Respirations, 14; temperature below normal. She was kept in the horizontal position. Liquid nourishment was given, with small doses of whiskey, and Basham's mixture ℥ss four times daily. The brain worked slowly, and she spoke only when roused up, and then dropped back into semi-consciousness. The tongue was coated, and had a slight tendency to dryness; bowels costive; appetite poor. Her improvement progressed slowly, but at the end of seven days she was able to sit on a chair by the side of the bed. The pulse increased somewhat in volume, but the patient remained drowsy, falling into the same dull condition, unless when roused by noise, of which she complained greatly, saying it hurt her head. She also complained of intense pain in her back, running down the legs. At no time in the progress of the case did her urine contain either albumen, sugar, or tube-casts. Her blood was not examined.

Patient continued in about the same condition for three weeks following the accident. The Basham's mixture having been succeeded by pills of carbonate of iron, and the whiskey omitted. Pulse 60 to 70; temperature varying greatly from slight causes, from 98° to 103.5°, but mostly normal; anæmia very marked.

On the morning of the twenty-first day following the accident, the patient, while sitting on a chair, was taken very ill. A deadly pallor overspread her countenance, the jaw dropped, the limbs relaxed, and she became unconscious, convulsive twitchings passing through her body. We quickly placed her in the recumbent posture, and, after a hypodermic of whiskey, she slowly opened her eyes and asked, in an excited tone, "What is the matter?" The supposed cause for the sudden change, was that our patient's digestion since commencing the iron had been gradually growing worse, the tongue drier and more coated, the appetite poorer. I had realized that this digestive trouble was from the iron, but continued it up to this time on account of her profound anæmia. I now reluctantly stopped it, and

put her on dilute muriatic acid, ten drops every three hours, with pepsin after food, and enjoined absolute rest in the recumbent posture. The temperature on reaction reached 102°; pulse 120. The pupils were still further dilated; the reasoning power was all gone; answered questions with difficulty, and in monosyllables. The tongue became very dry, and it was almost impossible for her to protrude it. Stools were watery, frequent, and involuntary.

At this time the patient was seen by Dr. J. M. Da Costa, who advised the continuation of the acid, careful nourishment, and keeping the bowels open. The treatment resulted favorably. In forty-eight hours the tongue regained its moisture, the appetite improved, and the dulness of the mind diminished, though the patient still continued to have delusions and hallucinations, and the memory for certain words, and familiar words, was poor. On Dr. Da Costa's second visit on the twenty-sixth day of her illness (April 3d), the acid alone having been continued in the meantime, our patient was much better, tongue moist and clean, bowels natural, and, excepting the anæmic appearance and mental dulness, she was doing well. We then put our patient on the same diet, milk, beef-tea, mutton broth, etc., without solids, and stopping the muriatic acid, gave tinct. ferri chlor. ten drops, liq. potas. arsenitis, five drops, four times daily. This treatment was continued off and on until April 19th, the forty-second day of her sickness, when it was finally abandoned. Its use for a few days was invariably followed by dry tongue, loose bowels, and increased mental disturbance. This was also the case when we tried the arsenic without the iron. On resuming the muriatic acid, the tongue would regain its moisture, the bowels become regular, and the mind somewhat improved, but the anæmia, as shown by feeble pulse, pale skin, bloodless conjunctiva, continued.

On April 19th I noticed twitching in her left forearm, which was firmly flexed on the arm, and the hand on the forearm; the mouth was slightly drawn towards the left side. I then stopped the iron and arsenic and returned to the muriatic acid treatment. The rigidity of the left arm was followed by partial loss of power in the same, the patient raising it with difficulty, and not being able to grasp with it as firmly as with the right. Her mouth became drawn still further towards the left; it was, therefore, a case of alternate paralysis. She swallowed with increasing difficulty, and had involuntary movements of urine and feces. Sensation in the fingers remained good. Patient remained about the same, except that the bowel movements decreased in number, and the tongue regained its moisture, after again substituting muriatic acid for iron and arsenic, until Dr. Da Costa's third visit, on April 26th, the forty-ninth day of her illness. He advised the continuation of the muriatic acid. She also had an application of dry cups to the back of her neck. The paralysis, which we concluded was probably caused by an effusion near the base of the brain, slowly passed away, but the anæmia was almost as marked as ever.

On May 5th we began the use of ferri phos. cum ammon. cit. gr. ij, dissolved in 10 ♏ of distilled water, hypodermically, daily, but, as it was followed by some hardening of the cellular tissues, and produced disturbance of pulse and temperature, we abandoned the use of the iron hypodermically, and gave it by the mouth in two grain doses, morning and evening, also continuing the muriatic acid. From this time the improvement was progressive. The appetite increased, bowels became regular, the left hand and arm continued to regain their power, the deviation of the mouth to the left steadily diminished, and the patient became interested in her surroundings, and asked and answered questions with increasing intelligence. The pupils gradually diminished in size, and on May 20th, seventy-three days after the accident, our patient was sitting up, and four days after was able to walk into an adjoining room.

Dr. J. M. DaCosta said: In regard to this case, which has been so thoroughly worked out by Dr. Graham, there are several points which strike me as being of special interest. In the first place, the serious parts of the case came on late. For a time the patient was apparently doing well, and then, in the midst of the affection, she is paralyzed with a comparatively rare form of palsy, with paralysis of one side of the face and of the other side of the body. This was preceded by muscular twitchings; the case seemed to be hopeless; but she got over the palsy in ten or twelve days. Another point was the persistence of anæmia, with all that that implies, including anæmia of the brain. The aphasia, also, was very marked. This was all the more striking, because she was a woman of decided mental force and culture and ready expression. The extreme aphasia which was present for a time was probably due to low nutrition of a portion of the brain from anæmia. Another point, and one which has been well brought out by Dr. Graham, is in reference to the therapeutics. Until quite late in the case the symptoms were aggravated, rather than improved, by the use of iron. Improvement always followed the use of muriatic acid, and it is to this and the steady nutrition that her recovery is to be attributed. Late in the case a form of iron, which I have found to be well borne, the phosphate of iron with citrate of ammonia, was well tolerated and well digested; but this may have been due to the fact that the patient had so far convalesced that she could digest iron, whereas previously she could not do so.

Dr. Henry Leffmann said that poisoning from carbonic oxide is essentially different from that by most other gases in the fact that a compound is formed by the carbonic oxide and the hæmoglobin which is very difficult to break up. The compound formed by carbonic acid and hæmoglobin can be easily broken up by increasing the tension of the free oxygen present in the blood, but the carbonic oxide compound cannot be. The anæmia was due to the modified condition of the hæmoglobin, and not to the absence of iron, and, therefore, did not yield to the ordinary remedies. An examination of the blood by the microspectroscope and a counting of the blood-cells would, doubtless, have yielded important results.

CORRESPONDENCE.

THE INTERNATIONAL SANITARY CONFERENCE AT ROME.

Rome, May 7, 1885.

The subcommission composed of the technical delegates to the International Sanitary Conference has completed its labors, and will submit a detailed report

to the *conférence plenière* within two or three days—as soon as it can be printed. In the meantime the members are supposed to be in need of a little relaxation, and are offered by the government an excursion to Naples, which will include a sail about the harbor on an Italian man-of-war, and a visit to Pompeii. The delegates have been very handsomely treated by the Italian government, and the dinner given to the members of the Conference at the royal palace, by King Humbert, will be remembered with special pleasure. This is not the place to describe a State dinner, and it will suffice to say that it was regal in every respect; that His Majesty was extremely civil; that each delegate was presented to him individually; and that he took pains to converse for some minutes with each as he was presented, and again after the dinner.

It as supposed that the business of the Conference will be completed within two or three days after the return from Naples. But no one anticipates that an International Sanitary Convention treaty will be effected at the present time. This was the object of the Italian government in inviting each country to send a diplomatic as well as a technical delegate. But it is generally understood that these delegates are for the most part without authority from their respective governments to subscribe to a convention, and that whatever is agreed upon must be *ad referendum*.

The subject of cholera occupied the entire attention of the technical subcommission up to the last session, and it is probable that an adjournment would have been made without reference to any other disease, but for the action of the American delegate, who at the last moment introduced the following proposition:

"The measures recommended to be employed against cholera are, in general, applicable to yellow fever, and to other diseases which prevail epidemically under the influence of bad sanitary conditions, and which are transmissible by the intermediation of man. The most efficacious means to prevent the propagation of the diseases of this class are the sanitation of cities, and of vessels leaving infected ports; the isolation of the sick, and the disinfection of their effects, and of infected or suspected places."

This was passed by a vote of 17 in the affirmative, with 3 abstentions. The abstentions meant that the means named were secondary, as compared with quarantine, and it is probable that if the quarantine party in the Conference had had a little more time to consider the fact, that the measure which they insist upon as the most important was not named in this resolution, they would not have assented to it so readily.

The delegates have been practically divided upon the quarantine question into three groups, and the discussions have for the most part had reference to this question. The English delegates insist upon it that quarantine is useless. Sir Joseph Fayrer, Sir William Hunter and Dr. Lewis, have all spent much time in India, and assume that their superior opportunities for observing cholera have given them very *advanced* notions with reference to this disease. From their point of view, all of the other delegates are laboring under a serious error in assuming that cholera is transmissible by human intercourse, or may be carried across the ocean in ships. They insist that all of their Indian experience negatives this supposition, and assert that when cholera appears in our country, for example, soon after the arrival of a ship having cases on board, it is simply because the "*cholera wave*" has reached our shores, and the cases on the ships are due to the fact that these ships encountered this "cholera wave" while at sea. Cholera travels entirely independently of ships or persons; it is in no sense infectious; the dejections of the sick are harmless; disinfection is a farce. Consequently, quarantines of all kinds are useless, and to detain English ships coming through the Red Sea and Suez Canal for the protection of Europe is a superfluous and unscientific proceeding.

It is doubtful whether these gentlemen represent the state of medical opinion in England at the present day, but they represent a respectable body of English medical officers in India, whose views have been very well stated by Surgeon-General Cunningham, in a little book recently published. These gentlemen are very sincere, and are practically in the same position with reference to cholera as were many reputable medical men in our southern seaboard cities, as regards yellow fever, some twenty-five years ago. There are still a few who adhere to the opinion that this disease travels independently of human intercourse, and is endemic in our Southern States. Those who study a disease in the territory where it prevails endemically, are too apt to assume that their familiarity with it gives them special advantages over those who only encounter it occasionally in epidemic form at places remote from its normal habitat. The conditions are greatly complicated in the area of endemic prevalence, and local prejudices often have a certain influence in giving a bias to the judgment even of the fairest minded men.

Our knowledge of the etiology of these diseases has been gained rather from the independent labors of unprejudiced observers who have studied local epidemics at a distance from the endemic centres and who have carefully recorded the facts relating to them; and from bringing together these histories made at different times and in different parts of the world. Certainly the facts, as observed in the United States, do not at all sustain the view of our English friends, and there are probably very few well-informed persons in the United States who believe that cholera comes to us across the broad Atlantic independently of ships and human intercourse.

With the exception of the English delegation it is safe to say that the members of the Conference are unanimous as to the transmissibility of cholera, and by far the largest majority look upon the dejections of the sick as the medium through which the infectious agent is propagated. All are agreed that theoretically quarantine should be an important prophylactic measure; but there is great difference of opinion as to the practical benefit to be derived from quarantine restrictions.

The majority of the delegates are convinced that the arbitrary quarantine of the past is worse than useless, and there is a general desire to substitute for a time quarantine a system of medical inspection, with isolation of the sick, disinfection of infected articles and localities, etc. The French delegation desire in addition to this to detain healthy passengers from an infected port for several days for observation—practically quarantine—but to keep them in separate groups and well removed from the sick, and to release each group at the end of

five days observation if no case has occurred in the mean time.

This modified system of quarantine has received some support, but has been opposed by some of the delegates on the ground that it is unnecessary, and by others on the ground that it is insufficient. The countries which demand a time quarantine of ten, or at least of seven, days are Turkey, Roumania, Spain, Brazil, and Mexico, while the other countries are in part in favor of the system proposed by the French delegates, and in part opposed to any restrictions as regards ships and passengers not sick, other than those required by a rigid medical inspection and the thorough disinfection of soiled clothing, etc. No doubt, the quarantine question will come up again in the general conference, and the special measures which have been recommended for the Red Sea will be stoutly contested by the English delegation.

Two propositions relating to international notification of cases of infectious diseases were passed at the last session of the Technical Subcommission. These propositions are as follows:

1. The Technical Committee expresses the wish that the International Conference affirm the necessity of publishing a bulletin of international statistics for each important city, a bulletin on a uniform plan, and publishing each week the total deaths and the number of deaths caused by each infectious disease, and particularly by cholera and by yellow fever.

2. As concerns cholera and yellow fever, notification of the first cases which appear in different localities, and particularly in maritime ports, should be immediately sent by telegraph to the various governments.

The application to yellow fever was introduced by the delegate from the United States as an amendment, the proposition as first reported having taken no account of this pest of the West Indies, which from an American point of view is quite as worthy of consideration as is the Asiatic pestilence which has almost exclusively occupied the attention of the International Sanitary Conference of Rome.

NEW INVENTIONS.

A DIOPTRIC SCALE OF FOCAL LENGTHS.

BY EDWARD JACKSON, M.D.,
OF PHILADELPHIA.

IN measuring the power of accommodation, when the distance from the eye to its near point has been determined in centimetres or inches, quite a problem in arithmetic must be solved before one can express in dioptrics the amount of accommodative power.

Again, if the distance from a myopic eye to its far point be measured on any ordinary scale, the same problem is to be met before the number of dioptrics of myopia can be known.

This is the chief disadvantage of the metric system for numbering lenses and recording states of refraction. The number of dioptrics expressing the degree of refractive power stands in no such simple relation to the divisions on the common metre measure, as does the expression of the refractive power in inches to the divisions on the yard-stick. Thus, in inches, the expression, one-sixth, is instantly deducible from the six inches marked on the yard-stick. But the 6 D. lens has no corresponding mark on the ordinary metre measure indicating its focal distance, one-sixth of a metre.

This defect of the metric system can be remedied by using a scale divided, not into equal parts, as centimetres or inches, but so as to indicate the focal lengths of the different lenses of the dioptric system. Thus, starting from zero, a mark at one-fiftieth of a metre indicates the focal distance of the 50 D. lens at one-thirtieth of a metre; that of the 30 D. lens at four-fifths of a metre; the five-fourth or 1.25 D. lens, and so throughout.

This scale does away with the necessity for calculating each time the number of dioptrics that a given focal distance represents; and these calculations, though singly brief and easy, have in practice to be made so frequently as to demand a considerable aggregate of labor. I have used such a scale with satisfaction for some years; and recently, at my suggestion, J. W. Queen & Co., of this city, have placed it upon the edge of the metre-inch measures they furnish for the measurement of accommodation, etc. Such a scale is very convenient in the measurement of refraction by the shadow-test. (See *American Journal of Medical Sciences*, April 1885.) It may also be used to determine, in metre-angles, the amount of convergent strabismus.

215 SOUTH SEVENTEENTH STREET.

NEWS ITEMS.

CHICAGO.

(*From our Special Correspondent.*)

TRANSACTIONS OF THE CHICAGO MEDICAL SOCIETY.—As very general dissatisfaction has been expressed with the manner in which the transactions of the Society have been reported during the past two years, a stenographer and committee on publication were elected. Dr. John A. Robison was elected stenographer; Dr. Edmund J. Dorring and Dr. Robert Randolph were elected members of the committee on publication. Only such reports of the Society's proceedings as bear the signatures of these gentlemen are official.

It was determined that in future reporters for the secular press should be excluded from the Society's deliberations.

THE BRITISH MEDICAL ASSOCIATION will hold its Fifty-third Annual Meeting at Cardiff, on July 28th, 29th, 30th, and 31st, under the presidency of Dr. W. T. Edwards, of Cardiff. The Address in Therapeutics will be delivered by Dr. W. Roberts, of Manchester; the Address in Surgery, by Mr. John Marshall, of London; and the Address in Public Medicine, by Mr. Thomas Jones Dyke, of Merthyr Tydvil.

CHOLERA IN SPAIN.—The French Government has decided to send a commission, headed by M. Brouardel, to Spain to study the origin and progress of the cholera epidemic.

THE BRITISH GYNECOLOGICAL SOCIETY has appointed a committee to collect evidence on the subject of menstruation in its physiological and pathological relations, and has voted £50 toward the furtherance of this object.
